16. Abstract

This Special Bibliography prepared from the magnetic-tape files of the Railroad Research Information Service, contains selections which were accessioned between 1973 and 1976. Although the literature which is referenced does in a few cases date back three decades, all listings are considered pertinent to contemporary railroad safety problems. The volume is divided into three main categories (with sections listed after each): Improved Track Structures Research (Track Accident Reduction, Improved Track Performance); Rail Vehicle Safety Research (Rolling Stock/Safety, Rolling Stock/Track-Train Dynamics, Locomotives/Safety, Locomotives/Track-Train Dynamics, Hazardous Materials Cars, Grade Crossings, Human Factors, Control Systems); Improved Inspection, Detection and Testing Research (Track Inspection and Testing, Automated Track Inspection, Vehicle Inspection, Life Cycle Testing). All of the citations in this Bibliography appear also in one of the regular RRIS semiannual publications. Because it cites only safety-related topics, this Bibliography should not be considered a comprehensive collection of RRIS citations; it incorporates about one-fourth of all RRIS holdings. There are 4,368 listings, involving 3,131 abstracts of research reports and journal articles, and descriptions of computer programs with some individual citations appearing in more than one of the 14 sections. The categories in this Bibliography are based on the functional responsibilities of the groups comprising the staff of the FRA Office of Rail Safety Research; these categories differ from the regular RRIS classification scheme. While categories differ, the accession numbers are common under either type of classification and may be used for identification.

List of Figures

PREFACE

This bibliography, prepared for initial distribution at the Thirteenth Annual Railroad Engineering Conference at Pueblo, Colorado, in October 1976, contains references pertinent to the conference theme, "Railroading Challenges in America's Third Century: Improved Reliability and Safety." The references can, however, be of long-term interest to those involved in the design, maintenance, operation, and regulation of railroads.

The material in this volume is compiled from the magnetic tape files of the Railroad Research Information Service. RRIS was developed within the National Research Council under contract to the Federal Railroad Administration of the U.S. Department of Transportation. The RRIS computerized data system incorporates information on the planning, building, managing, operation, and regulation of rail transportation systems. The scope of RRIS includes rail rapid transit, and some references to this technology do appear in the following pages.

The selections in this volume are categorized by areas corresponding to the functional responsibilities of the FRA Office of Rail Safety Research, which has sponsored this publication. The subjects include the design, maintenance, and safe operation of railroad track and rolling equipment. The categories under which entries appear in this volume are *not* those used in the regular RRIS classification system and in the semiannual Railroad Research Bulletins that are published by RRIS. All the entries here do appear, however, in one of the regular RRIS publications. Although RRIS has been operational since 1973, the abstracts of technical reports and journal articles and descriptions of computer programs cited do cover some of the significant investigations made during the past 3 decades. Comprehensive coverage is given to the published material of the past decade.

In addition to the acquisition and selection of material, RRIS work includes the classification, indexing, storage, retrieval, and dissemination of abstracts, descriptions, and ongoing project summaries. Concepts and procedures are similar to those of the other transportation research information services within the National Research Council: the Highway Research Information Service and the Maritime Research Information Service. The Railroad Research Bulletin, published semiannually, contains the material added to the RRIS file during the preceding 6 months. Each bulletin includes summaries of ongoing research projects in the railroad field, none of which is included in this bibliography. The Railroad Research Bulletin is available on a subscription basis from RRIS.

The material appearing in this bibliography gives thorough coverage to only a portion of the RRIS holdings at the time of publication. Information may be obtained from RRIS about holdings in other subject areas, about subsequent accessions in the areas covered by this volume, and about ongoing research in all its areas of coverage.

USING THIS BIBLIOGRAPHY

This volume is a collection of abstracts of technical reports and journal articles and descriptions of computer programs, which are divided into three major sections: improved track structures; rail vehicle safety; and improved inspection, detection, and testing. Each of these general categories is again divided into more specific subject areas, which are indicated in the Contents. The categories and sections correspond to the functional responsibilities of the FRA Office of Rail Safety Research, which sponsored the preparation of this bibliography. There are also indexes by source, author, and subject.

If you are interested in reviewing reports of completed research and other published documents, find the subject area and code in the Contents and turn to the appropriate section. The subject area and code also appear at the top of each page on which abstracts are printed.

If you can identify your interest by subject, turn to the Subject Term Index. Each term in this index is followed by a document record number, which consists of a 2-digit subject area code and a 6-digit TRIS accession number that identifies that individual document under the category. Although many of the citations in this bibliography appear in more than one section because they may be applicable in each, the indexes indicate only the first such listing in this volume.

If you are looking for publications by a specific author, turn to the Author Index and find the author's last name in the alphabetized listing. Again the document record designation indicates only the first such listing, even though it may appear again in subsequent sections.

If you are interested in abstracts of articles or reports that appeared in a particular publication or were the works of a specific organization, turn to the Source Index. Again the document record number may be used to find the first (and often only) listing in this publication.

Although this Subject Term Index gives a general idea of the scope of RRIS classification, it includes those terms applicable only to this bibliography. There are many others that do not appear in this publication.

AVAILABILITY OF RESEARCH REPORTS AND JOURNAL ARTICLES

An availability statement is included with most abstracts. Addresses for ordering documents are given with the abstracts or with the publisher listing in the Source Index. Copies of reports and articles listed in this publication are not available from the Railroad Research Information Service. When ordering from any source, give full information on the item wanted. When ordering from the National Technical Information Service, be sure to give the NTIS accession number as well as the title and other information. When no availability is specified with an abstract, consult an established transportation library. Because a large number of documents are available from a few sources, space and printing costs have been reduced by abbreviating sources as follows:

RESTRICTED AVAILABILITY OF UIC/ORE DOCUMENTS

Certain publications of the International Union of Railways (UIC) that are cited in the holdings of the Railroad Research Information Service are subject to restrictions on use. These apply particularly to the reports of the UIC Office for Research and Experiments (ORE).

The president of ORE indicates those reports that can be made available to third parties (industrial firms, individuals, universities, and technical colleges). For each report a price per copy and a separate fee for the right-of-use are established.

Members of ORE—certain railroad administrations that are members of UIC and, in the United States, the Federal Railroad Administration of the U.S. Department of Transportation—receive the ORE reports and possess, by virtue of their membership, the right to use these reports. Possession by virtue of ORE membership or the acquisition of a right-of-use covering a specific report only authorizes the holder of the information in the report to use such data for his or her own needs. This right-of-use is nontransferable. Possession of right-of-use does not authorize the holder to communicate, even in part, the contents of such a report to third parties who have not also acquired a right-of-use. An exception may be made, with special ORE authorization, for use by contractors of those organizations that have the right-of-use. Patent rights and design rights associated with solutions developed by ORE research and disclosed in reports are not acquired automatically when right-of-use is acquired. Such rights must be arranged separately between the report user and the owners of the patent or design.

Certain international standards organizations (such as ISO) and certain universities, technical colleges, and libraries are not subjected to right-of-use fees. However, these organizations must ensure that ORE information is not used for commercial purposes, and reports distributed under these conditions are stamped "right-of-use not acquired."

Those wishing to acquire the information in ORE reports that are referenced in the RRIS system should contact the Director, International Union of Railways, Office for Research and Experiments, Oudenoord 60, Utrecht, Netherlands. The report should be carefully identified, and the use to which the information is to be put should be completely explained. ORE will then indicate whether the report is available to third parties and specify the charges involved. The collections of ORE reports held in the United States by the Federal Railroad Administration are not available to third parties, except when they serve as contractors to that agency or other U.S. Department of Transportation elements. In such cases, the request for use must be directed to ORE through the Technical Planning Officer, RRD-1, Federal Railroad Administration, Washington, D.C. 20590.

LOAN AND PHOTOCOPY SERVICE FOR PUBLICATIONS IN THIS VOLUME

The Northwestern University Transportation Center Library and the University of California Institute of Transportation Studies Library are functioning as TRISNET Centers in the operation of a prototype document delivery system under contract to the U.S. Department of Transportation. The publications in this volume may be requested from either of these Document Delivery Centers.

The objective of the TRISNET Centers is to provide the documents identified through search of the Transportation Research Information Service (TRIS) abstracting and indexing services (RRIS and the Highway, Maritime, and Air Transportation Research Information Services).

In referring your requests for publications to either of these libraries, please cite the following:

Accession number
Author
Article Title
Publisher or journal title
Date of publication

The request may be for either loan of the publication for a period of 2 weeks plus estimated mailing time (Northwestern accepts a user's request directly, but University of California requires submission of an interlibrary loan request) or for photocopies of articles or conference papers. If the document is unavailable at the library, referral to the best available source will be made.

Loan services are free when publications are mailed at the book rate. If the user requires priority mailing, the library will charge for mailing costs. Photocopies of articles or individual conference papers are made at the rate of 10 cents per page plus a handling charge of 50 cents per item. In all cases, invoices are mailed with the loan or photocopy.

The TRISNET Center at either library may be contacted as follows:

Transportation Center Library
Northwestern University
Evanston, IL 60201
312-492-5273
TWX 910-231-0872

Institute of Transportation Studies Library
University of California
412 McLaughlin Hall
Berkeley, CA. 94720
415-642-3604

RRIS FILE SEARCHES

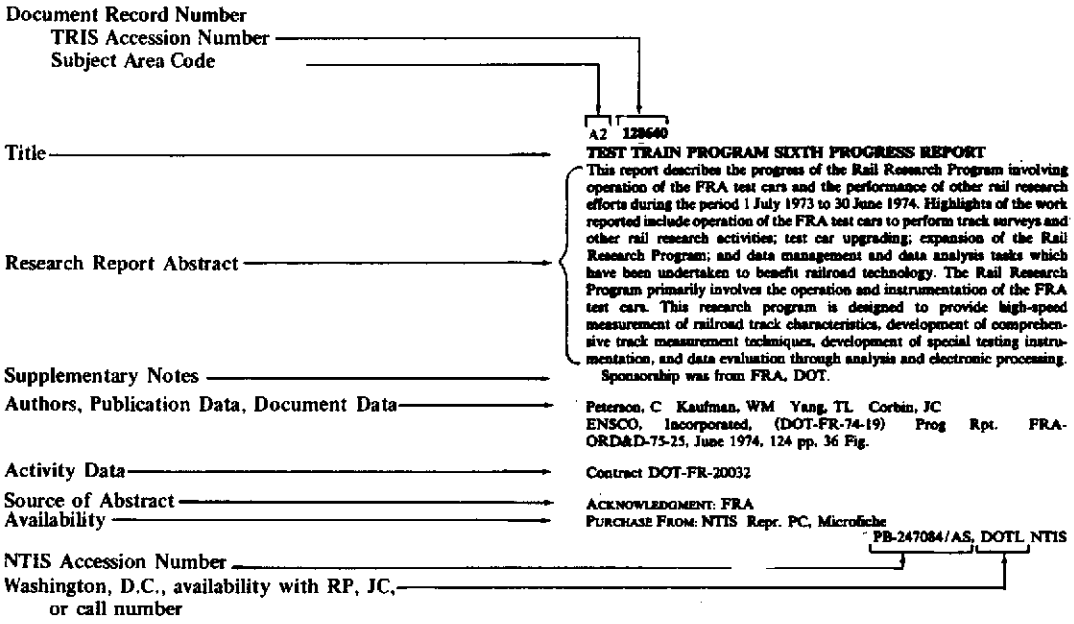
The RRIS file is maintained on magnetic computer tape and is available for searches for information related to specific inquiries. The key to searching is RRIS categories and appropriate subject terms. The search is normally done by computer. Output may include abstracts of articles and reports, descriptions of computer programs, and summaries of ongoing research. The output is a computer-printed listing similar in format to listings that appear in this publication.

The fee schedule for RRIS file searches reflects the primary support for the service from the Federal Railroad Administration and the nonprofit nature of all National Research Council information services. The charge for computer retrieval from the RRIS file is $50 per request plus $0.25 per printout page, which is screened by RRIS. A written authorization or purchase order is required before the retrieval is made.

SAMPLE ABSTRACTS

Abstracts are classified according to an 8-digit document record number: The first 2 digits indicate the subject area code, and the last 6 digits indicate the TRIS accession number, which is a unique number assigned to each document. The subject area code and the subject area appear at the tops of the pages in the abstract and summary sections. The document record number appears at the top of each abstract. Abstracts within each subject area are listed in ascending order of the accession numbers, although these usually will not be consecutive. Examples of a report abstract and of a journal article abstract appear below.

ABSTRACT OF A REPORT



ABSTRACT OF A JOURNAL ARTICLE

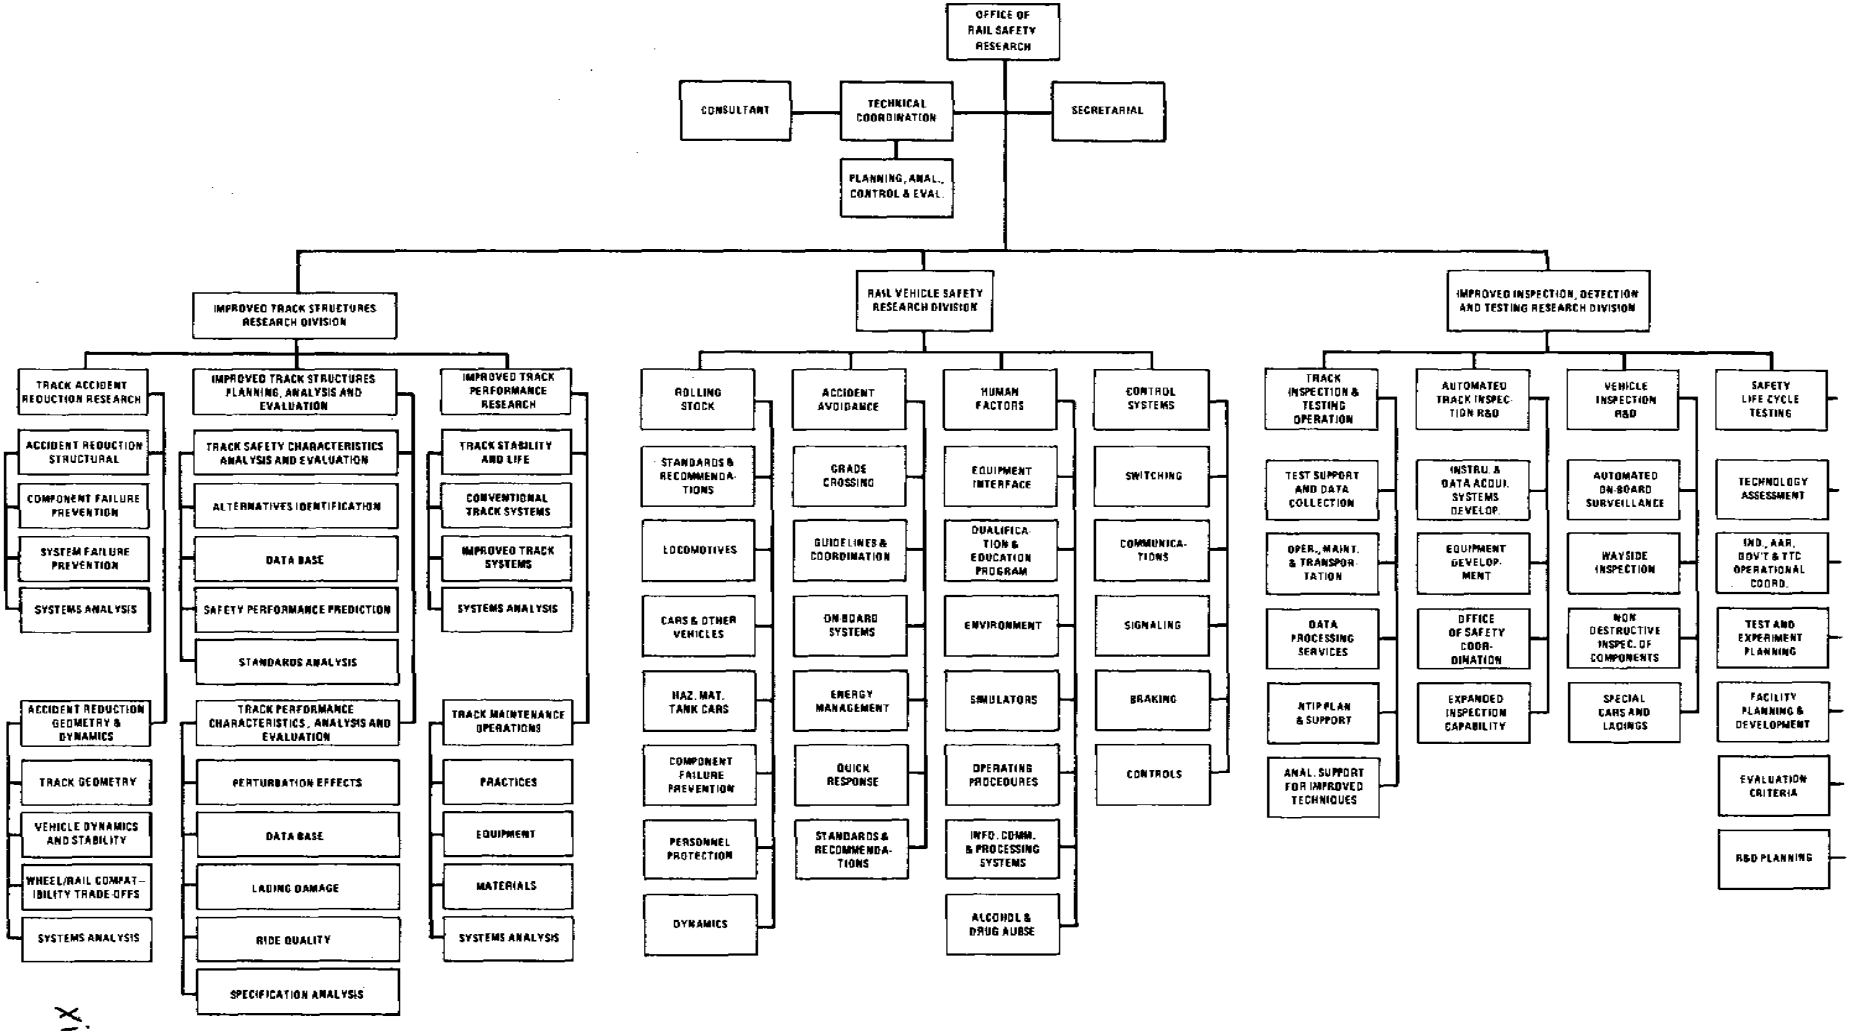
Figure 3. Organization of the Office of Rail Safety Research.



INTRODUCTION

The Federal Railroad Administration was created pursuant to section 3e1 of the Department of Transportation Act of 1966 and is composed of the Office of the Administrator, the headquarters offices, the Transportation Test Center, the Office of Northeast Corridor Project, and the Alaska Railroad. Included in the act was the transfer of railroad safety activities from the Bureau of Railroad Safety and Service of the Interstate Commerce Commission.

Under the Railroad Safety Act of 1970, FRA was given the responsibility to conduct and administer a program to ensure safe operating and mechanical practices within the railroad industry. The Office of Research and Development was organized and given the mission to "plan, conduct, promote, and coordinate research, development, and demonstration of all aspects of intercity ground transportation and railroad safety." As a result of continuing problems in existing rail systems, FRA's research and development activities were redirected in 1975 to near- and intermediate-term problems. Consistent with this redirection was the structuring of the research and development program into three offices to address specific customer needs.

The Office of Passenger Systems concentrates on developing practical improvements to existing technology that can be implemented by AMTRAK and other rail passenger operations. These developments will achieve lower operating and maintenance costs. The main areas under investigation include traction and propulsion, suspension braking, equipment, controls, train evaluations, and systems developments.

The Office of Freight Systems was established (a) to provide component and system performance specifications to the railroad industry (operators and suppliers) that will lead to reduced life-cycle costs and more profitable operations and (b) to establish a technical basis, including analytical tools and facilities, for the development of more productive freight systems in both the near and long term. Current research programs include dynamic analysis and evaluation, systems analysis and technology assessment, classification yard technology, equipment performance analysis, energy and environment, and intermodal freight systems technology.

The Office of Rail Safety Research was also created under the reorganization to plan, sponsor, and implement research and development programs designed to improve rail safety. In broad terms, the goals of the office are to reduce the rate of fatalities and injuries and the rate and severity of railroad accidents through the application of research results. To achieve these goals, the office is divided into three divisions, each of which conducts research in one of three main areas: improved track structures, rail vehicle safety, and safety inspection and defect detection of track, rail vehicle components, and systems.

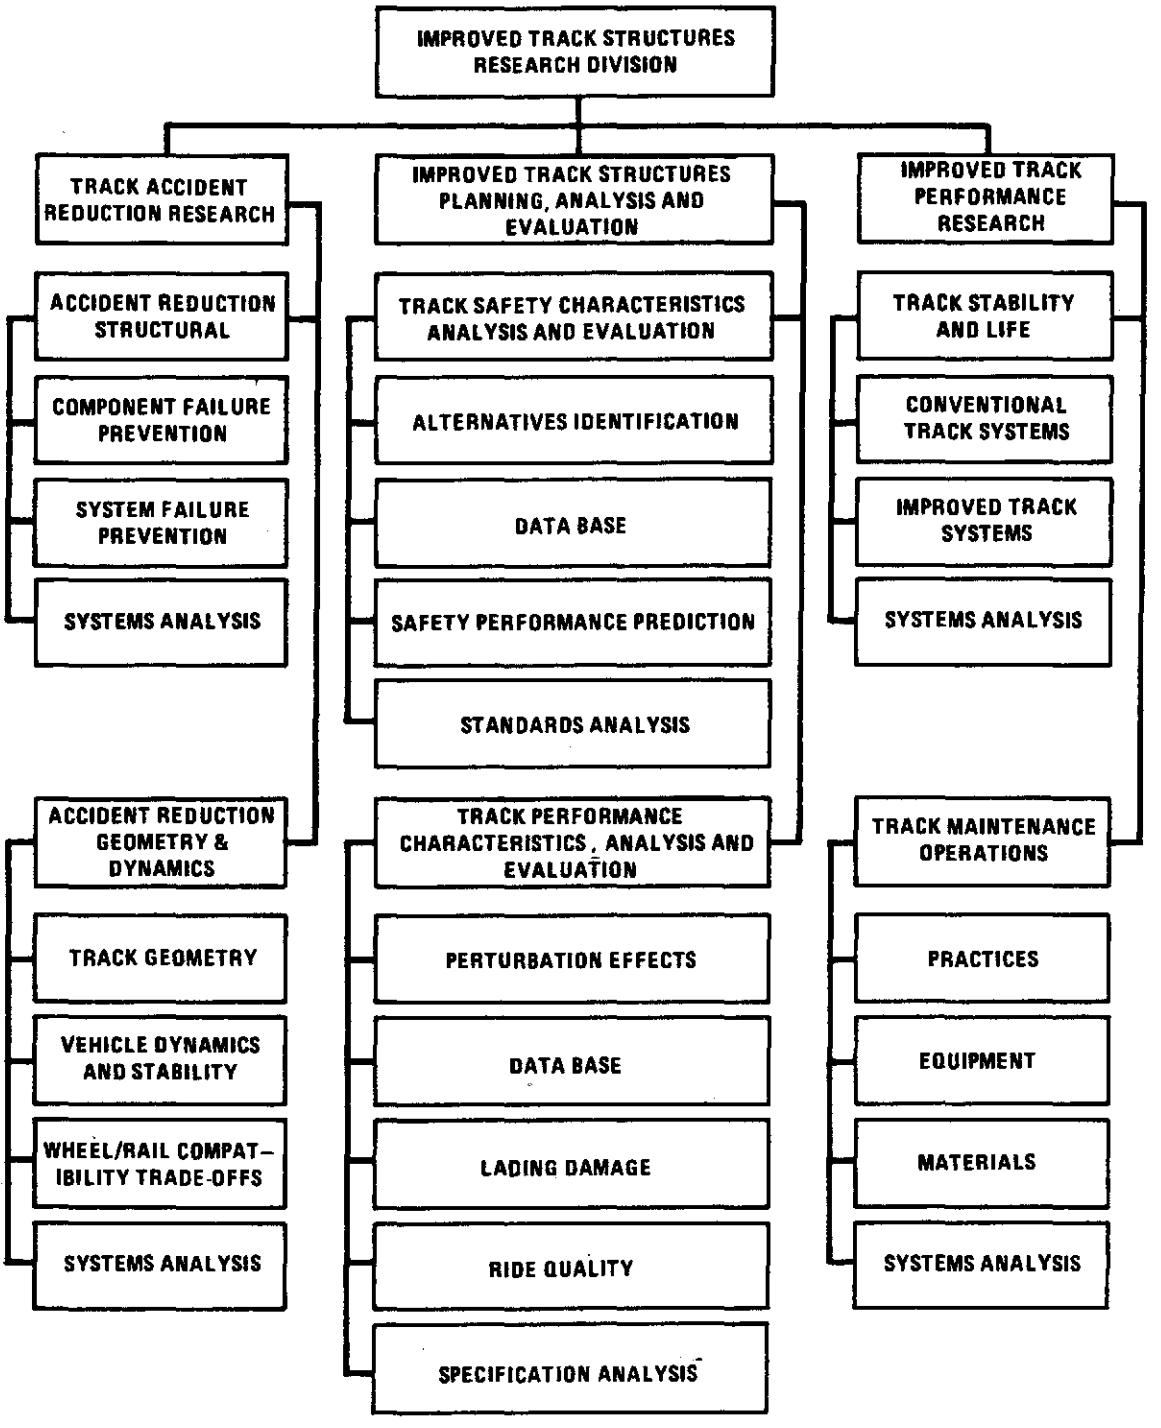
Research efforts are both planned and coordinated with potential users of the research results, e.g., FRA Office of Safety and Northeast Corridor Project Office, AMTRAK, and the railroad industry, including various government-industry-union research groups such as the Railroad Safety Research Board, the Locomotive Control Compartment Committee, and the Track-Train Dynamics Program jointly sponsored by the Association of American Railroads, the Railway Progress Institute, the Transportation Development Agency of Canada, and the Federal Railroad Administration.

IMPROVED TRACK STRUCTURES RESEARCH

Improved track structures research is directed toward (a) reduction in the number of track-caused train accidents and (b) more cost-effective track construction and maintenance procedures. The first case includes identification of safe minimum behavioral limits of track systems and components. The second addresses the domain of service-oriented, cost-effective track construction and maintenance methods.

Attainment of these two goals is being pursued through two distinct strategies. In the case of track safety, the objective is to identify the limits to which the track system and its components can be safely exercised. This includes specification of maximum track deflection under load, track geometry characteristics that adversely affect rolling stock, stress and fatigue limits of system components, and other conditions that cannot be exceeded without jeopardizing safe train operation. The research approach employed to reduce track construction and maintenance costs is to determine how the system breaks down and then work with typical materials to discover how to repair or reconfigure the system to achieve greatest durability at the least cost and to determine the most efficient method for maintaining the track structure.

Figure 4. Organization of the Improved Track Structures Research Division.



Abstracts of Reports and Journal Articles

A1 033083
WHEEL-RAIL ADHESION
The subject of adhesion between locomotive wheels and rails has been an area of vital interest to locomotive manufactures and to the railroads. Horsepower of internally powered locomotives has continued to increase significantly, thereby providing more power for traction. The trend of increasing horsepower has been the product of progress in technology and engineering development. Wheel-to-rail adhesion within the lower speed range has been a limiting factor in tonnage ratings for locomotives in drag service on U.S. railroads. Factors Affecting Adhesion are: (1) Vehicle Factors, (2) Track Factors, and (3) Contact-Area Common Factors. Additional discussion of the conclusions follows.

FRICTION CREEP PHENOMENON OF ADHESION BETWEEN STEEL WHEELS AND RAILS
The purpose of this article is to present a summary of the laboratory and field tests which have been conducted by EMD to evaluate the friction and creep phenomenon of adhesion between steel wheels and rails. The available adhesion coefficient between the driven wheels and rail is a primary factor in determining the amount of power that can be converted to tractive force by the locomotive. For this reason, experimental investigations into rolling contact friction-creep phenomenon were conducted on model equipment in 1968 along with full scale field tests on an SD-45 model locomotive.

STRESSES AT RAIL JOINTS AS INFLUENCED BY BOLT HOLES
The failures of rails caused by bolt holes of joints (end breaks) have recently come to occupy the majority of rail breaks. In order to prevent such breaks it was customary to reduce the diameter of the bolt holes or to keep the holes away from the rail ends. The present writers conducted experiments upon joints of the structure actually used for 50 kg/m rails, bolts of different diameters, rails with bolt holes of different intervals and fishplates with bolt holes of different diameters and different intervals with an aim of ascertaining what type of a fish joint is the most durable.

RAIL WEAR LIMITS
The Southern Railway, after reviewing rail wear conditions which were thought to have been a principal contributing factor to derailments, found that approximately 40 percent of loss of rail head wear for 130-132 lb. rail was the amount beyond which such derailments had occurred. Limits to show the top wear limit and side wear limit to be allowed for the different rail sections for various classes of track. The corresponding limits for the smaller sections of rail were pretty much a matter of judgment, using the limits for the 130-132 lb. sections as a guide.

EXPERIMENTS ON LOCAL STRESSES OF RAILS IN PRINCIPAL USE IN SEVERAL COUNTRIES
There is room for improvement in the current JNR standards for rail section with respect to their effectiveness as beam members and also to their pattern of distributed local stress. The project of the new Tokaido trunk line construction now being pushed forward has prompted JNR to the renewed design of its rail section from various angles since 1958. Laboratory and field tests were conducted for contributing to a better design to the two tentatively designed rail sections of 67 kg/m for the new trunk line and to the current 50 kg/m one, as well as to the five sections of imported rails.

FIELD TEST OF CORROSION PREVENTED RAILS ON THEIR ENDURANCE LIMIT TO RAIL END FRACTURE
In order to prevent rail end fracture by corrosion fatigue cracking, various measures for prevention of corrosion were examined by field tests. In the

preliminary test, 25 measures for prevention of corrosion were examined in tunnels under steam traction. Considering the test results, 4 measures were selected for life test. The most remarkable result of life test was as follows: In the tunnel, in which the mean life of non-treated rail was only 3 years, that of shot-peened rail covered with zinc metalicon was elongated up to 5 or 6 years.

FATIGUE STRENGTH TESTS ON RAILS
Fatigue strength data on rails have seldom been published. Japanese National Railways, in connection with the adoption of long rails (0.5, 1.0, 1.5 or 2.0 km) and speed-up of train operation, is vigorously pushing fatigue strength investigations as well as qualitative study of rails. Soundness of the welded rail is hard to evaluate through a mere external inspection; therefore, nondestructive testing methods such as ultrasonic, magnetic detection and mechanical methods such as static bending, repeated drop weight should be coupled with it. Present demand is to secure a sound welded rail in the field through fatigue strength comparison between the base metal of rail and the welded joint.

BEHAVIOUR OF THE METAL OF RAILS UNDER THE REPEATED ACTION OF WHEELS. STUDY OF THE FIELD OF STRESSES IN THE ELASTO-PLASTIC ZONE
This report contains the results of the various calculations effected so far. These can be considered as preliminary calculations carried out before proceeding to the complete calculation of the stresses in a railhead. The report likewise contains several analytical studies, both for the purpose of gaining a better insight of the stresses (the methods and the formulae are, as a rule, well known, though, generally speaking, the numerical results are not published) and for rendering possible a comparison of the results obtained by means of the numerical method with those obtained by means of exact calculations.

Restrictions on the use of this document are contained in the explanatory material.

MUTUALLY PERMISSIBLE WEAR PROFILES OF WHEEL TYRES AND OF POINTS AND CROSSINGS. ASSESSMENT CRITERIA FOR THE PERMISSIBLE WEAR PROFILES OF WHEEL FLANGES AND SWITCH COMPONENTS.
Studies include the investigation of the wear forms of a great number of worn wheel flanges used on various types of vehicles (passenger coaches, wagons, railcars, electric and diesel bogie locomotives) and of worn rails in areas containing points and crossings so as to obtain an adequate basis, adapted to practical demands, for arriving at a judgment. Starting from a characteristic wear profile of a flange a track guage was developed, permitting the verification of the compatibility of the wear profiles of the ironwork of switches with such a flange.

Measurements conducted using the gauge enable development of wear forms of rails endangering the traffic to be detected (particularly in sections containing switches and stock rails) and they indicate, at the same time, how this risk can be eliminated and how their use can be prolonged by reprofiling operations. The results of the studies are that it will be possible to deduce, from an analysis of the geometry of the contact between flange wear shapes and track, the compatibility criteria adapted to practical conditions and only requiring simple measures to be taken on the wheel and the switch work items (checking by means of the gauge). This procedure will lead to a decisive improvement of the riding safety of vehicles.

LATERAL STABILITY OF RAILS, ESPECIALLY OF LONG WELDED RAILS. ENQUIRY RELATING TO LAYING IN CURVES
This report discusses the results of a questionnaire to determine the state-of-the-art of welded rail. Includes discussion of the history of the uses of long welded rail, and of tests to determine the characteristics of such rail under varying climatic conditions. Report also covers track buckling tests at Karlsrule and London in the late 1950's and includes a chapter on the characteristics of track incorporating long-welded rail. Various theories on the stability of long welded rails are covered briefly, and an extensive bibliography is included.

Restrictions on the use of this document are contained in the explanatory material.

AN ANALYSIS OF THE RAIL CLIMBING TENDENCY OF A WHEEL AXLE SET AT VARIOUS ANGLES OF ATTACK
This analysis examines the rail climbing tendency of a wheel at various angles of attack. Static conditions (incipient motion or constant speed motion with no lateral acceleration or track irregularities) are assumed. The analysis shows no tendency for the wheel to climb the rail at any normal angle of attack.

RELATION BETWEEN SUPERELEVATION AND CAR ROLLING
Springs and links between car body and axles can be thought as a mechanical filter to isolate the car body from axle motion (except axle revolution). Then the problem to know the relation between track irregularity and car vibration is the problem to know the characteristics of this filter. there are three methods to study the characteristics. The first method is to calculate the characteristics theoretically from the parts constants. The second method is to know the characteristics by measuring the output of filter for special input. The third method is to determine the characteristics by analyzing the input-output relations for normal operation. No special equipment except measuring instruments is needed. Second, the effect of random noise can be cancelled out by statistical treatment of data. An application of this method is described.

TESTS OF PENNSYLVANIA RAILROAD ELECTRIC LOCOMOTIVES AT CLAYMONT, DELAWARE
In 1934 studies were made by the Pennsylvania of larger size electric motive power in anticipation of the heavier trains to come. A class R-1 locomotive was designed and built in 1934 with a 4-8-4 wheel arrangement. It was considerably heavier on the axles than the consulting firm which electrified the Pennsylvania deemed desirable, and they persuaded the Pennsylvania Railroad to borrow one of the new New Haven locomotives, which had a wheel arrangement of 4-6-6-4 and had a comparable axle load to the earlier class of Pennsylvania locomotives. The R-1 could not match the tracking flexibility of the GG-1, wheel arrangement of which was articulated. The GG-1 was safer and smoother riding at high speed with less destructive forces being exerted on the rail than the R-1.

ACCOUSTIC EMISSION TECHNIQUE FOR THE DETECTION OF FLAWS IN RAIL WELDS
An acoustic emission technique of testing for flaws in welded rail was conducted in June and July of 1969 at the Bellevue, Ohio, rail welding plant and at the Roanoke, Va., gas welding plant. Several welds by thermite, gas and electric welding processes were prepared for these tests under controlled conditions, with several samples of each process having artificially induced or included defects. This technique is entirely non-destructive and is accomplished immediately after welding so authoritative corrective action can be taken. Correlation was found between poor welds and high AE activity and good welds and lower AE activity. It appears that innovations and refinements will be required to obtain a practical "black box" of this type suitable for use on the railroads.

TRACK-TRAIN DYNAMICS STUDY PROJECT TR-14 RAIL-VEHICLE INTERACTION STUDY REPORT NO. 1 (PRELIMINARY ANALYSIS OF SAMPLE DATA)
As a result of various derailments, a task force was formed to investigate the

dynamic forces exerted by locomotive and freight car wheels against the rail. Critical study was directed at the 3 and 2 axle trucks of high horsepower locomotives, 85 feet TFC cars, and 50 feet box cars. The objective of this investigation was to determine if dynamic forces of sufficient magnitude to cause derailment were being generated by equipment, track structure and operating practice, and to recommend whatever corrective action might be indicated. Extensive field tests of wheel-rail interaction were conducted in various territories between Los Angeles and Pine Bluff, Arkansas. An analysis of these test results led to the following general conclusions: 1. Dynamic forces of sufficient magnitude to cause derailments are being generated in every day operation of revenue trains. 2. The forces are also sufficient to cause greatly accelerated wheel and rail wear. 3. Forces of sufficient magnitude to exceed the ability of the track structure to resist permanent deformation in alignment are also being generated.

THIRTEENTH PROGRESS REPORT OF THE COOPERATIVE INVESTIGATION OF FAILURES OF RAILROAD RAILS IN SERVICE AND THEIR PREVENTION

Since control cooling of railroad rails came into general use at all rail mills in 1936, a procedure has been established to study and properly classify all failures reported as transverse fissures in control cooled rails. It has been found that several of the reported transverse fissures are wrongly classified; however in a few cases such failures have been found to develop from defects other than shatter cracks, the usual cause of transverse fissures. Investigations have also been made of end-hardened rails in service. New methods of end-hardening rails are now being developed at several rail mills. Some laboratory tests have been made of these end-hardened rails and other tests are planned. A few control cooled rails developed transverse fissures or compound fissures from porosity, but no rails failed during this period from improper control cooling or shatter cracks. The detail fractures from shelly spots and head checks had mostly been incorrectly classified as transverse fissures while the web and base failures were sent to the laboratory for special investigation of each failure. Porosity is a newly recognized cause of transverse fissures which have been found in control cooled rails. No fissures from porosity have been found in rails from the three mills which do not reheat their blooms. This is rather strong evidence that the overheating of the blooms is the cause of the porosity. Rail fissures and porosity are illustrated in several photographs.

FATIGUE TESTS OF RAIL WEBS

The study of the fatigue strength of rail webs has been continued. Tests were made on T-shaped specimens cut from the web of a 112-lb RE rail, under a range of stress which simulated as nearly as possible stress conditions encountered in service, namely, a bending stress ranging from a maximum compressive stress at the surface to a tensile stress 20 percent as great. Since the fatigue failures were in compression, the cracks progressed very slowly, and the criterion of failure was taken to be the number of cycles when the crack could be first detected. Eight T-shaped specimens were cut from the same piece of 112-lb rail and were shot peened. Tests indicated that shot peening raised the endurance limit approximately 32 percent over that for the unstamped specimens with the surface as rolled. To get some measure of the reduction in fatigue strength resulting from corrosion, it was suggested that fatigue specimens be cut from a corroded or rusty rail and tested in the same manner to determine the amount of weakening due to a rusty, pitted surface. A short piece of very rusty rail was obtained from which specimens were cut for these tests. The curve for these date indicates an endurance limit of 57,000 psi at 10 million cycles, or a reduction of slightly less than 3-1/2 percent below that for the non-corroded specimens. To observe the effect of water corrosion on fatigue strength, several specimens were tested with tap water dripping continually on them. The fatigue curve shows an endurance limit of 56,000 psi at 40 million cycles, which is approximately the same as for the rusty rail specimens.

FIFTH PROGRESS REPORT OF THE SHELLY RAIL STUDIES AT THE UNVERSITY OF ILLINOIS

Several specimens of alloy steel were received for rolling-load tests to study their resistance to shelling. The chemical analyses, Brinell hardness and some physical tests of these steels, are given in Table 1. The heat-treated specimens were short lengths of rails and very little materials is available for physical tests until the rolling-load tests have been completed. Photographs of the shelling cracks for some specimens are shown. Heat-treated low alloy rails were much superior to any other specimens and compare very favorably with the 3-percent chromium rails and heat-treated carbon steel rails. The 3-percent chromium rail stood up to 5,000,000 cycles and the laboratory heat-treated carbon steel rolled 4,560,000 cycles before complete failure. The two tests made on the silico-manganese spring steel rails were discouraging as these specimens developed a brittle type of fracture after only 983,000 cycles and 657,000 cycles, respectively. Photographs of both of these failures are shown. The rolling-load tests of the as-rolled alloy steels were also discouraging as the best of these ran approximately one million cycles in the cradle-type rolling machine. These alloy steels could, or course, be heat-treated to produce physical properties which would give much better rolling-load tests.

DEVELOPMENT AND CHARACTERISTICS OF FRACTURES UNDER ENGINE BURNS IN RAIL TOGETHER WITH INVESTIGATIONS AS TO THE EFFECTIVENESS OF WELDING UP ENGINE BURNS BY OXYACETYLENE OR ELECTRIC METHODS

This is a progress report covering rolling-load tests and metallurgical investigations on engine-burned rails. In summary: a driver burn of a rail causes extreme hardness because of the development of a martensitic structure. This constituent develops from the process causing the burn, namely, (a) friction heating and (b) rapid quenching. The martensite transformation apparently creates quench cracks because of the volume change. The quench cracks greatly reduce the fatigue resistance and the rail may fail in a shorter time. Attention should be given in the repair of driver burns by welding, to removing parent metal containing quenching cracks beyond each end of the burned area in addition to the burned metal, before weld metal is applied. Study should also be given to means of making the weld to obtain a minimum of oxide inclusions. Numerous photographs document engine burns and quench cracks in rail.

THE EFFECT OF THE RATIO OF WHEEL DIAMETER TO WHEEL LOAD ON EXTENT OF RAIL DAMAGE

This is a report of progress on studies of pressure as affected by the area of contact between wheel and rail. One phase of this investigation involves the conduct of rolling load tests of rails subjected to wheels of various diameters and loads. To summarize, a depth hardness survey on a 112-lb rail removed from service after approximately 12,000,000 tons of traffic shows the maximum hardness to be at a depth of approximately 0.04 in. at a distance

of 1-3/6 in. from the center of the head toward the gage side, the maximum hardness being Rockwell C 34.6. Tests on a full section 131-lb rail under a 75,000-lb load after 1,333,000 cycles (100,000,000 tons) of testing are as follows: For the 33 in. wheel--a hardness of Rc 15 on the tread and a maximum of Rc 32 at a depth of 0.15 in.; for the 50 in. wheel--a hardness on the tread of Rc 23 and a maximum hardness of Rc 27.4 at a depth of 0.10 in. Using "mutilated" head specimens and a 50-in. wheel it was found that a 58,000-lb load could be carried for 100,000,000 tons, but that a 63,000-lb load would break down the rail tread after 15-45 million tons.

A1 033309
SECOND PROGRESS REPORT OF THE SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS
The laboratory studies of the cause and prevention of shelling of rail surfaces are carried on in cooperation with the AREA Committee on Rail, Assignment 11-Investigate causes of shelly spots and head checks in rail surfaces for the purpose of developing measures for their prevention. Low strength of the steel, as indicated by low Brinell hardness, seems to be a significant factor in the development of shelly spots on rails. No defects were found in the metal of these rails which might have contributed to the development of shelling. It was also found that the shelling on these rails developed differently from that described as starting internally in last year's report on shelly rails. Several photographs are presented to illustrate the shelling that occurred. The rolling-load tests to compare the flow of various kinds of rail steels under laboratory controlled conditions, described in the 1942 report, have been continued, and the results are now complete on 21 specimens. Eight rails have changed less than one hundredth of an inch and a ninth rail was only slightly over this value. In contrast to these rails are 12 rails which changed in profile over two hundredths of an inch. It will be noted that all the rails except two which changed in profile over two hundredths of an inch were below 300 in Brinell hardness.

A1 033311
INVESTIGATE CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL SURFACES FOR THE PURPOSE OF DEVELOPING MEASURES FOR THEIR PREVENTION
As the subcommittee investigates this subject more fully, it has been found that shelling is a much more serious and wide spread condition than was first realized, and while the shelly condition may be visible in some cases, in many others fractures of the rail may occur without the defect becoming noticeably visible on the surface of the head; therefore, it is doubly important that a solution be found. In addition to a study of rail-steel compositions, heat treatments, wheel and rail contacts and pressure, the subcommittee may turn to a study of mill practices as a possible cause of shelly steel, or it may finally resort to a consideration of larger diameter wheels or lighter loads on the wheels. If the answer lies in some special composition of rail steel or in heat treatment, the investigation must enbrace a study of the possibility that the new chemistry or heat treatment may give rise to some other types of defects or that they may lead to excessive difficulties or expense in production. While this assignment covers both shelling and head checking, very little mention has so far been made of the latter. At one time the subcommittee was of the opinion that one solution would cover both defects, but recent developments indicate that this may not be true. This report covers shelling only.

A1 033314
STUDIES OF THE PRESSURE AS AFFECTED BY THE AREA OF CONTACT BETWEEN WHEEL AND RAIL. EFFECT OF WHEEL SIZE
The following is a progress report on one phase of this investigation, namely, rolling-load tests in which wheels of various diameters are rolled to and fro on a short length of rail for the purpose of determining the number of cycles of load application required to produce failure. The results of the rolling-load tests to fracture show considerable "scatter" and no very marked difference between the results of tests under a 50-in. wheel and those from tests under a 33-inch wheel. The vertical wear on rail 757C (33-in. wheel) was 0.046 in. at failure, whereas the wear on rail 757C1 (50-in. wheel) at 580,900 cycles was 0.041 in. At failure, 750,100 cycles, the wear on rail 757C1 was 0.0425 in. A second type of test being tried to ascertain the effect of wheel size on the rail is to measure the depth of work hardening in the rail head. The rail head appeared to have been work hardened down to a depth of about 0.45 in. by the 33-in. wheel with a maximum hardness of 296 at a depth of 0.15 in. A test on a section from the same rail rolled with the 50-in. wheel appears to have been work hardened down to a depth of 0.20 in. with a maximum hardness of 269 at a depth of 0.10 in.

SPECIAL COMMITTEE ON STRESSES IN RAILROAD TRACK. SEVENTH PROGRESS REPORT
Since 1914 this committee has conducted analytical and experimental investigations on the action of railroad track under the loads of locomotives and cars running at various speeds and for a variety of conditions. The tests herein reported were made to obtain information on the action of various types of rail joints in track when subjected to the loads of locomotives and cars at speeds up to 90 miles per hour. Testing equipment enabled tests to be made accurately and expeditiously in a way that had not been accomplished before. Tests were undertaken particularly to obtain information on the action of different forms of rail joints in track under the traffic of locomotives and cars running at various speeds and to learn the magnitude of the bending moments developed in the joint bars as compared with those developed in the full rail away from a joint. It was also desired to learn if possible how speed of train affects these various matters. To serve as a basis of comparison, the stresses and moments and depressions of the full rail in the same track under the action of the same locomotive and cars were needed. Tests were conducted at Elkton, Md. The test site was on a 14-min. curve to the right with superelevation of 1-1/2 in. Ahead of and behind this curve the compound curve became 33 min. The total curve extended over a distance of about a mile.

ON THE LIFE OF RAIL
Annual trend of rail failures of the Japanese National Railways in recent years amounted to 5264 in 1963. There are included in rail failures the numbers of broken rails, cracked rails and defective rails all together, they do not always cause interference to train operation. It is known from the figures that end break ranks the first and amounts to more than 60 percent. The number of end breaks is divided into two parts, namely in tunnels and out of tunnels. End breaks in tunnels are more frequent for their track length and the rails in tunnel have shorter life than the ones out of tunnels, due to unfavorable conditions of corrosion in tunnels of our country. End breaks almost occur as results of rail fatigue by train loads. Stress induced on rail varies in magnitude according to train speed, wheel load, lateral force and position of wheel contact on rail, and the stress distribution was found in many measurements to be a normal distribution or its combination in most cases.

A THEORY OF THE DERAILMENT OF WHEELSET
In this study, in order to find out an allowable limit of derailment, the author made four assumptions and analyzed the simplest case where a wheelset derails. In order to prove the theory, the author made experiments by 1/10 and 1/5 scale model wheelset. The results of either case of 1/10 or 1/5 models coincide with theoretical values, and no difference was observed on the limit value of derailment by stationary side thrust having various kinds of radii of wheels.

A1 033324
SEVENTH PROGRESS REPORT OF THE JOINT INVESTIGATION OF FISSURES IN RAILROAD RAILS
The development of detector cars made possible the detection of many fissures before rail fracture had occurred, but it did not touch the problem of prevention of fissures. A "rolling-load" testing machine was designed and built which subjected a specimen of rail to repeated cycles of wheel load and bending moment. Before testing in this machine an etch test to detect the presence of shatter cracks was made on the rail from which the specimen was cut. Rolling-load tests showed the following results: Only shatter-cracked rails developed fissures, but not all shatter-cracked rails developed fissures. It is the complex stresses directly under a wheel load which cause cracks to develop into fissures. Bending moment tends to cause fissures to take a transverse direction, and accelerates their spread. No greater wheel load was required to start a fissure in a heavy rail than in a lighter rail. The minimum wheel load which started a fissure in the rolling-load tests was 40,000 lb. The wheel load necessary to start a fissure, the theoretical shearing stress in the zone where shatter cracks are located, the fatigue strength of rail steel, and the weakening effect of minute cracks (shown by fatigue tests of specimens) form a coherent picture of the mechanism of fissure formation and spread. The solution of the problem of preventing shatter cracks in rails was attacked by making tests of specimens from rails cooled in air and also controlled cooled. A large amount of study has been given to the problem of finding a nondestructive test which could be used to detect shatter cracks in new rails. Shatter cracks are so minute that changes, due to these shatter cracks, in properties or structure of metal around them, are masked by other variations in the metal. Unfinished work of the investigation relating to fissures includes formulation of proposed standards for control cooling of rails and for bend tests for acceptance of rails. Numerous photographs detail rail defects of the type described.

INVESTIGATE JOINT BAR FAILURES AND GIVE CONSIDERATION TO THE REVISION OF DESIGN AND SPECIFICATIONS
This assignment to investigate joint bar failures, included the study of cracks which may or may not lead to ultimate breakage. The two most common types of cracking are illustrated in Figures 1 and 2, namely, (1) fatigue cracks originating in the spike slot, and (2) fatigue cracks originating at the upper contact surface of the bar. To study possible means of eliminating the cracking of joint bars, tests in track and tests in the laboratory are being conducted along the following lines. 1. Resistance to cracking by improving the physical properties. 2. Photoelastic studies as to effect of design and bolt tension. 3. Fatigue tests, using full size bars of various design in assembled joints. 4. Observations as to the effect of saw swelling of the rail end.

SECOND PROGRESS REPORT--JOINT INVESTIGATION OF CONTINUOUS WELDED RAIL
Report of committee on welded rail includes a brief resume of past research and then continues into the present research area. The first covered is the testing of welded rail joints under repeated wheel load. The procedure, the endurance limit and fractures developed are included. A comparison between welds and joint bars was included. Metallographic tests of the welds are included and such tests as hardness, etching and metallographic examination of the welds are also included. Mechanical tests of the welded joints were also part of the test sequence. A complete comparison of the test are indicative of metal qualities rather than joints, and that the quality of metal is important to the joint strength as weld outline, cracks and other stress raisers in the joint.

ELECTRONIC EQUIPMENT TO ESTIMATE THE STANDARD DEVIATION OF TRACK IRREGULARITES
Discusses the data processing equipment used in a track inspection car of the JNR New Tokaido Line. This car uses the less expensive less complex system than that used in the MAYA 341. The car under discussion uses mechanical type equipment to inspect track for irregularities, changes because of slack, cant, etc.

MAXIMUM VALUE OF TRACK IRREGULARITY
To know maximum values of track irregularities in a certain length of track is necessary for those who maintain track for the safety of traffic and for those who are in charge of maintenance of way. States of track irregularities are represented by the following indexes: P: Index of track irregularity (probability exceeding plus or minus 3 mm) m: Mean value of track irregularities sampled at random sigma: Standard deviation of track irregularities sampled at random. If the mutal relation between the maximum value of irregularity and the irregularity index is ascertained, it will be very useful.

DYNAMIC EFFECT OF A FLAT WHEEL ON TRACK DEFORMATION
A series of riding tests was made to clarify dynamic effects of wheels (whose treads were set with flat spots) on the rolling stock as well as on the track at various speeds up to 200 km/h on the test run section of the New Tokaido Truck Line on December 7-11, 1963. In the present report, major test results concerning track deformation are outlined. Shock values resulting from rail bending stress and pressure between rail and sleeper grow rapidly with train speed, showing the peak at 20 to approximately 30 km/h, and thereafter up to 100 km/h, they gradually decrease.

PROTECTION OF RAIL JOINTS FROM CORROSION TO PREVENT RAIL END BREAKS
Many parts of the railway track including the rails are made of carbon steel. Carbon steel excels in strength but is prone to be corroded. Rail end breaks are considered as fatigue destruction caused by corrosion. Since stress and corrosion act at the same time, cracking is developed easily. It is because the fatigue strength of a rail decreases sharply in acid environments, that end breaks are more liable to occur in non-electrified sections than in electrified sections. Since corrosion has much to do with end breaks of rails in tunnels, the application of a proper protective method prevents end breaks of rails.

SHELLING OF RAILS EXPERIENCED IN JAPANESE RAILWAYS
In some local lines of the Japanese National Railways and in major privately owned railways and subways in the Kanto and Kansai districts, rail failures caused by shelling of rails are showing signs of increasing. AREA Committee for Rail Shelling says that in curved tracks, if the rail heads and wheel flanges are lubricated, the incidence of shelling increases, but if lubrication is stopped, head checks, flaking and shelling conspicuously decreased. Rate of progress of the fatigue caused by contact should be made to balance with the rate of the progress of the wear. Allowing some wear to arise and also preventing for large plastic flow to occur, such failure may be prevented.

EFFECT OF WHEEL FLAT ON THE CAR VIBRATION
A series of running tests was performed with the prototype "B" train for the new Tokaido line. The object is to investigate the effect of the wheel flat on the car body and truck vibration. The data were expected to give a reference for design and maintenance of car, and to give a base for determining the allowable limit of the flat length in practical operation. The running speed was 200 km/h for the flat up to 90 mm, and 50 km/h for 110 mm. So far as the truck and car body vibration is concerned, flat caused more vibration at a low speed than at a high speed. So car vibration is not considered the most decisive factor limiting the allowable length of flat.

CALCULATION OF THE LONGITUDINAL STRESSES, ACCORDING TO VARIATIONS IN THE TEMPERATURE, IN A SECTION OF LINE LAID WITH LONG WELDED RAILS
A comparison of these various hypotheses and their simplified diagrams, shows that the elastic behaviour of the ballast has a great influence upon the distribution of the reactions which start in the sleepers as a result of a variation in the temperature. Seeing that all the sleepers have elastic displacements, we can no longer speak about the fixed part or "respiration length". If concerned with large plastic deformations, the length will be found to be smaller than that taken for the rigid behaviour of the ballast. The exponential distribution, corresponding to the elastoplastic behaviour of the ballast is the closest to reality.

STRESSES ACTING ON THE RAIL--RECENT FINDINGS
Increased axle pressures and reduced wheel radii give rise to higher stresses in the rail head. If the permissible shearing stress is exceeded, fatigue fractures will occur in the rail head. This can be counteracted by using a steel of greater strength and purity. Also of importance are the additional flexural tensile stresses at the lower edge of the rail head. This permits an indirect measurement of the guiding efforts.

MEMORANDUM DESCRIPTION OF DERAILMENT
A memorandum discussing a derailment includes the vehicles involved (4 diesel locomotives, 112 loaded and unloaded freight cars) and the probable causes of the derailment. The scene of the accident is described, list of possible causes, with each discussed in detail. Causes are not clearcut, but probably the rolling of an empty car, the wheel of one track on that car hitting a rail joint on the outer rail of a curve, the upward force from car roll, the bad joint caused the wheel to run over the rail causing the derailment. It is suggested that differences in rail height at joints be limited to 1/16 in. and rail wear be limited so that wheel flanges will not be raised by joint bars when hit by wheels with worn treads.

FIRST PROGRESS REPORT LATERAL ACTION OF COMMON DESIGNS OF FREIGHT CAR TRUCKS HAVING AXLES WITH AND WITHOUT END COLLARS
The objective of certain instrumentation in the tests was to obtain fundamental information on the lateral action of different common designs of freight car trucks having standard and modified parts in the journal box assemblies, and having axles with and without end collars. It was desired to determine the motions of truck parts, and relation between these motions and lateral car body accelerations, and the origins of lateral disturbances to the car body, relative importance of these origins, and manner of transmission of these disturbances from the rail through the truck to the car body. A mechanical recorder was attached to one truck to obtain records

of the relative lateral movements of truck parts (axle, bearing, wedge, frame) at both ends of one axle, and records of the vertical and lateral displacements of both side frames relative to the bolster. The conclusions are as follows: The most important origin of lateral disturbance to the car body is the nosing of the wheel-axle assemblies and truck, due to coning of the wheel treads. The effects of axle end collars on truck action are to increase the activity of truck parts but to limit the forces transmitted through the truck. Increase of lateral clearance, which does not reduce the beneficial effects of axle end collars, should improve the lateral riding quality of conventional trucks with snubbers. Curved track produces a quieting influence on truck action and improves lateral riding quality. Definite improvement in lateral riding quality should result from the use of a device which would cause the car body to seek a centered position between lateral clearances.

TRACK-TRAIN DYNAMICS STUDY PROJECT TR-14 RAIL-VEHICLE INTERACTION STUDY--REPORT NO. 2 (COMPLETE ANALYSIS OF DATA USING COMPUTER TECHNOLOGY)

Following a description of the problem involved in preparing a hybrid computer program for the analysis and reduction of transient data taken in the actual field tests of the TRACK-TRAIN DYNAMICS STUDY PROJECT and an explanation of the computational approach, there is a description of the method of interfacing the digitized data with the digital computers used to obtain an in-depth engineering analysis of the results of the tests. The evaluation of the numerical data indicated that under controlled operating conditions, the L/V ratios were significantly repetitive, which fact can be helpful in future studies. However, the inability to measure the track lateral deflections simultaneously to obtain the combined effect of vertical and lateral displacements in the rail was a severe limitation, and it was not possible to derive any information concerning track stresses and probable damage due to high dynamic loads. Graphs and bar charts were developed from the computational results to show the relationship between speed, drawbar load and L/V ratios for locomotives and cars, and graphs were used to illustrate the accumulative distribution of dynamic rail deflections on various segments of the railroad where the tests were run. Parameters that were not included in the field measurements which could have possibly contributed to the establishment of a more definite pattern include: the relative velocity between instrumented cars, track curvature and truck hunting action and the cross-level of track.

JACKKNIFING OF DIESEL ELECTRIC LOCOMOTIVES REPORT OF THE JOINT COMMITTEE ON RELATION BETWEEN TRACK AND EQUIPMENT

A number of railroad companies had been reporting difficulties with diesel electric locomotives under buffing or pusher operation. This action was evidenced by lateral instability between the several units, especially those under the largest buffing forces and resulted in lateral displacements and lateral forces of such magnitude that the rails were turned over and derailments caused in some cases. To obtain as complete an understanding of the jackknifing action as possible it was decided to make measurements on both the locomotive and the track. A test location was picked on a right curve of 8 deg. 6'. The grade was 1.72 percent at the curve but within a mile became 2.20 and 2.40 percent so that part of the train on the steeper grade when the recordings were made. The rail was 131 lb. RE Section laid in 1946 and rather badly curve worn. The test locomotives were GP-7 Electro Motive general purpose road switchers. The following conclusions were drawn: Jackknifing is the result of lateral instability of the several units and its severity is dependent on the magnitude of the buffing force and the eccentricity of the force. It is evident the eccentricity of the force will depend on the amount of overhang and the clearance available for lateral movement. Reduction of the bolster clearance to a small amount improves the conditions sufficiently that operation is not excessively difficult. Lateral forces are reduced about 50 percent. Operation of the general purpose units with full bolster clearance and standard couplers under buffing forces is not practicable with four units and probably undesirable with three units. Forces of almost 25,000 lb were measured at 10 mph and 140,000 to 175,000 lb tractive force and higher forces can be developed at lower speeds or under impact conditions. These laterals applied continuously will be very detrimental to rail and wheels, cause journals to run hot, and may cause derailment. The use of the alinement control coupler attachments reduced the forces to a normal amount for the curvature of the test location. The lateral forces under full regenerative braking with alinement control couplers for an undetermined reason were a little higher in the few tests made than in the pusher operation which had twice the tractive force. However, they are still quite moderate. The jacknife position, once assumed, remains until the train is stretched out.

HUNTING PROBLEM OF HIGH-SPEED RAILWAY VEHICLES WITH SPECIAL REFERENCE TO BOGIE DESIGN FOR THE NEW TOKAIDO LINE
This paper describes the preliminary experiment on hunting by means of a model vehicle; the hunting tests of an experimental bogie and the prototype bogie at the rolling stock testing plant; a considerable amount of various hunting calculations carried out in the design stage; running test, with casual hunting observed, of the prototype bogies on the test track section of the new Tokaido line; and the construction of a bogie finally designed--and gives a number of major results with some discussion on the points to be considered. Elaborate running tests of six prototype cars were carried out on the test track section of the new Tokaido line. In designing this bogie, special attention was paid to the following two points to prevent hunting: (1) Mode of axle-box support and its stiffness: (2) Combination of frictional and elastic restoring force against bogie rotation. According to the running test at 246 km/h this bogie exhibited a very high running stability.

SOME ASPECTS OF THE HUNTING OF A RAILWAY AXLE
Equations of motion are derived to describe the hunting mode of a railway axle running at constant velocity along straight track. It is assumed that the wheel and rail-head profiles take some arbitrary shape. This shape gives rise to non-linearities in the equations. The equations are first linearized, and approximate expressions derived for the frequency of the oscillation and conditions of stability. Asymptotic stability for all initial conditions of the non-linear system is then considered in the manner of Aiserman, and the equations are examined for stable limit-cycle by applying the first approximations of Kryloff and Bogoliuboff. It is shown that, when running at low velocities, the axle will execute limit-cycle oscillations even though the wheel's flanges do not contact the rails. Small increases in velocity, however, quickly result in flange contact.

WELDED RAIL JOINT FRACTURES AND THEIR EFFECT ON 200 KM/H OPERATION
JNR conducted a series of tests to determine the effect of broken welded rail joints on trains running at high speed. A rail gap of 20 to approximately 30 mm was employed since this was considered the likely amount just after a rail fracture in winter on the New Tokaido Line. The train used for this test consisted of six 2-axle bogie type electric rail-cars with an axle-load of 15 tons. Items measured included: rail deflection, rail stress, stess on the fastening device, track vibration acceleration and sleeper stress and the like; most of these were measured using wire strain gauges. On-the-rolling-stock measurements included: wheel side thrust, whee load, bogie stress, car body vibration, axle box vibration and similar forces. The results of the test indicate that train operation on the New Tokaido Line is judged as completely safe from the point of view of possible broken welded rail joints, in that even the lateral discrepancy of ends of the broken rails and wheel side thrust at the train passing the broken point were found to be less than 1/2 of respective maximum limits for safe train operation, and values for car body vibration and other items were also found to be sufficiently small.

DERAILMENT OF ELECTRIC PASSENGER TRAIN
The derailment of the last coach of an electric multiple-unit down passenger train on December 13, 1963, which subsequently came into glancing contact with the side of another passenger train, was caused by axle fatigue. This fatigue would have been detected if the prescribed frequency for ultrasonic inspection had been observed. It was suggested that no axle be tested less frequently than every 18 months. One passenger was killed and 31 injured.

INQUIRY INTO DERAILMENTS ON THE VICTORIAN RAILWAYS
This summary of a committee of Public Accounts inquiring into derailments during the years 1954-1964 examines the incidence of hot boxes, fracture of axle-box guides, track defects, mileage and ballast with total derailments.

The conclusions were that the recent increase in freight trains derailments was due to the use of four-wheel wagons and poor track conditions on low traffic country lines. Also, cross ties were in poor condition on some lines, and ballast was inadequate.

RAIL FAILURE DETECTION IN THE UNITED STATES
The major components of inductance, residual magnetic, and ultrasonic instruments for detection of flaws in rails are described. The Association of American Railroads report for 1964 correlated the drastic reduction in service failures due to transverse defects with the success in controlled cooling of the rails during manufacture, although the number of failures detected using the above NDT methods remained fairly constant. It was concluded that the $400,000 cost of the flaw detection services was well worth while in the USA, but could not be justified in the United Kingdom due to the use of different steel for the rails.

TRACK STRESS RESEARCH
The purpose of this work was (1) to verify the speed allowance formula, (2) to investigate the increment of stress over and above the static effect under normal conditions from track defects, (3) to investigate the conditions of support at rail joints, (4) to investigate the stability of ballast, and (5) to investigate the effects on rails and sleepers of the lateral forces set up by the hunting movement of locomotives. In regard to (1) and (2) it was found that experimental static deflections and stresses are in reasonably close agreement with calculated values. In regard to (3), it was concluded that stronger fishplates are needed to facilitate maintenance and rail joints of inadequate strength are the cause of much of the impact effect. Increasing the number of sleepers will reduce this impact effect. In regard to (4), the shape of the sleeper was found experimentally to have no noticeable influence on its deflection under a given load, but stress distribution between the sleepers and subsoil requires investigation. In regard to (5), further investigation on curved track was recommended to confirm the consideration that design to rolling stock to reduce nosing on the sharper main-line curves would reduce the secondary stresses and thus offset the increased stress due to centrifugal effects.

DERAILMENT AT KENTISH TOWN
The accident report describes the incident of derailment of an empty freight train and the consequent collision with a passenger train. Cause of the derailment was due to part of the brake rigging on the leading bogie of the fourth coach striking and operating an economic facing point lock with the result that the trailing bogie and following coaches took the wrong route. Evidence showed that the trailing end of the brake pull rod of the coach had been dragging along the track during an overnight journey. The pin which should have secured the pull rod to the fulcrum lever was missing, and both safety loops were broken. An on duty coach examiner improvised safety loops of wire. Conclusions reached were: (1) the improvised safety loops were ineffective, (2) the examiner made error in judgment in not removing the brake pull rod completely from the bogie, or at least releasing the brakes on the coach before securing the pull rod, (3) failure of R.R. staff to detect broken safety loops indicates examination of the train was not adequate.

ACCIDENTS ON BRITISH RAILWAYS IN 1960
A comparison of accidents, deaths, and equipment failures for the years 1959 and 1960 show that there were a total of 1213 train accidents in 1959 (1175 in 1960). Out of these, passenger and freight trains were involved in 416 in 1959 (415 in 1960). The total accidents at level crossings were 231 (1959) and 242 (1960). Deaths at level crossings totaled 37 (1959) and 35 (1960). Railway personnel deaths were 160 (1959) and 143 (1960). Failures, including engines, couplings, and rails amounted to 1271 in 1959 and 1395 in 1960.

FLAT-BOTTOM RAIL DEFECTS
In 1944, 38,708 transverse fissure failures were reported, of which 31,781 were discovered in advance of actual failures by patrolling detector cars, and 6,927 were in rails that broke in the track, in certain cases with disastrous results. The use of flat-bottom rails in Great Britain will increase the need to control the cooling process during formation of the rails. The British medium manganese rail is less susceptible to fissure failure due to its lesser carbon content, 0.6 percent carbon in British rails compared to 0.7 to 0.8 percent in U.S. Rails. In the U.S. a troublesome defect is the shelling or flaking of rails on the gauge corner of the head. This problem is prevalent on the high rail of curves where traffic conditions are severe. No direct connection has been found between the chemical composition of rails and their susceptibility to shelling, except in so far as the hardness of the steel is affected; heat-treated rails and rails containing 3 percent of chromium have given better results than rails of standard composition. Water quenching can produce weeping cracks in steel. Steel with Brinell hardness after end quenching in the range 360 to 375 were not susceptible to weeping cracks. There is a continuing need for a fishplate steel of reduced notch sensitivity. High manganese alloy fishplates have given good results, but are costly.

LATERAL TRACK STABILITY TESTS
On January 15, 1966, an Illinois Central train south bound near Barkley Dam, Kentucky displaced the track without derailment under the loaded train. The train consisted of five locomotives, one of them isolated with 140 cars loaded mainly with coal and 53 empty totaling 14,999 gross tons. The train displacement was 10 inches off line. The train was braking due to a shallow decline at the displacement. This series of memos describes the displacement and the design and results of tests to determine the displacement face necessary to move the track 1/4 and 1 inch. A conclusion is not reached as to the cause of the displacement. Two opinions are given as to possible causes.

RAIL FAILURES
A train, travelling at slow speed on the down line between Tweedmouth and Kelso in 1941, was derailed by a rail broken in 12 pieces. The rail, laid in 1890, was a 90-lb one, with an average yard weight at the time of the accident of 83 lb. It was situated inside a 19-ch. curve, provided with check rails and 3 in. of super-elevation. Slipping with a heavy load when accelerating from rest was the cause of the rail failure. The heat generated by the slipping was estimated to reach about 700 C. Slipping had occurred over a several week period, but was most pronounced within two days of the derailment. Sections of the rail were subjected to falling weight tests. One piece dropped with the head up broke at 7 feet. The other piece dropped head down, broke at 1 foot.

HOW RAILS BREAK
The manufacturing defects described are in ingots; in rolling methods; a transverse fissures, the fractures caused by stresses set up in cooling. The failures described arising from service conditions may be caused by excessive wear; fatigue or impact; rail-end batter; corrosion in tunnels, at water troughs, or at wet ashpits; slipping by wheels; faulty heat treatment, welding or cutting; corrugation; or war damage. Rail failures in India in 1929 due to rolling defects resulted in the use of impact testing on the side of the rail-head being added to test specification. The temperature equalization scheme adopted by British mills in 1928 to avoid transverse fissures is given.

PURPOSES AND REQUIREMENTS OF TRACK INSPECTION AND MEASUREMENT
This is the first part of a two-part study prompted by recent interest in automated inspection devices and systems. This first portion, deals with the general questions about inspection such as why is track inspected, what is being looked for, when and how often inspection should be done rather than how it should be done. The first is as a fundamental guide to procedures and purposes of inspection, and for an examination of what may or may not be wrong about the way inspection is now being performed. The track materials inspection should include: the load bearing function of the track; the effects of loading on deformation and rupture and wear and abrasion, and on fatigue; and the environmental effects. The present inspection methods are given for rail, cross ties, switches, turnouts, crossings, and ballast.

DETECTION OF RAIL FAULTS ON SNCF
French National Railways methods of magnetic examination of rails in service are so successful that 95 percent of all rails lifted in 1967 for transverse cracks were as a result of inspections made on only one-sixth of the main lines. The development of transverse cracks in the rail head generally follow an exponential law related to the traffic carried. A transverse crack increases by 10 percent of the section of the rail head and with an initial detection at 55 percent by the electromagnetic process, the risk of breakage is reached when about 15,000 tons have passed over the track.

SETBACK IN BR SAFETY RECORD FOR 1967
The marked increase in the number of freight train derailments, from 1963 to 1967, is attributed to the rapid changeover from steam to diesel locomotives hauling unbraked or partially-braked trains consisting largely of old short-wheelbase four-wheel cars. The British Railway is retiring the short-wheelbase, four-wheel cars and replacing jointed track with continuously welded track to reduce accidents.

DERAILMENT NEAR HITHER GREEN
An express passenger train, consisting of two six-coach diesel-electric sets, derailed near Hither Green at about 70 mph, when the leading pair of wheels of the third coach struck a wedge-shaped piece of steel that had broken away from the end of a running rail, and became derailed. The initial derailment was caused by the fracture of a rail as the train was passing over it. The fracture was caused by excessive working of the joint resulting from unsatisfactory support conditions including: inadequate clean ballast under the two original concrete joint sleepers; the absence of a rubber pad under the rail seat; and substitution of a wood sleeper for the running-off concrete sleeper which cracked because the pad was missing. Due to unsatisfactory track maintenance, a speed restriction of 60 mph was placed on the track.

DERAILMENT NEAR AMBLE JUNCTION
The train, travelling at 75 mile/h, became derailed at a broken rail. A piece had broken away from the head of the six-foot rail at the running-on end. The rail had also broken completely about 8 in. from the end. All eight keys for four sleepers on the approach side of the joint, and the cess rail keys for the first four sleepers beyond the joint, were out and lying beside their chairs. Examination of the broken rail stated that the 95 lb/yd bullhead rail had broken to detach a piece of the head and a section of the web and foot. Both fishing surfaces were highly polished, indicating that the four-hole fishplate had been working for some considerable time. The small flaw at the upper fillet radius of the rail end would be impossible to detect with the Audigage instrument because of its small area. Similarly a crack less than 1/4-in. in extent is unlikely to be found at the bolt hole.

BROACHING HOLES IN RAILS
Anything that can be done to reduce bolt hole stresses will increase the fatigue life of rails. The perfect result is achieved by completely eliminating fishbolt holes. Four methods of improving fishbolt holes are: 1. careful drilling to produce holes of smooth fish; 2. radiusing the edges of the holes; 3. reducing the diameter of the holes; 4. work hardening the internal surface of the holes. Work hardening the hole is achieved by forcibly increasing its diameter after the initial drilling. The fatigue strength of the drilled rails is improved by at least 25 percent by work hardening.

TRACK STRESSES AND VEHICLE MOTION AT HIGH SPEEDS
The high speed test runs made with the locomotives E 10 299 and E 10 300 and 8 wheeled track recording cars and passenger cars are described. Extensive measurements were made of the stresses to which the track is subjected at train speeds of 140 to 200 km/h, and of the dynamic wheel loads and lateral pressures against the rail, as well as the effect of these forces on the roadbed. The results of these tests on curved and straight track are given and illustrated by charts. The present usual track structure will suffice for the high speed operation. The minimum radius of curvature should not be under 1890 meters. Continuous welded rail improves the riding qualities in high speed operation. A desirable riding comfort level is attained in the passenger cars at 200 km/h speeds.

A1 037597
THE NATURE, MAGNITUDE, AND FREQUENCY OF LOADS AND FORCES APPLIED TO RAILROAD ROADBED
The magnitude, nature and frequency of loads imposed on railway roadbed by track structures and by traffic on the track structure is summarized for use by engineers in designing alternate types of roadbed construction. An SD-40 locomotive was studied to test severe loads Magnitude of reactions in the roadbed depends not only on the loads themselves but also in the spacing of the loads and the type and composition of support. In conventional track, the contact pressure on the bottom of a tie is not uniformly distributed either laterally or longitudinally. The total load on an individual tie depends on track conditions, size and distribution of load, and size, spacing and condition of the ties. There are traditionally two ways of handling impact loads, i.e. "equivalent static load" and "energy load." Of the two, "equivalent static load" is usually given for railroad situations and will be used here. Longitudinal loads come from inherent stress (from manufacture and laying of rails), reaction to locomotive traction, wheel flange friction and braking, thermal rail stress, and longitudinal component of train weight on grades. The longitudinal component of train weight can be calculated statistically knowing gross weight, grade, length of train, etc. Fortunately, this load is not concentrated but is spread out over a considerable distance. With conventional track construction the perpendicular component of train weight increases the frictional restraint of ties in ballast so that this is of little consequence. Longitudinal loads applied to the track by traffic have been the subject of considerable study in both this country and Europe. They are difficult to analyze because they are affected by so many variables, and uncontrolled variables at that. Transverse, or lateral, forces are particularly important since if they exceed roadway resistance they cause unstable alignment or buckled track and likelihood of derailment. Mathematical calculations show the rail reaction for the SD-40 on 122 lbs rail.

LATERAL RAIL FORCES DUE TO VARIOUS LOCOMOTIVE AND TRAIN CONSISTS
A series of tests was performed to determine the lateral forces developed by various types of locomotives and train consists. Analysis of the data indicates that no excessive lateral forces were developed by any of the test consists. The maximum average force, 7,400 pounds was developed by the T.P.F.C. freight. The effect of roadway irregularities on lateral forces generated by normal consists remains largely unknown. Based on the results of this test series, it is concluded that light locomotive, passenger and freght consists generate relatively low lateral force on good roadway. There is a slight reduction in maximum lateral forces as training tonnage is increased. A study of the available research literature on the forces required to overturn rail shows that the maximum pressures measured were about 30% of the forces theoretically needed.

MAUL BLOWS ON WEBS CRACK RAILS AT LOW TEMPERATURES
The fact that the webs of rails can be fractured readily in cold temperatures by heavy spike maul blows has been demonstrated by laboratory tests. These tests in which rails were chilled to a temperature of 20 deg below zero and then struck on the web with a spike maul while at temperatures ranging from 13 deg below zero to 25 deg above zero, point to the danger of heavy blows on the web of a rail, particularly under low temperatures, at any time during its life. The second series of tests were made for the purpose of determining to what extent if any rail design might influence the development of cracks from spike maul blows. Summarizing this second series of tests, it was observed that cracks were produced in one or more specimens of all rail sections included in the tests. Concerning all of the tests, it is of interest to note that cracks were produced irrespective of the branding, stamping, rail position in the ingot or rail section. "It may be concluded from these tests that it is entirely possible to produce cracks in the rail web by striking the web a heavy blow when at a low temperature."

LONG WELDED RAIL INVESTIGATIONS
The Western Region of British Railways has been carrying out valuable investigations into the behavior, control, and economic factors relating to long continuous lengths of welded rail. The test lengths of long welded rail in South Wales were subjected to apparatus for measuring and recording movements of the rail. Nine pairs of instrument stations 100 yd. apart were initially established with recording instruments grouped at a central point. The behavior of the track recorded was mainly longitudinal movement due to changes in temperature but transverse movement was also registered. Laboratory static tests were for resistance to longitudinal movement of a rail through its fastenings, and a dynamic testing machine was also evolved for equating track loading and deflection under the equivalent of the passage of a locomotive at 60 mph. Long continuous rail lengths carrying fast traffic must be provided with ample ballast and a firm foundation. Maintenance must be to a first-class alignment and special attention must be paid to the maintenance of the fastenings. More accurate means of costing maintenance will also have to be devised for ascertaining the economics of long welded rails.

WELDED RAIL IN THE U.S.A.
The elimination of rail-joint maintenance is claimed to be more than covering the additional cost of welding, transporting the welded strings to site, and handling them. In general, few troubles have been experienced. Expansion and contraction at the ends of welded strings has been little more than normal, and has been restrained by increasing the number of rail anchors applied over the last six lengths of rail (234 ft) at the end of each string. Given proper anchorage, no trouble is experienced with buckling, but that considerable care has to be exercised as to the temperatures at which continuously-welded rail is surfaced.

LONG-WELDED RAILS ON EAST COAST MAIN LINE
The first long-welded rails on the East Coast main line were laid on a section of line where a continuous stretch of almost a mile now exists. Normal 60-ft. rails were first flash butt welded into 300-ft. sections. On the site, the ends of the rails to be joined together were held in a mold and heated. A mixture of powered metal and magnesium was ignited and the powered metal melted into the gap between the rail-ends. The mold was knocked off as soon as possible and spare metal trimmed by cold chisel and grinder. Each weld took about 45 min. to complete.

A1 037669
"FROZEN" RAIL JOINTS
The Delaware and Hudson, on its main line stretching from Albany, New York, to Montreal, has experimented with frozen joints for continuous-welded rails. For frozen joints, the rails are laid tight, allowing for no expansion at the joints. The elimination of joint maintenance is a main argument in favour of welding into long lengths. The weld itself is expensive, not to speak of the extra cost of handling the long lengths of "ribbon rail." Furthermore, if a rail is damaged, it can easily be replaced, whereas with ribbon rail the section damaged has to be cut out. There may be extensive potential maintenance economics to be effected by laying rail tight with frozen joints.

LONG-WELDED RAILS
A comparative study of methods for welding very long rails was made for Great Britain, South Africa, New Zealand, Australia, Sweden, Japan and the U.S.A. The use of long rails is largely experimental and no definite policy has been reached as to the length of section to be laid with them. Wood, steel, and concrete sleepers are being used and their numbers vary from 1,240 to 1,920 per km. Methods of fastening the rails to the sleepers include dog spikes, elastic spikes, clips and bolts, and cast iron chairs with keys. The most favored method of manufacturing long-welded rails is by flash-butt welding in the depot into transportable lengths and then by thermit welding into long sections on site.

SPECIAL COMMITTEE ON CONTINUOUS WELDED RAIL
Rolling-load tests were made of specimens of continuous welded rail in the 12-in stroke machine on four acetylene welds, 4 electric welds, and 4 thermit welds. All of the thermit welds failed in this test. One acetylene weld also failed just below 2 million cycles. Other rolling-load tests were made in a 33-in. stroke rolling machine primarily to test the welds in the rail bases. All the acetylene and electric welds ran to over 2 million cycles without failure. Two thermit welds developed failures in the rail heads. A few other observations on possible causes of weld failures are listed, including grinding burns electrode burns, and cases where the flame goes out in oxyacetylene welding. The fastenings subcommittee reports five methods used to anchor welded rail across open-deck steel viaducts or long deck steel spans.

FURTHER THREE-DIMENSIONAL PHOTOELASTIC STUDIES OF STRESSES IN RAIL HEAD DUE TO WHEEL CONTACT PRESSURE
A transparent model of a rail head about two-thirds scale was constructed and tested. The model testing showed that the three principal stresses are compressive immediately under the wheel, but as we go away from the wheel both to the right and to the left, all these compressive stresses become tensile. The main difficulty in this study was not studying the stresses in the model of the rail head or the rail, but rather from the difficulties of interpreting the meaning of the stresses in relation to shelly rail failures, or failures in general.

MEASUREMENT OF RAIL HEAD WEAR
A novel method of rail wear measurement is being used on the London Midland and Scottish Railway in order to compare rails of special composition or rails which have been specially treated to increase resistance to wear. The apparatus is simple, and consists of a jig formed to the contour of the part of the rail to be measured, and a dial gauge reading to 0.5 in. by 0.001 in. graduations. The actual gauging can be done at the rate of about one minute per section.

VEHICLE DESIGN RELATED TO TRACK CONDITIONS
Recommendations which may influence improvements in the safety and comfort of passenger-train rolling stock are made in a paper, Vehicle Suspension and Bogie Design in Relation to Track Conditions, by Mr. R.M. Hancock of British Railways. The paper deals with the necessity of relating vehicle suspension and bogie design to the track conditions likely to be encountered in practice, particularly where lateral and crosslevel wave shape are concerned, as these are most likely to produce discomfort. The vehicle-response basis of systematic testing main routes as carried out with the Western Region track-testing car has provided much of the experience from which the illustrations in the paper are drawn. The effects of coning and track shape, in relation to the riding of four-wheel vehicles, are considered with reference to an investigation of their derailment in fast trains.

LATERAL FORCES BETWEEN WHEELS AND RAILS, AN EXPERIMENTAL INVESTIGATION
The paper deals with a new method of measuring continuously the lateral forces between the wheels and the rails over long distances. Fundamental knowledge concerning these forces has been obtained both from studies of the results from short test runs and from statistical assessments of the results from long sections of the Swedish railway network. Since the tests are concerned only with a single locomotive, the results should not be generalized. It is clear, however by means of the individual diagrams of curve forces as well as the statistical evaluation of about 40 curve runs, that the lateral forces between the rails and the wheels of the leading axle are on the whole substantially greater than the resulting force on the permanent way. This factor should be all the more noticed, since the utilized friction coefficient can assume such unexpectedly high values, as is shown from the measurements.

THOUGHTS OF A CURVE DERAILMENT
The derailment of the New York Central New York to Chicago express on April 19, 1940, at Little Falls curve is described. The train was about half-way around the curve travelling 14 mph in excess of the stipulated limit when derailment occurred. Speed alone was not responsible for the accident. A locomotive inspector had instructed the driver to brake. It is believed that the driver either became confused and closed the throttle or applied the brakes which slowed the locomotive much slower than the remaining train and caused the jack-knife action between the engine and tender.

THE EFFECT OF LONGITUDINAL FORCES ON CONTINUOUSLY WELDED TRACK AND ON TRACK BALLAST
The properties of the ballast under the influence of longitudinal forces or longitudinal stresses in continuously welded track are discussed. The first

part of the paper deals with the different causes of longitudinal stresses. The second part is concerned with research on the mechanical properties of the ballast. From theoretical considerations and on the strength of test results, characteristic data for the resistance to longitudinal displacement are obtained. The third part deals with measurements of rail stresses encountered in tracks under traffic. A description is given of investigations based on train braking tests on continuously welded track.

TRACK MAINTENANCE AND HIGH CAPACITY TRUCKS
The high capacity truck from the maintenance of way standpoint is the means by which the increased gross weight of the large modern freight car is transmitted to the track, roadbed, bridges, trestles, viaducts and culverts, over which it must pass. As such, its design, dimensions and position are of vital concern to those responsible for the satisfactory operating condition of the railroad. Stress in rails and joint bars, track deflection, maximum load on ties and effect on undergrade bridges require specific consideration in determining whether or not a car can be accepted for movement; and if so whether it will be free-running or whether it will be restricted as to speed and routing. An immediate concern in relation to high capacity car trucks is the anticipated increase in shelling rail failures due to increased bearing pressure. Shelling rail failures are the result of the plastic flow of metal from the middle portion of the head toward the guage corner under high shearing stresses produced by intense wheel loads eventually starting a horizontal crack. The Joint Committee on Relation between Track and Equipment has recommended maximum axle loads of 52,800 pounds on 33 inch wheels, 58,400 pounds on 36 inch wheels, and 62,400 pounds on 38 inch diameter wheels.

CAR ROLL AND WHEEL LIFT, PROBLEM CHARACTERISTICS
The problem of car roll becomes more acute as the height of the center of gravity of the car body and lading is increased by greater car heights; and as car lengths are increased to the extent that the distance between truck centers approximates a standard rail length. While severe car roll is objectionable the most serious immediate consequences are wheel lift and resultant derailments. Commulative roll can develop very quickly to cause wheel lift. With rail joints 3/4-inch low, wheel lift can develop in four rail lengths at critical speed. Wheel lift can also be obtained on track with joints only 3/8-inch to 1/2-inch low if the joint stagger is midway and uniform, all joints are equally low, and the critical speed is maintained for about ten rail lengths. Fortunately, only a small percentage of wheel lifts result in derailments. When car roll is severe enough to cause wheel lift, there is a sizeable lateral force in the direction of the wheels staying on the rail, so that on tangent track, the wheels that are lifted simply come back down on the rail. In addition to the derailment hazard possibility there will be an increase in fatigue failures of journals, wheels and rail near joints as the result of the repeated high wheel loads being sustained due to severe rolling of heavier cars on track with less-than-perfect rail joint conditions.

CAR ROLL AND WHEEL LIFT, PROBLEM SOLVING APPROACHES
The author discusses the problem of derailment and larger hopper cars as a two step process, (1) problem definition and (2) the selection of possible solutions or alternatives. It is pointed out that not all 100-ton cars derail. Only a relative few derail and, those which do, derail at more or less predictable locations. In the rail-versus-car controversy, it is obviously not very reasonable to spend the money to overhaul every mile of railroad track, nor is it any more reasonable to condemn the 100-ton car since it is one of the major factors contributing to increased railroad business. One possible solution might be to correct the very bad areas of track where the rail joint conditions produce severe dip, and the track arrangement is such that roll is reinforced; then do enough to the car itself to make it tolerate the remaining track. A few solutions on which there has been some work during the last year or two include improvement of the track and roadbed, and control of operation of the train so that susceptible cars don't move over troublesome curves at the critical speed or under certain conditions of draft or buff. Most derailments occur with newer cars, and when substantial milage is accumulated so all contact surfaces are worked in and maximum freedom of movement is attained there is a distinctly lessened tendency toward derailment. However, work on hopper car derailments has not produced a generalized solution which is widely adopted.

CAR ROLL AND WHEEL LIFT TESTS ON SIMULATED SERVICE TRACK: TEST CONDITIONS AND RESULTS AT PRR ALTOONA TEST SITE
The class H-43, 100-ton hopper car began derailing at increasing rates beginning in the Spring of 1964 as more and more of these cars were placed in service. It was decided to set up a test track to simulate the rock-off phenomena and determine what modifications could be made to the car to reduce wheel lift and car roll. All cars were tested first on a tangent track with rails shimmed 3/4" to produce an 1-1/2" total change in cross level at each 39-ft. joint over a distance of ten rail lengths at speeds in the range of ten miles per hour to 22 miles per hour at approximately one mile per hour increments or until the critical speed was exceeded. The cars were then tested on a 3 degree curve having a 4-1/2" super-elevation with an 1-1/2" change in cross level superimposed at each joint over a distance of six rail lengths. Speeds on the 3 degree curve did not exceed 15 miles per hour. After testing, it was decided to adopt the following truck modifications:--1. Replace the 2-1/2" travel springs with 3-11/16" travel springs. 2. Add two friction snubbers to each spring group to absorb energy input into the spring group: 3. Move the side bearings in from 50" centers to 46" centers. 4. Machine the bolster gibs to permit more bolster lateral freedom. Even though a truck modification eliminate wheel lift on the test track, it was not certain just how close the wheel is to becoming unloaded.

SOME RECENT FACETS OF CONTINUOUS-WELDED TRACK PRACTICE IN BRITAIN
Maximum working temperatures have been laid down for continuous welded rail above which it is not permissible for consolidation of the track or work to be undertaken on it. With slag or crushed stone ballast this temperature has been set at 32 deg C. Should slewings at any time exceed 1-1/4 in. the whole of the rail length affected must be restressed. An important aspect of continuously welded track is the strict adherence to restressing and destressing procedures. These have been developed to ensure that continuously welded track is kept in a uniform and safely stressed condition at all temperatures.

WEAR OF RAILS ON CURVES
Abrasion caused by locomotives and electric motor coaches, the condition of the track, and methods of alleviation are discussed. Insufficient information is available to say what type of vehicle produces the most rapid wear in the outer rails on curves. Increase in tractive effort may result in increased transversal reaction and greater lateral wear of the rails. Rate of wear varies inversely as the radius of the curve, but no quantitative relation between degree of wear and radius has yet been established, nor have the effects of irregularities in curvature. What is certain is that excess or deficiency in cant causes unequal wear on rails.

ASHCHURCH: DERAILMENT AND COLLISION
The derailment was due primarily to the excessive speed of the goods train. Responsibility must rest with the driver who drove his train well in excess of the permitted maximum of 35 mile/h. The derailment was initiated by one of the loaded mineral cars near the front. These cars are normally stable up to 45 mile/h. As several of the cars derailed they collided with four cars of an express passenger train. The condition of the track contributed to the accident but had the goods train been driven at its correct speed or even up to 45 mile/h derailment would most probably not have occurred. Speed was estimated at 50 mile/h.

DERAILMENT AT BERKHAMSTED
Two derailments are described, one at Berkhamsted and another at Auchencastle in June 1968. The prime cause of both accidents was attributed to track instability. At Berkhamsted the rail had not been made stress-free at 75 degrees F after the laying of continuous-welded track in freezing conditions, though the temperature at the time of buckling was not sufficiently high as to cause unacceptable expansion pressure within the rails. The bad welded joint and reverse curve alignment were also contributory causes to the disturbance of the track. At Auchencastle the speed may have been over the limit but track stability should have been sufficient to have withstood the effect of the vehicles at that speed. To increase the stability of continuous-welded sleepered track further investigation should ensure that compressive stresses are never more than the planned maximum, to reduce maximum compressive stresses and to improve and maintain lateral stability.

DERAILMENT AT HATFIELD
Details of a derailment that occurred at Hatfield England in January 1966 are presented. This accident developed when the trailing bogie of the sixth

coach of a seven-coach train derailed after dislodging a fractured piece of railhead. It was concluded that the increased vertical deflection at the joint coupled with the small fatigue crack at the bolt hole caused the brittle fractures. It was noted that insufficient care was taken during relaying operations in November 1965 in matching the fishplates used at the joint with the worn fishing surfaces of the expansion switch stockrail and the adjacent closure rail. To reduce the risk of fatigue failures, work hardening of bolt holes is being introduced on switches and crossings.

DERAILMENT NEAR SITTINGBOURNE
The train comprising 24 empty continental ferry vans and a brake van, became derailed on plain track approximately one mile west of Sittingbourne Station. The train was running at 55-60 mile/h when it derailed, a speed substantially in excess of the 45 mile/h limit. Since the intermittent side-cutting of the high rail contributed to this derailment, the possibility of reducing it by making some change in train behavior over the curve deserved consideration. Train behavior itself should be altered if the cant were reduced to three-fourths inches at which equilibrium speed would be 39 mile/h. The fast trains which appeared to cause the intermittent side-cutting would then run more firmly against the outer rail and the intermittent side cutting would be checked.

DERAILMENT AT ROTHWELL HAIGH
Derailment of a train comprising three empty six-wheel milk tank wagons marshalled next to the 2,500 hp Type 4 diesel-electric locomotive, and eight passenger coaches two of which were sleeping cars is described. It was travelling at about 60 mile/h. The rolling of the leading tank wagon as it approached Rothwell Haigh may have synchronized with the natural slight impact of the first common crossing, and its pattern could have matched the reversals in cant through the obtuse crossings, thus accentuating the roll. The tendency under the influence of the roll would be to lift and the falling cant gradient of the crossing was 1 in 93 for about 3 feet, it did so lift coming down on its next roll on the head of the rail at the point of derailment.

DERAILMENT AT HEST BANK STATION
Derailment at Hest Bank Station is described. The sleeping car express became derailed over water troughs when travelling at 70 mile/h, and broke into three portions. The cause of the accident was a broken rail, a portion of the cess rail about 13 feet long. The fracture had occurred 15 feet from the nearest weld apparently started as a transverse crack through the rail head, underneath an old wheelburn, subsequently turning horizontally in the direction of travel along the web until it had turned down to the foot and up to the head leaving a piece of rail head 4 feet 7 inches long detached. An ultrasonic flaw detector examination five months prior to the derailment failed to detect the vertical crack in the railhead. The final failure occurred because of low temperature on the night of the accident which caused a tensile stress to be set up in the long welded rail, causing an increase in the stress concentration round the edge of the fractured zone.

LONDON TRANSPORT RAIL DE-STRESSER
A new device was designed for de-stressing long-welded rail after any disturbance to them in cold weather. The machine, a rail-heating trolley is so geared that it is easily propelled along the track by one man at the low operating speed required--about 2 mile/h. At each corner of the trolley is carried a 100-lb bottle of propane, and from these, flexible hoses run to the rail heaters. The equipment is designed for use on the open sections of line. De-stressing is not necessary in tunnels as the temperature remains almost constant throughout the year. On open lines, rails are de-stressed after they are installed, and it is only necessary then to de-stress them again when they have been disturbing for changing a block-joint or resleepering outside the mid-range temperature.

WEAR AND CORROSION OF RAILS
The use of the Shaw Rail Contourograph to measure vertical wear is described and illustrated. The wide limits of specific rail wear on the British Railways and London Transport are shown as a result of corrosive influence of atmospheric pollution in tunnels and industrial areas. Annual wear is approximately proportional to the square root of the number of axles passing per annum. A comparison between the British and American rail wear values shows much lower values in America for specific wear at the same traffic intensity. This may be partly because of the higher carbon content in America where the relative humidity is above 80 percent for much fewer hours per annum, and atmospheric pollution from industry is less concentrated than in Britain. The effects of steel composition, axleload and braking on rail wear are discussed.

RECENT PROGRESS IN RAIL FISSURE DETECTION
The experience with Sperry detector cars during 10 years of service in the U.S. is reported. Changes in the design of the car to increase sensitivity and reliability are reported. The rails are pre-energized by a magnetic flux, followed by the magnetic flux from the search unit. The searching unit has four-coils which are staggered rather than in line. The Type 80 modification is described which contains special amplifiers and recording pens to differentiate defects of certain types. During 5 years of experience 40 percent of the defects detected were transverse or compound fissures, 40 percent were vertical split heads, 15 percent were horizontal split heads, and 5 percent were miscellaneous defects. Five hundred miles of fissure-containing rails have been removed during the last 10 years after detection with Sperry detector cars.

RAILWAY ENGINEERING AND RADIOGRAPHY
When X-rays penetrate a substance opaque to visible light they are partly transmitted, partly absorbed, and partly reflected or scattered, the amount of each depends on the substance and its thickness. Substances of high density and atomic weight usually absorb X-rays to a much greater extent than those of light weight, for the latter tend to scatter the rays rather than absorb them. An outline arrangement for taking a radiograph is shown. In welds, unsoundness of the weld metal, imperfect penetration of the weld head and cracks in both bead and parent plate may be sought for. In castings, any such defects as porosity, draws and hot tears are likely to be revealed. Radiographs are shown of various welded and cast specimens.

EXPANSION IN LONG RAILS
Experiments have been conducted on rails up to 1 mile long. These rails are fixed by means of the resistance of the fishplates, sleeper fastenings, and sleepers themselves embedded in the ballast; thus, for a 75 degrees F temperature variation above and below the temperature at which the rail was laid, a total force of about 61.3 tons (137,800 lb) is brought into play for a 96-lb rail, and the tendency to push the rail ends away from the center of the rail is resisted, and contained within the rail in the form of compressive stress (or with the tendency to contraction, tensile stress). The prevention of a rail from expanding or contracting causes an internal stress of 195 lb per sq. in. for each 1 degree F change in temperature. To minimize these high internal stresses, it is customary to lay long rails at the mean average annual temperature, and thus reduce the tendency of the rail to buckle, if the fastenings should become weakened. One of the great difficulties with long rails, apart from the practical limitations provided by transport, is that the opening up of the track can be done only at approximately the same temperature as that at which the rail was laid. The London Transport railways has used sliding expansion joints at the ends of the long sections. this expansion joint enables the keys to be knocked out, and any tendency toward expansion or contraction which may be imprisoned in the rail can exhaust itself at each end before further operations are begun.

LONG WELDED RAILS IN THE CASCADE TUNNEL, U.S.A.
The long welded rails were used in the recent renewal of four miles of track in the Cascade Tunnel. The tunnel, which is 7 miles 1,397 yd. long carries the main line of the Great Northern Railway from St. Paul to the Pacific coast through the Cascade Mountains. The railway was laid with 110-lb rails, rolled to the standard American length of 1,326 feet de-stressed by heat treatment, tested magnetically for flaws, cleaned, and given a coat of anti-corrosive paint. The new rails are secured by four cut spikes in every baseplate. The rails are anchored by 48 grip-type anchors in each 39-foot panel. To provide anchorage in both directions, these are applied in pairs for each rail against both faces of alternate sleepers. Insulated joints are inserted in the track at intervals of one mile.

LONG WELDED RAILS
The item gives an historical and an evolutionary account of the development of long welded rails. Mention is made of the practice in the U.K., U.S.A., Germany and elsewhere. The use of welded rails has proven technically sound and comparative maintenance labor costs between continuously-welded rail and fishplated rail show savings in lining and surfacing ranging from 31 to 46 percent, and in gauging of from 33 to 39 percent.

LONG WELDED RAILS IN THE U.S.A.
Experience to date with continuously-welded rail has revealed the following facts: (1) A sound practicable welded joint can be made. (2) Welded rail in long lengths can be transported and installed readily. (3) In the climate of that part of the U.S.A., welded rail should not be installed at a temperature under 60 degrees. (4) Welded track can be surfaced, lined, and otherwise worked without risk when done at a temperature equal to or less than that at which laid. (5) There are fewer failures in welded rail than in jointed rail. (6) Proper superelevation must be maintained on curves for the type of traffic handled to secure the maximum life of the rail on curves. (7) It is practicable to transpose welded rail on curves to increase rail life. (8) It appears that a less expensive fastening for welded rail is possible. (9) Difficulties experienced with continuously-welded rail can be eliminated by proper construction and maintenance. Considerable statistical data are included on costs and number of welds.

THE RAIL CORROSION PROBLEM
Hitherto the problem of rail corrosion has found no completely satisfactory solution. Innumerable remedies have been tried, but most of them have proved to be no more than palliatives, effective over a limited period. Welding the rails into continuous lengths reduces the number of joints, and the number of fatigue failures also, but does nothing to reduce the corrosion. The Norfolk & Western Railway has made a new approach to this problem. A preservative coating used for the rails is Texas No. 45 oil, which contains 45 per cent of asphalt, and it is applied after the rails have been flame-cleaned with oxy-acetylene jets. It is in the flame-cleaning that the novelty lies, and

the value of this treatment is that the steel surface is not merely cleaned, but is dehydrated also, and provision is thus made for a good bond between the oil coating and the rail. The flame-cleaning has been found more effective and cheaper than sand-blasting for the same purpose.

A1 037943
CONTINUOUS RAIL WELDING
One of the most extensive examples of continuous rail welding yet laid was completed by the Elgin, Joliet & Eastern Railroad of the United States, between Joliet and Coynes, Illinois. The total length is 5-1/2 miles, and the longest individual rail is 3,503 ft. The principle interest in this installation lies in the fact that the rails were welded at a depot, then moved in continuous strings up to 1,750 ft. long, to the sites at which they were to be laid in. The rails were of the 131 lb. per yd. flat-bottom section, in 39-ft. lengths, and 1,156 tons were required for the work. Butt-welding by the oxy-acetylene process was the method used. The total cost of the continuous rail was about $1,150 a mile greater than that of the conventional type of track with 131 lb. rails 39 ft. long and bolted joints. A minimum saving in maintenance of $100 a mile should justify the investment. The absence of joints is expected to increase the life of rails, eleminate excessive wear of joint sleepers and the constant attention needed to packing at the joints.

A1 037949
THE PROBLEM OF THE TOP RAIL
It is a matter of common knowledge that the least reliable part of any normal steel ingot is the top. Standard rail specifications require that the rail shall be free from all top-of-the-ingot defects, and though in principle this requirement is carried out, in actual practice the average top rail from the ingot is not 100 percent free from the influence of these defects, as the broken rail records of every railway show. Theoretically the top rail should be the equal in quality of the middle rail or the bottom rail; practically it is not always so. Things that can and cannot be done to insure sound top rails are reviewed. From the manufacturing point of view, additional precautions can be taken to assure sound top rails, but they add to manufacturing costs. One is to cast the ingot large end up and provide it with a head encased in a refractory lining, which keeps the top of the metal molten until the ingot proper has solidified. Another precaution is to cast a larger ingot, so that a greater percentage of crop may be removed from the top end.

MINISTRY OF TRANSPORT ACCIDENT REPORT
This accident report relates to the derailment of a passenger train at 55 mph on straight track near Kingsbury. It was concluded that the engine was hunting on the approach to the point of derailment and for some distance past it and that this distorted the track. The hunting was caused, it is considered, by the significant variations in cross level some distance back, followed by lesser ones coinciding with the period of hunting of the engine, and partly by uneven loading of its bogie and coupled wheels which, with the tender axle side play, made it less stable.

A1 037955
MINISTRY OF TRANSPORT ACCIDENT REPORT
This accident report describes an occurrence on September 2, 1950, near Mansfield, England, when a passenger train derailed on plain straight track. A derailment on plain track usually is due to (a) excessive speed, (b) defective locomotive, (c) defective track, (d) an obstruction, or a combination of two or more of these. There was no evidence to suggest that the train was travelling at high speed and no reason for the driver to do so. Examination of the engine showed excessive side play in the pony truck and the broken springs mentioned above, which would have affected the balance of the engine. The only track defect was the variation in cross-level, which was remarkably regular, though the actual differences at any one point were not excessive. It is likely that low joints on the curve set up minor oscillations, slightly increased perhaps by water surging in the tanks, but not becoming serious until the straight track was reached, where regular cross-level changes increased them. Then build-up must have been unusually rapid, probably due to short pitch cant variations synchronising with the periodicity of the engine. The theory of engine hunting is borne out by the track distortions, etc., all tending to show that the leading wheel became forced over the rail when it was carrying little weight.

MINISTRY OF TRANSPORT ACCIDENT REPORT
An accident occurred on May 12, 1950, on the Chesterfield-Lincoln line when a passenger train became totally derailed. The derailment was caused by the condition of the track and to a lesser extent by that of the engine. The principal fault in the track was the rapid and very considerable reversal of cross-level. Side cutting of rails suggested that side to side oscillation of engines was usual as they passed through the junction and it may have persisted for some time. A feature of this derailment was that the track had been inspected within the previous week. All concerned were experienced men, but their standards of maintenance were not perhaps as high as they should have been, and they allowed themselves to fall into an error of judgment. Further, the engine was allowed in traffic with three broken springs.

DERAILMENTS IN INDIA
The results of an 18-month derailment study during 1949-1950 are summarized. Primarily a statistical analysis, the derailments are categorized according to: (1) gauge, (2) type of train or yard, (3) railway, (4) month of occurrence, (5) cause, (6) time of day or night, and (7) whether at a large station. Further, the derailments are analyzed by principal causes (1) track

defects, (2) locomotive defects, (3) carriage and wagon defects, (4) faults of traffic staff, (5) faults of power staff, (6) obstructions, and (7) miscellaneous causes. Specific findings for 12,993 derailments during the 18-month period revealed the following: 56 percent were due to traffic staff faults and 8.3 percent to track defects, 7.6 percent resulted from carriage and wagon defects, and another 7.6 percent from obstructions on the track; 6.5 percent were caused by faults of the locomotive staff, and 1.3 percent by locomotive defects. The remaining 12.7 percent are classed as "miscellaneous causes."

TRACK TESTS ON THE ILLINOIS CENTRAL RR
This article describes a number of tests conducted on the Illinois Central. One test was conducted to determine whether the removal of the mill scale from the rail ends and fishing surfaces of the plates would reduce the initial rate of bolt tension loss or have beneficial effects on fishplate wear. Insulated joints were also tested. Tests were also carried out with various types of bearing plates in an attempt to eliminate the cutting of soft wooden sleepers by such plates. To prevent creep, 14 rail anchors of different types were fitted per rail length, and in addition 12 rail clips to the rail length were used. Eight different arrangements of the anchors were installed. Various kinds of sleepers and ballast were also tested.

HOW LONG CAN A RAIL BE?
The continuous welding of rails as practiced in the United States by five railways is summarized. Summarizing the collective views at the time of this article, it was clear that expansion and contraction would not present problems. It was equally clear that there are appreciable savings in the costs of maintenance as compared with standard jointed track. There are good prospects of longer rail life, because destructive action on the part of the rails is reduced. Rolling stock rides more quickly and smoothly. Track circuits give less trouble, and can be lengthened.

A CALCULATION OF THE LATERAL HUNTING MOTION OF A TRACKED VEHICLE
The lateral hunting motion of a vehicle running on tracks is not only prejudicial to riding comfort, but may also cause dangerous derailment. The initial step in the design of a safe high-speed train is a theoretical and experimental investigation of this lateral hunting motion and a practical method of preventing it. The usual railroad train may be idealized as a system consisting of a number of cars connected end to end like links of a chain. The transfer-matrix technique purports to be applicable to such a system, whereby once the transfer matrices of each component (car) are derived, it is only necessary to perform successive matrix multiplications to fit the entire system. It is demonstrated that the transfer matrix method may be applied successfully in a study of lateral hunting motion. The stability problem associated with this motion, and forced vibrations caused by irregularities and lateral distortions in the rails may also be investigated by the use of the transfer-matrix technique. STRESS AND STRAIN IN ROLLING BODIES IN CONTACT
The three-dimensional solution of the stresses and strains in the contact region of a rolling wheel which carries normal, lateral and tangential loads is sought. Because of the complexity of the general problem a preliminary step has been to seek the solution for two spheres of similar material rolling on each other. The approach has been to divide the 'locked' region into a grid of n cells formed by fixed circular grid lines and variable grid lines which have a shape similar to an assumed shape for the boundary between the 'locked' and 'slipped' regions. The equations and boundary conditions were formulated and a computer program solves 2n simultaneous equations to find the stress distributions. If all boundary conditions are not satisfied by the solution the computer program shifts the grid points according to an error criterion and reiterates the solution. The results were encouraging although the final solution is not yet available. The results for the two spheres can be extended to the case of a wheel rolling on a surface of dissimilar material. This solution is of considerable importance for high speed rail travel because forward and sidewise creep (which are vital parameters in stability calculations) and rolling stresses (fatigue, etc.) can be calculated from the complete picture of stresses and strains in the region. A MODEL STUDY FOR VERTICAL TRACK BUCKLING
The paper contains a study of two models which represent the mechanism of vertical buckling of a track when subjected to a mechanical or to a thermal compression force, respectively. The postbuckling equilibrium curves and their stability are discussed and a stability criterion is defined. The effect of various track model parameters upon the buckling load or buckling temperature, are shown. The nonlinear equilibrium equations were then linearized. It was found that the buckling loads, or temperatures, obtained from a linearized analysis have no relevance to the actual values obtained from a nonlinear analysis; the difference in results being substantial for buckling temperatures. EXPERIMENTAL RESULTS OBTAINED ON THE LATERAL PROBLEMS OF THE LONG WELDED RAIL CONTINUOUSLY LAID ON SEVERAL SPANS OF THE BRIDGE WITHOUT BALLAST
To show the lateral stability of continuous welded rail on a bridge, and the character of the lateral load to the bridge as a result of such rail, a test was conducted by the JNR on an actual bridge. The data resulting from this test shows that even though there were no problems resulting from unballasted rail on a bridge, the lateral forces between rail and sleepers varies and may reach a value which is ten times the calculated value. The phenomena is a result of continuous rail laid on a bridge resulting from the high lateral elastic coefficient of the rail supporting system.

STRESSES IN THE TRACK SUBSTRUCTURE RESULTING FROM TRAFFIC LOADS
Experimental research has led to findings concerning the interactions between the different structural components of the track under quasi-static loading conditions. The tests were intended to show whether the results found for the quasi-static range can also be regarded as valid under dynamic conditions. Results showed that there is a linear correlation between the measured sleeper reaction and the pressure or stress in the ballast and formation. The results showed a relatively high degree of scatter, amounting to 17.5% for a concrete sleepered track without rail joints, and to 25% for a track on wooden sleepers with rail joints. The maximum vertical stress in the formation decreased in the course of time due to changes in the stress distribution. For certain soils, there is a definite limiting stress. If this stress is exceeded, repeated load applications will lead to a rapidly increasing deformation and to plastic setting. Below this (limiting stress), repeated load applications will merely cause permanent deformations.

THE MOVEMENTS OF RAILWAY VEHICLES ON THE TRACK AND THE FORCE ARISING THEREFROM
A critical analysis is given of the interaction of flanges and rails, together with a resume of the scientific principles involved. The friction arising between wheel and rail is fundamental for all railway transport. The frictional force R is equal to or less than the product of the frictional factor f and the wheel load Q, which are the variable quantities. As the direction of force R coincides with the resulting sliding motor between wheel and rail, its action is opposed to the direction of motion. Force R determines not only rolling resistance, but also that due to curves, guiding pressure, security against derailment, maximum tractive and braking power, axle strain, wear of rail and flange, and--last but not least--freedom from hunting. Methods to determine the precise position and value of R are discussed.

RAIL FAILURES ON BRITISH RAILWAYS
Every rail or portion of rail that has to be removed from a running line prematurely because of a break, crack or other defect has to be reported as a failure; failed welds that are repaired by re-welding in situ without the removal of a rail must also be reported. Information relating to the rail and its conditions of service is coded and punched on computer tape. This enables the failures in any year to be easily and quickly analyzed according to region, rail section, age, traffic carried, class of line, manufacturer or any other feature considered to have or suspected of having an influence on the failure pattern. Failures in tunnels and on water troughs are analyzed separately from failures elsewhere, as are failures at welded joints. Types and causes of failure for 1961-1963 are reported. Comparisons between regions and manufacturing process used to produce the rail are also made.

DERAILMENT AT CHEADLE HULME
The train which consisted of a steam locomotive and nine coaches ran on to a temporary underline bridge immediately before Cheadle Hulme Station, at a speed in excess of the 10 mile/h restriction, burst the track, derailed, and parted between the fourth and fifth coaches. Two children and a railway representative were killed and 27 injured. Standard indicators had been provided at the beginning and end of the restriction but the warning board near Branhall Loop was non-standard. The train ran on to the bridge where the speed restriction was 10 mile/h at a speed of at least 45 mile/h. The warning board was not as conspicuous as it should have been. Such boards should be of standard design and brightly painted. The weakest point of the temporary bridge design was shown to be the fastening of the track to the waybeam by transoms and clamps to every other sleeper.

AREAS OF CONCERN FOR FREIGHT CAR ENGINEERING
The aims of containerization are to provide cheaper, safer and quicker transportation for commodities which can be placed in standard size boxes. To obtain maximum benefits, special equipment is necessary and economically justified. The size of the containers, loading and securing methods, and size and capacity of the cars are described. A series of tests were made to determine the source and methods to eliminate the poor ride qualities of 60 feet container cars used on the Canadian National Railways. The tests were run over the same track at a range of speeds. The acceleration was measured in the vertical and lateral directions. Track hunting was apparent above 45 mph. The results of the tests are shown.

ENGINEERING CRITERIA FOR FUTURE FREIGHT CAR TRUCK DESIGN AND PERFORMANCE
To establish the criteria for design and performance of freight car trucks, the environmental effects on the truck must be examined. These environmental effects are grouped as: external environment from track conditions, carbody and train speed; and internal environments which are induced by the truck design, the specialty components, such as roller bearings and the state of the art in developing the most desirable elements in the truck assembly. Each of these effects is described. The lack in the U.S. of a full-scale wheel-rail dynamics research facility to test trucks and tracking has hampered the efforts on truck design. A British Railways test using a U.S. truck design and their Freighliner test equipment is briefly described.

THE PROBLEMS
Considerable fore and aft wear in the body and bolster Center plates on cars in service up to 1962, was due to action when the car is in motion. By applying manganese steel wear rings into the truck bolster, the wear disappeared. It was also found that the body center plate was cracking. When a change of construction material was unsuccessful in correcting the problem, a fillet weld was tested. After three years, no center plate cracks around the bowl have been found. Several design changes for the center plates being considered to increase strength are mentioned.

CARBUILDER'S APPROACH TO THE SOLUTIONS OF THE TRUCK–CAR BODY RELATIONSHIPS
Three failure modes for center plate areas are discussed and illustrated. Wear of vertical wall inboard and outboard has been reduced by the wear ring and harder center plate. By use of these modifications, the 50 and 70 ton service experience should be approached. Cracking of center plates was prevalent prior to 1967, and was a function of the center plate center filler contact area. Failures had not occurred at conference time of the solid forced plate designed to eliminate the cracking problem. Cracking of the cushioned underframe center plate is a function of the overall bolster design and with proper design and reinforcement, this mode of failure should not occur.

PULLMAN'S APPROACH TO CENTER PLATE PROBLEMS
Tests were conducted on fabricated cushioned underframe center plates using a Hy-Cube car, using a car rocking device designed to excite a fully-loaded car at its natural roll frequency. Results were correlated with field service reports. Tests were in progress on the rocking device using a 100-ton covered hopper car. The conclusion of the two-year test program on cushioned underframe cars has indicated these results: rock and roll is instrumental in center plate wear and breakdown; breakdown originates in the transition radius and propagates into the transverse and longitudinal reinforcement; the 3/8" radius is not satisfactory for today's fatigue environment; longitudinal reinforcement on the center plate should be located over the outer circumference of the bowl; a flat center plate application significantly reduces the attachment pre-stress in the transition radius; both fabricated and cast center plates can develop cracking unless fatigue design is considered; the center plate application is related to car configuration; and supplemental snubbing devices that reduce car body roll would increase the fatigue life of center plates.

CARBUILDER'S APPROACH TO THE SOLUTIONS OF THE TRUCK-CAR BODY RELATIONSHIPS
In early 1967 General American standardized on a cast steel combination center brace, center plate, and rear draft lug. This casting is attached using the two-piece rivet; that is, the Huck or Townsend bolt. Laboratory tests were conducted for all capacities through 125-tons with impact loads beyond AAR design requirements. This design has operated successfully in service. Test results on the center plates on car built from 1960 to 1967 are given. The test showed that a solid bowl is not as good as the recessed type bowl because of slight deviations in the bolster.

RESUME OF LONG CAR TRACKING PROBLEMS
It was necessary to employ a special coupler in the design of the 86'6" Hy-Cube box car for automotive stampings. To permit those cars to negotiate curves it was necessary to use a nonstandard 60-in. "F" shank coupler with a Type "E" head. The coupler carriers have been broken on several of the cars as they were passing over vertical curves of lesser radii than the cars were designed to negotiate. Coupler carriers on other cars coupled to Hy-Cube cars have been literally torn off while negotiating vertical curves. The most prevalent difficulty with the long couplers on cars with long overhangs, is caused by missed couplings. Accidents of this kind smash angle cocks, train line nipples, uncoupling mechanisms and in many cases causes much damage to the center sills, especially to sliding center sills. The answer to longer trains and reduced draw-bar pull may be automatically controlled locomotives spaced in trains.

DETAILED INVESTIGATIONS INTO SLEEPER DEFECTS
In 1950-51, 400,000 failed wooden cross ties were examined and classified as to the type of failure: (1) decay, (2) plate-cutting, (3) splitting, (4) shattering, (5) spike killing, (6) braking (7) ring separation, and (8) accident. Five types of wood were involved, but 85 percent of the sleepers examined were of pine or fir species more universally used then the other two, oak and gum. Plate-cutting, splitting and shattering accounted for about 1/3 each of the total failures.

THE ULTRASONEL FLAW DETECTOR
The Ultrasonel instrument of Trevor-Johnstone Company for detection of flaws in locomotive frames and thin plates by measuring the intensity of ultrasonic waves is described. The Ultrasonel will detect either internal or surface defects. The internal defects may be revealed by either transparency or echo methods as may be convenient, whereas the surface flaws are detected by inclining the feelers at an angle to the surface. The feelers are set at an angle to the surface so that the ultrasonic waves move along the surface without penetrating the test material.

RAIL FLAW DETECTION BY UNTRASONIC BEAM
The Audigage flaw detector, of Branson Instruments Inc. consists of a small-battery-operated ultrasonic frequency generator and receiver, carried in an 11-1/2-lb. pack on the operator's back, a crystal in a special holder on the end of a long handle, and a pair of headphones. The crystal is applied to the head of the rail and the presence of a crack indicated by a lowering of the continuous tone produced in the headphones by a perfect rail. In a cracked rail the wave is reflected by the flaw, and a change in tone--or loss of tone--is produced in the headphones. The nearer the crack to the head of the rail, the greater is the drop in frequency. The instrument has been in use by London Transport for about three weeks, during which time some 15 miles of rail have been inspected with it. Several minor defects which were not revealed by visual inspection were discovered in sections of rail covered by the fishplates.

TRACK MAINTENANCE PROBLEMS
This summary of track maintenance problems was obtained from the railway administrators of the International Railway Congress. All the railways consulted are studying possible modifications in the traditional maintenance organization, but investigations are still in the experimental stage, and there are no indications what the final pattern will be. The experiments can be grouped into two categories: (1) Concentration of smaller into large gangs, and the various methods of transport for their mobility, and (b) mechanization. The article summarizes activities and equipment used by various countries in the areas of track recording equipment, speed restrictions and signals and mechanical tools and mechanization problems. Economic and financial aspects are included as well as the use of medium-sized gangs for maintenance.

LONG WELDED RAILS
If very long weld rails are used to circumvent the many disadvantages of the jointed form of track, important safeguards are essential. The standard types of doubly-flexible rail-to-sleeper fastenings in use on the French railways are among the most efficient deterrents to the risk of fracture due to tension. With an 800 m. length an expansion joint of the sliding switch-blade and stock-rail type is used, allowing of a relative movement of up to 7 in. between the rail-ends. The French railways use arc-welding plant equipped with special finishing devices, in the shape of precision grinding and truing units working in both plan and profile, assisted by hydraulic jacks. It is too early to access precisely the economies resulting from welded track, but the smallest calculated saving so far is about 30 percent, and was secured on the Paris-Marseilles line near l'Etang de Berre.

CONTINUOUSLY-WELDED RAILS
To offset the increased cost of laying welded as compared with bolted rail ($1000/mi) important savings are being effected. The first is in general track surfacing work. The initial 5-1/2 miles of Elgin Joliet and Eastern Railroad welded track, laid in 1943, will not require general surfacing for another two or three years yet, though it carries 20,000,000 gross tons of traffic annually; in the normal course it would need general surfacing every seven years, and joint surfacing, now no longer needed, at much shorter intervals. Also, construction methods, maintenance benefits and costs are discussed.

BURSTING A CROSSING
The Doncaster derailment attracted great attention, not only because of the resultant causalties but also from the fact that the train had just started and was not traveling at any speed. The train was passing through a scissors crossover, up slow to up main, where superelevation had to be such that the run-up of the cant was very steep— in certain circumstances a disagreeable necessity. Of recent years a speed limit of 10 mph has been in force over the slow line approach from the station and through this connection, but unfortunately, as in so many places, it has been indifferently observed. The conclusion, supported by practical tests, was that the train concerned passed at from 20 to 25 mph. There was no reason for supposing that the condition of either locomotive or train contributed to the accident. It was concluded, from a review of all those cases and every relevant fact revealed by the inquiry, that the disaster was initiated by the bursting of the crossing. All crossings form inherently weak points in the track and their components are subject to constant shock.

RAIL-END DEFECTS
Of all steel rail defects, probably the most difficult to detect are those which occur at the rail-ends and are concealed by the fishplates. The major cause is the pounding and vibration to which rail-ends are subject because of the gap between the rails over which the rolling load must pass. This may encourage the development of corrosion fatigue cracks from any sharp edges, such as those of the fishbold holes or in the fishing angles of the rails, which stresses are concentrated. In the course of ordinary inspection, the only way to discover whether or not a rail is cracked at the end is to take off the fishplates but this is a costly operation from the labour point of view. In the United States certain railways are now supplementing the regular patrolling of their tracks with Sperry or other detector cars by supersonic testing of rail-ends. One of the problems arising from such inspections has been to decide at what stage of development a crack becomes sufficiently serious to demand the removal of the rail from the track. To remove all rails in which small cracks are found would appear to be an unjustifiable costly proceeding. The present practice of classifying the cracks and removing from the track only rails that have cracks of over a certain length, would appear to be reasonably safe, and far less costly than the indiscriminate removal of all rails show ing the slightest sign of cracking.

A NEW FATIGUE DEFECT IN RAILS
The shelling defect has been most commonly encountered in the 131-lb standard flat-bottom section, though it has been reported in some degree in all sections from 100 lb. upwards. The first manifestation of the trouble is the appearance, on the running surface of the rail near the running edge of dark spots, which indicate the presence of horizontal planes of separation of the steel within the rail-head; these may occur at a number of different levels in the same rail. The shelling is the result of wheel action on the rail causing failure of the metal, either by direct stress exceeding the elastic limit, or by loss of ductility which is the outcome of constant reversals of stress. Factors which may influence the relative severity of the shelling are the inclination of the rail, the superelevation, the bearing pressure exerted by the wheels, the radius connecting the flanges and the treads of the wheels, and the radius of the gauge corner of the railhead.

RAIL WEB FAILURES
Out of 30,881 failures of new rails in U.S.A. tracks in 1942-51, and removed during that period because of defects, 13,554, or 44 percent, were web failures. The great majority of the latter were failures within the area of the rail joint. Laboratory and track tests showed that many web failures could be explained by corrosion-fatigue but not by corrosion alone. Various factors increase the web stresses at rail ends. One is poor or irregular fit of fishplates; loose or worn fishplates or loose fishbolts have a bad effect, as they are liable to cause greater impacts to develop under the rolling load. Excessive gaps at the rail-joints or battered rail ends similarly tend to increased impacts.

EXPERIENCE WITH WELDED RAILS
The railroads in the U.S. in the early 1950's began substituting 78-ft. rails for the 39 ft. standards. The 78-ft. rails decreased the number of joints by 50 percent, which justified the longer rail on the basis of a corresponding savings on maintenance. The same equipment can be used to lay both size rails. Wild grinding to reduce the bulge at the weld is discussed. The repair of continuously welded rail is described.

THE SAFE LIFE OF RAILS EXAMINED
The rail sections considered are the 109-lb. fb and rBS 95-lb. bh rail, both in common use on British Railways. Among the conclusions reached by the authors is the fact that the rail sections standardized by British Railways are of sufficient strength for long life under existing steam traffic where maintenance is good and corrosion not severe. But, they believe that rail life should be governed by the type, speed, and quantity of traffic carried rather than by loss of weight. Furthermore, they suggest that any practical way of altering rail joints to increase their life should be investigated and that the development of special joints for the ends of welded rails would appear necessary irrespective of any stress-relieving requirement.

ACCIDENTS ON BRITISH RAILWAYS IN 1959
There were a total of 1154 accidents in 1959. Of these, 609 were attributed to the human element, 113 were caused by technical defects, and 432 resulted from other causes. Within the causes of the human element category there were 276 collision, 119 derailments, 174 running into obstructions, 7 fires, and 2 miscellaneous accidents. In the technical defects category there were 12 collisions, 69 derailments, 14 running into obstructions, 13 fires and 5 miscellaneous accidents. The other causes category accounted for 130 collisions, 27 derailments, 205 running into obstructions, 42 fires, and 28 miscellaneous accidents.

CAPABILITY OF FASTENERS TO RESIST RAIL OVERTURNING
The purpose of the investigation was to determine the overturning resistance of the rail fastened to either wood or prestressed concrete ties when subjected to various loading conditions. No effort was made to include the torsional resistance of the rail. The procedure used in testing the rail on the wood ties was accomplished by fastening a short piece of 136 lb. rail and tie plate to a new treated oak tie by four spikes in pre-bored holes. The rail on the prestressed concrete tie was fastened by two bolts and two AREA Specification clips with a 3/16 in. polyethylene plastic pad between the rail and concrete. It was found that rail on the prestressed concrete ties is capable of carrying considerably more lateral load than the rail fastened to wood ties with spikes. An analytical study conducted at the Research Center indicates a definite relation between the wheel lifting off the rail, wheel climbing the rail and the lateral and vertical loads on the rail. The results of the analytical study shown on Fig. 11 indicate that all values of P(sub v)/P(sub L) smaller than 0.78 have no significance as the wheel will climb the rail and thus relieve the lateral load component on the rail. Lateral wheel loads as large as 30,000 lb have been recorded and for this condition, the analytical study indicates the wheel will not climb the rail until the vertical component of the rail load is 23,400 lb or lower. It was concluded that the method of fastening the rail to the prestressed concrete ties, as recommended in the Preliminary Specification for Design, Materials, Construction and Inspection of Prestressed Concrete Ties, is satisfactory for the imposed lateral forces.

TRACK GAUGE WIDENING ON TANGENT TRACK--ROLLER BEARING TIE PLATE TESTS--MILE POSTS 614.08 AND 626.61
A problem of gauge widening on tangent track led to these tests with instrumented ties with roller bearing tie plates and an instrumented diesel-electric locomotive. The road bed was in average condition, with the track of 133 lb. rail. Conclusions drawn from these tests were as follows: No class of locomotives or cars individually were found to exert a lateral force at the test site sufficient to result in the gauge widening being experienced. The cars created a greater number of and higher values of lateral forces than the locomotives involved. Dynamic braking of the trains produced no noticeable lateral forces in the trailing unit of the locomotive consist or the head end cars. The faster trains created higher forces than the slower trains. Apparently the gauge widening had resulted from the high utilization of the track and high train speeds.

GP-7 LOCOMOTIVE WHEEL TO RAIL LATERAL LOADING TEST ON ILLINOIS CENTRAL RAILROAD
The report is based upon testing conducted by EMD to determine causes of derailments which involved GP-9 locomotives. The EMD Test Car was used to determine wheel loading levels for the GP-9 locomotive to determine

wheel loading at the derailment sites. The test train from which data for this report was obtained represented a typical freight train operating in normal service through the areas where previous derailments occurred. The loads measured between wheel and rail during the testing were substantially below levels which are normally considered necessary to cause derailment by wheel climbing rail, rail turn-over, or shift of entire track structure. The maximum steady state net lateral load measured on the guiding wheel was 13,200 lbs. which represents 41.2% of the nominal wheel vertical load. Accompanying this load was a 5,400 lb. axle lateral load which represented 8.5% of the nominal axle vertical load. The above loads were measured in a 6-1/2 inch curve. Threshold tendency of wheel climbing rail is generally expected when net lateral force on guiding wheel is 90 to 100% wheel vertical load. Rail turnover demands that total lateral load compared to total vertical load on an entire rail length unsupported, or practically unsupported, by adjacent lengths gives a ratio great enough to cause the load resultant to fall outside of the base of the rail. Dynamic instanteous peak loads which are of very short duration resulting from sudden rail irregularities (joints) are not believed to affect wheel climbing rail or rail turn-over. Train speed did not significantly change steady state forces in a particular curve. However, increased speed did significantly change the level of dynamic loading as much as 200%.

MINISTRY OF TRANSPORT ACCIDENT REPORT
A fully-braked screw-coupled freight train, consisting of 34 cars and a caboose, derailed June 21, 1955, at a running speed between 40 to 45 mph. The derailment occurred at the 21st car, which had faults in its spring attachments. A drawing shows the securing spring shoes of the type that failed on the derailed car. The springs were of the ordinary laminated type designed to bear on the axlebox centers, with their two ends bearing against steel shoes fastened to the underside of the wooden solebar. It was concluded that looseness of the spring shoes combined with uneven loading would have permitted excessive oscillation and diagonal pitching and that this motion caused the derailment.

THE RAIL SHELLY CRACK IN JAPAN
Investigation into the growth mechanism of shelly cracks and a method of prevention is reported. Examinations included track condition, materials quality, loading condition and friction and wearing phenomenon of affected rails. It was found that in the ordinary contact condition, the contact stress between tyre and rail is so large that plastic flow is caused. With the progress of plastic deformation, steel becomes hard and its elastic limit rises. After these changes, rail surface becomes fit for ordinary wheel load. Though before this time the progress of plastic flow nearly stops, the crack grows through the fatigue due to rolling with slide. It was also found that the existence of ferrite in the surface layer seems to take part in the growth of the crack. As a first step in preventing shelly cracks, rail steel should be strengthened against fatigue. Water decreases the wear of rail and accelerates the development of crack. These conditions promote the growth of the crack due to the rolling fatigue. Secondly, though the decrease of stress is difficult to realize in general, the decrease of lateral force and the decrease of contact stress by decreasing the difference of both curvatures in contact part of wheel and rail are found effective. Thirdly, as it is clear that the existance of water is unfavourable, total stop or restraint of watering is very effective. Since the same effect is achieved by oiling, it is necessary to be careful not to oil excessively.

MEASUREMENT OF LATERAL STRENGTH OF RAILWAY TRACK BY "LATERAL STRENGTH TESTING CAR" (1ST REPORT) MECHANISM OF TESTING CAR
The "Lateral Strength Testing Car" represents a two-axle bogie car additionally attached with a one-axle testing truck which carries a mechanism, which applies a vertical and a lateral load to the center axle, a mechanism which lifts the said testing truck above the rails and an oscillograph for recording the vertical and lateral loads. The car answers the questions: How much lateral load can the track withstand? and under what conditions and in what process a derailment of a car takes place? Procedures for measuring these quantities are provided.

SOME EXPERIMENTS ON SHELLING CRACKS IN RAILROAD RAIL (NO. 1) TWO DIMENSIONAL PHOTOELASTIC EXPERIMENTS ON A MODEL HAVING A FINE EDGE CRACK UNDER CONTACT LOAD
The shelling cracks grown in the head of rails are said to be fatigue cracks which are produced by excessive rolling pressure of wheels passing over them. The detailed mechanism of failure, however, has not yet been made clear. To find whether the growth of cracks be due to repeated shearing stress or mainly to repeated tensile stress is necesary both for clarifying the

mechanism of shelling and for selecting the rail material. Two dimensional photoelastic investigations were carried out on half planes having a fine edge crack to which a contact load was applied and the fringe patterns at the end of the cracks were observed. When a semicircular model is pressed to a model which has an edge crack inclined at an angel of 30 degree to the contact surface, there grows a tangential force along the fracture surface when the contact load comes above the crack. When the contact load has an inclination toward the crack the tangential force along the fracture surface has a tendency to increase. When a semicircular model is pressed vertically to a model which has a vertical edge crack and the contact load comes adjacent to one side of the crack, there acts the largest tangential force along the fracture surface and the shearing stresses concentrate at the end of the crack, but the tensile stress does not appear. It is supposed from the above facts that the direction of a shelling crack in rail developing under contact loading will be affected by the shearing stresses solely or at least predominantly.

CONTACT PRESSURE BETWEEN WHEEL AND RAIL AND ITS INFLUENCES ON MECHANICAL PROPERTIES OF RAIL STEEL
Since it was felt that there was still some uncertainty regarding various investigations on the very high contact pressure between wheel and rail and in relation to failures occurred in the heads of rails. It was decided to obtain additional data on the phenomena. This article addresses the following: contact pressure between rail and wheel, plastic deformation of rail steel due to local compression hardness distribution under running surfaces of used rail, and workbrittleness of rail steel.

TRACK SURFACE AND CAR DERAILMENTS
Tests under laboratory conditions to determine the effect of warped track surface as a cause of derailment of freight cars and the flange pressure required to turn the trucks under freight cars have led to certain conclusions contrary to the accepted beliefs of many competent engineers and railroad officers. Among the definite conclusions indicated by these tests may be mentioned the following: That a rigid and a flexible track are equally effective in resisting a tendency to derailment caused by warped track surface; that center-plate resistance plays little part in the total resistance which must be overcome in turning trucks on curves, and that grease lubrication of center plates has no appreciable effect on truck turning resistance. It is interesting to note that, in general derailment occurred with less depression than super elevation of the outer rail. In general, it is evident that side-bearing clearance is the most important single factor, so far as the car is concerned, affecting derailments caused by warped track surface, and it is evident that flexibility of car structures plays no small part in keeping cars on the track where side-bearing clearance is small or altogether absent.

INVESTIGATION TO DETERMINE THE CAUSE OF "SUDDEN" WIDE GAGE ON THE DELAWARE AND HUDSON RAILROAD
The purpose of this investigation was to determine the cause of this "sudden" gage widening. It would appear that this gage widening would most probably be caused by a jackknifing condition. This investigation measured the jackknifing forces developed under heavy pushing. The first part of the investigation was made on a 3 deg curve. A special test train was used consisting of a number of diesel units in dynamic braking and 15 loaded hopper cars, including one 100 ton car, to provide the pushing resistance at one end, an 89 ft. TTX flat car and short hopper in the middle and the pushing diesel units under test at the other end. Four special ties and eight roller bearing tie plates were installed near the middle of the 3 deg curve to measure and record the lateral forces exerted by the equipment on both inner and outer rails. Strain gages were placed on the rail webs to measure the vertical wheel loads. The lateral displacement between the first and second diesel units and the total locomoitve drawbar force were also measured. The investigation did not result in finding any clear cut and specific answer as to the cause of the occurrences of "sudden" wide gage. However, it appears most likely that the occurrences were due to lateral forces exerted against the outer rail as a result of locomotive jackknifing under dynamic braking.

REPORT OF BOARD OF INQUIRY ON ACCIDENT AT COLISEUM STATION, BAY AREA RAPID TRANSIT DISTRICT, SAN FRANCISCO, CALIFORNIA
The accident occurred during test operations at the Coliseum Station on November 2, 1971, when a BART vehicle travelling about 25 MPH, collided with the rear car of a parked BART train. The train operator was injured. The accident, which occurred in manual mode, underscores the wisdom of the early planning decisions to design the BART system on the most fully automatic basis possible. Such a collision will be very unlikely once the automatic system is in operation because of the basic fail-safe design. Despite the speed of impact, there was little damage beyond the bulk heads of the attendant's compartments in the impacting cars. The accident was attributed to human failure to apply the brakes in sufficient time or at a sufficient rate to effect the stop.

RECENT EVOLUTION IN ON THE RAIL INSPECTION ON THE S.N.C.F.
Ultrasonic probing enables an operator, shifting a transductor over the surface of the railhead, to assess the extent of a crack. Rail inspection by ultrasonic apparatus employs two methods: vertical probing by a straight line transductor where the steel is subjected to a longitudinal beam of waves; and oblique probing by a transductor subjecting the steel to a refracted beam of transversal waves forming an angle of 65 degrees to 70 degrees with the vertical. The transversal fatigue cracks due to rail-head fatigue often causing railbreaks are detected by oblique probing. The present permissible speed at which the transductors are made to move along the rail is 12 km/h. The annual number of rail-breaks on the inspected lines which was about 1,100 has fallen to under 400, the majority of breaks being due to defects non-spottable by probing.

TRAFFIC IN A CURVE WITH RAILWAY COACHES FITTED WITH INCLINABLE BODIES
Further tests of the pendular type coach have been effected, during which the body has been given a boost to speed up the time taken for it to get the correct inclination when negotiating connecting transition. This is done by means of a hydraulic ram monitored by a accelerometer detecting, permanently, the non-compensated acceleration. Another arrangement is being worked out with a coach for which the axis of oscillation is below the center of inertia of the body. Tests are described which show that it is possible to get a coach to negotiate a curve with 0.3 insufficient cant, which is considerable, by employing assisted pendular motion. The first tests have shown that the assisted pendular motion gives considerably improved smooth riding while negotiating the transition as compared with natural pendular motion.

THE INFLUENCE OF BALLAST BED THICKNESS AND TIE SIZE AND SPACING ON SUB-STRUCTURE LOADING
The steady increase in axle loading of railway vehicles and in train speeds not only cause greater stressing of the rails, but also higher loading of the sub-structure. Test results and theoretical considerations show the influence that the size, shape and spacing of the ties, the thickness of the ballast bed and depth of the formation, have on the loading of the sub-structure. Conclusions included the following: a ballast bed over a bad substructure that will carry 20 tons axle load, when over a good substructure, cannot carry more than 25 tons axle load. For axle loads of 30 tons, a protective layer over the substructure and a deepening of the ballast bed are necessary. With regard to the stresses on the ballast bed from an axle load of 25 tons to 30 tons, the tie spacing must be made smaller and with longer ties, the depth of the ballast bed and the thickness of the protective layer over the road bed can be kept to lesser limits. STUDY OF RAIL FAILURES IN THE TRACK--STANDARD RAIL FAILURE STATISTICS
The main object was to define the type and form of presentation of rail-failure information to be supplied by various ORE Member Administrations so as to permit the better use of such information-and to draw some concrete conclusions. Committee D 88 found great difficulty in identifying a suitable denominator to which the rail failures could be related for purposes of comparison between administrations. In the absence of a more reliable denominator rail failures were related to the kilometres of track concerned with the type of failure being compared. This should enable Administrations to decide whether their present policies in regard to choice of rail section, steel quality, rail welding, joint design, track maintenance policy, rail renewal frequency (only to quote the main factors), require any alteration.

LATERAL FORCES ACTING ON THE TRACK DUE TO NOSING OF CARS
Depending on the type of motion, equations for determination of lateral forces produced by motion of cars on tangent track can be divided into two main groups: (a) without contact of flange and rail, (b) with contact of flange and rail. it is pointed out that Verigo's equation for calculating lateral forces accounts for such factors as angle of impact, condition of track and suspension component and equivalent mass and overall elasticity much more realistically than previously developed solutions.

DYNAMIC LOADING AT RAIL JOINTS--EFFECT OF RESILIENT WHEELS
This study of a simplified vehicle model passing over an idealised dipped rail joint using values applying to a BR Class 86 locomotive shows that resilient wheels give an equivalent reduction in unsprung axle mass of 2,500 kg. The following conclusions were made: The suggested model for a broadened analysis of the vertical response of vehicle and track at a dipped rail joint is workable and produces dynamic wheel load values which are in full agreement with observed data. Fitting a Class 86 locomotive with resilient wheels will have the effect of reducing the dynamic wheel load increment at severe dipped rail joints by some 40 percent. The effect of resilient wheels on a Class 86 locomotive--based on the dynamic loading at rail joints--is equivalent to a reduction of the unsprung mass from 4,200 kg to 1,700 kg on the leading axle. Thus the results of the analysis suggest that a power-unit comprising axle-hung motors and resilient wheels is a highly competitive alternative to conventional, mechanically complicated and expensive arrangements used to obtain fully-suspended traction motors.

LOADING OF LIGHT RAILS
Highlights of a paper presented at a meeting of ICE. The author describes cases of known damage to rails and sleepers caused by excessive loading and reviews some investigations which have been carried out into the problem. It is suggested that further attention to rail design is needed to ensure that the maximum loading benefit is obtained. There is a need for establishing the maximum loading and best arrangement of locomotive axles for any given weight of rail. One of the conclusions reached by the author is that use of the continuous elastic-support theory as a means of assessing the safe loads and stresses caused on the track by locomotives is useful in designing the axleloading and layout, but with heavy axleloads the curve effects on rail-fillet stresses become the critical factor. With smaller wheel diameters the local railhead stressing effects must also be watched.

STABILITY OF LONG-WELDED RAILS
In 1953 an exhaustive testing programme was initiated by the Civil Engineering Laboratory to investigate the conditions and factors affecting the stability of long-welded rails, mainly pertaining to British Railways field conditions. To study the factors involved in track buckling, lateral deflection was induced on a 120-ft. length of track mounted on rollers with a distance between lateral reaction points of 20 to 106 ft. It was soon seen that conventional deflection formulae did not apply, especially in respect of overall stiffness of track, and that this varied with the length deflected,

amount of deflection, sleeper-spacing, type of rail fastening, and rail section. These preliminary investigations took no account of the effect of ballast. To obtain information on the behavior of sleepers, rails, and fastenings simultaneously, a lateral bending test was devised for deflecting a 30-ft. section of track under lateral point-loading. Various sleeper-spacings and types of fastening were used and suitable formulae were evolved. The effect of ballast was investigated in a series of tests to ascertain its resistance to the lateral and longitudinal movement of both timber and concrete sleepers. In the main buckling tests on a 120-ft. test-bed, a length of track was subjected to thermal stresses in such a way as to simulate the central portion of a length of long-welded rail which does not move with changes of temperature. Loss of load in the track when buckling occurred as a result of rail expansion could be calculated from the gauge readings and the alignment of the buckled track.

PROPULSION OF TRAINS ON SHARP CURVES
A model to simulate the forces resulting in overturning and flange-climbing with propelled trains on sharp curves led to a series of tests arranged on a sharp curve at Dover. An axlebox lateral-force gear was used to measure the elements of the flange force present at the axleboxes, and load measuring baseplates were fixed between the outer rail and the sleepers to measure the vertical loads imposed by the wheels as well as the lateral loads. The latter are equal to the flang forces, less the lateral tread friction at the outer rail. The results of these tests showed that the increased lateral force when propelling exceeded considerably the value attributable to the propulsive effort and the angle between the coaches.

HIGH LATERAL FORCES ON SHARP CURVES WITH PROPELLED TRAINS
In an effort to explain why the outward forces on the trucks of propelled trains are greater than can be explained by the angle present between center lines of the vehicles, British Railways conducted a test on curved track to determine vertical loads and lateral forces. Six special baseplates were installed on adjacent sleepers on the test curve to record vertical loads and lateral forces between rail and sleeper. It was found that lateral forces towards the outer rail when propelled are considerably greater than when hauled. A more severe speed restriction on a particular curve is of little assistance because speed, and hence centrifugal force, is low anyway. The increase of lateral force towards the outer rail when the train is propelled is accompanied, at the leading outer wheel of a bogie, by increased vertical load so that the possibility of flange-climbing derailment is not altered appreciably. Propulsion on a sharp curve produces an overturning movement on the train. For severe locations its magnitude should be restricted by a limitation on tractive effort.

DYNAMICS OF RAIL FAILURES IN THE TRACK
The propagation conditions of the following defects were studied: transverse cracks in the head; horizontal cracks in the head; and starcracking at fish-bolt holes. The main object was to attempt to determine the length of time after the appearance of detection of the failures during which the rails could be left in the track before dangerous failure became imminent. Laboratory tests failed to determine this time factor. Field test results from the Paris suburban railway are briefly described for the three types of defects. Laboratory measurement of transverse defects showed the electric method gave more accurate results than the ultrasonic method using pulse echoes.

1964 EARTHQUAKE DAMAGES TO THE ALASKA RAILROAD
The 536-mile Alaska Railroad, which operates from two tidewater ports, Seward and Whittier, on the north Pacific Coast, through to central interior Alaska suffered intense damage. Some 200 miles of railroad were totally immobilized. All communication with line points were disrupted. The damage was such that it was impossible to use the railroad to reach the distressed areas. In excess of 110 bridges were rendered unserviceable; miles of track were warped out of line and rails twisted. Landslides accounted for over 2 1/2 miles of lost grade, leaving rails suspended in mid-air. The port and terminal facilities at Seward were all but wiped out by a combination of seismic action, tidal waves and fire. Whittier fared somewhat better, but was far from operable. Two hundred and twentyfive pieces of rolling stock were either lost or badly damaged. The Railroad property loss was estimated at $35,000,000. Photographs of some damaged areas are shown. Railroad repair problems are briefly discussed.

DETECTION OF WHEELS WITH DEFORMED TREADS
The operation of rolling stock with defection wheels can have a detrimental effect on the track, causing additional rail stress and ultimately rail breakage. In addition, axleboxes and underframes can be damaged and to a lesser extent vehicle bodies. The degree of damage depends on the depth and length of wheelflat and the train speed. Presently, harmful effects of defective wheels are controlled through the implementation of regulations which define tolerances for wheelflats and wheels with material accumulations. Also, some administrations have adopted certain braking designs and procedures to minimize wheel damage. However, it is suggested that what is needed is better detection methods for early identification of problems.

REVIEW OF A RUSSIAN ARTICLE CONCERNING THEIR APPROACH TO TRACK DESIGN AND MAINTENANCE
Three means of reducing track maintenance are being instituted in Russia in order to counter the 30-60% reduction in productivity of gangs caused by heavy traffic. It is estimated that each kilogram of rail weight reduces cost of track maintenance by 1.4-1.6%. Therefore use of the lightest size P-43 is being discontinued. New standards of track design utilizing welded rail would reduce maintenance of way by 14-20%. A 5 cm. increase of depth of ballast in 20 x 10 to the 6th power ton/klm. areas reduces labor cost by 5-7% and an annual reduction of stone by 500,000 cubic meters. [Russian]

VEHICLE SUSPENSION AND BOGIE DESIGN IN RELATION TO TRACK CONDITIONS
The relationship of vehicle suspension to track conditions is expressed analytically. Significance of coning lies in its property to transmit and magnify the effects of track misalignment to the vehicle body. This effect will become greater as tread wear develops. In the event of build-up of wheel movement, flang-climbing and bogie hunting oscillations may occur. The effects of conicity can be reduced in new designs by the provision of positive guiding of axles by means of telescopic or other guides, together with roller bearing boxes and wheels having a minimum of coning, to avoid running against one rail. Frictional effects of laminated springs and suspension links transmit shock vertically and laterally from the track, and the elimination of such friction is desirable and beneficial. Suspension link length is important, and an increase in length will diminish the transmitted shock. A relationship has been established between track shape and vehicle response, which may be applied by a special application to an analog.

METALLURGICAL EFFECT OF RAIL-CROPPING METHODS
The results of a questionnaire, returned by 24 of 36 railroads, regarding uses of cropped rail and methods used for cropping are reported. Micrographs are shows of the grain structure and hardness resulting from cutting using a friction saw. The cutting caused the metal to flow. If cropped rail is to be used for welded rail by the flash-butt welding process, the heat effect of the cutting is of no consequence.

SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS
Three rolling-load tests of induction-hardened rails from Japan averaged 2,715,000 cycles. Two rolling-load tests of a standard carbon 115-lb rail averaged 3,063,000 cycles. Two rolling-load tests of 100-lb continuous-cast rail from Europe averaged 2,027,000 cycles. Flame-hardened high-silicon rails failed at 1,005,800 cycles and 3,834,000 cycles. Rolling-load tests of a series of rails flame-hardened at different speeds are reported. One group averaged 2,947,000 cycles and the other two groups all failed at less than 1,000,000 cycles. Rolling-load tests on one flame-hardened specimen from Dominion Steel Co. ran 3,857,000 cycles.

DISCUSSION ON STRESSES IN RAILROAD TRACK
The inspection tests of rail-joints in track made for the purpose of learning the source of the wear of the joint bars and the rail, the places of wear, information bearing on the mutual interaction of the worn bars and rail when under load and when the bolts are newly tightened, and other information relating to the stability and maintenance of the rail-joints have given desirable information. The occurrence of high stresses in the unloaded worn joint bars in track due to the tightening of the bolts was found to be as great as 30,000 and 40,000 lb. per sq. in. and in a few cases as high as 60,000 lb. per sq. in. The stresses were fairly proportional to the amount of the lateral bending put into the bar by tightening the joints, measured from the loose condition. The instruments designed and built to facilitate the measurement of profiles and shapes and straightness of joint bars and rail and their position with respect to each other in the joint have proved satisfactory.

WHEEL, AXLE, AND RAIL STRESS PROBLEMS RELATED TO HIGHER CAPACITY CARS--PART IV-EFFECT ON RAIL
Those items that have been found advantageous in reducing shelling caused by higher capacity (85 to 100-ton) cars are wheel loads should be limited in proportion to wheel diameter. Higher strength material in the rail will greatly reduce shelling but not entirely eliminate it (under the wheel loading conditions existing with 70-ton capacity cars before the allowable load was increased 5%). Modified rail head contours in today's modern rail sections which approach the average worn wheel condition, have been helpful in reducing shelling. Rail lubrication on curves extends the rail life but results in the removal of more rails for shelling rather than abrasive wear.

RESEARCH ON THE OPERATING STRESSES IN PATH RAILCAR AXLES, DRIVE SYSTEMS, WHEELS, AND RAIL JOINTS
This paper identifies the cause of premature cracking of axles with inboard bearings as being the bending-mode oscillation of the axle. It points out the importance of gear-tooth separation produced by torsional oscillations in the drive motor system in both right angle and parallel drive gear failures. A unique technique of simultaneous measurement of impulse and thermal loads on the wheel tread is explained and the test data are presented. The relation between the wheel impact loads and the dynamic behavior of rail joints is shown.

LATERAL LOADING BETWEEN LOCOMOTIVE TRUCK WHEELS AND RAIL DUE TO CURVE NEGOTIATION
Curve-negotiation mechanics and forces resulting when locomotive trucks negotiate curves are well recognized. However, meaningful and reasonable prediction of forces resulting in service conditions has been limited. An instrumented wheel-axle assembly was developed and used on 2,3, and 4-axle trucks to study the effect of creep and the transverse load reactions resulting between wheel and rail. Instrumentation was used to measure these forces and the reactions between axles and truck frame under operating conditions. Test results confirm predicted phenomena and indicate the effect of creep on resulting loads. This paper includes a brief and general review of curve-negotiation mechanics and presents the test results and their relation to the theoretical analysis.

CRACKS AT RAIL ENDS
The occurrence of cracks at rail ends in the upper fillet and at the first bolt hole were investigated by the Engineering Division Research Staff. It appears that the development of these cracks is related to the use of rail joint packing, consisting of a mixture of wood flour and oil. The accompanying photographs are typical of the cracks found; the corrosive attack is clearly indicated. Seven railways have reported the development of these cracks where joint packing has been used. Others have removed rail joints where the packing was applied and found no cracks. It seems evident that in some instances the rail joint packing has contributed to the development of rail end cracks, and the indications are that a corrosive effect has either so lowered the fatigue strength of the steel that crack developed or that stress corrosion cracking has developed in the areas of high tensile stress in the upper fillet and around the first bolt hole.

LETTER ON OCCURRENCE OF CRACKS IN RAIL ENDS
Results of a survey on inspection of rail joints with and without rail joint packing are presented. Table A includes those railways which report the development of fillet or bolt hole cracks where the packing has been used. Table B includes those railways which report no cracks. The Corrosion Research Laboratory of the Illinois Institute of Technology has been conducting tests with rail joint packing to determine whether stress corrosion cracks can be produced in accelerated laboratory tests in specimens of rail steel. These tests included both new packing and user packing removed from rail ends that had developed cracks. It has not been found possible to produce stress corrosion cracks with extracts from either the new or used packing in the accelerated laboratory tests. Accordingly, it has not been possible to determine that any chemical action of the joint packing is responsible for the cracks that have developed in service.

JOINT DEFLECTION AND RAIL END BATTER ON 130 LB RAIL EMPLOYING UNCONVENTIONAL METHOD OF LAYING
The purpose of this test was to determine if rails matched and laid in a continuous stretch of track with ends in same position as when passing through the hot saws at the rail mill show less joint deflection and rail end batter than rails received from the mills and laid in the usual way. The matching and laying of rails for the test produced 92 joints where ends were matched due to different ingots and rail classification. Initial measurements of joint deflections and rail end batter were taken during May 1930, and these measurements were repeated at intervals over a period of eight years. The final inspection was made during May 1938. It was concluded that to load, identify, distribute and lay rail matched in the same order as rolled and hot sawed at the mill would unquestionably result in higher manufactoring and rail laying costs than now exist. The results of this test with a limited number of rails matched, compared with rails not matched, show no improvement over the usual method of shipping and laying rail.

A1 040254
COMPARISON OF RAIL ABRASION, END BATTER AND DEFLECTION FOR 130 LB., 131 LB., AND 152 LB. RAIL
Rail abrasion, and batter, and joint deflection measurements were made on 130 lb., 131 lb., and 152 lb. rail on adjacent stretches of track east of Tyrone,

Pa. Various joint bars were employed. Maintenance cost records were also recorded for this stretch of track. Early measurements, particularly of joint deflection, gave large variations in deflections from joint to joint, and led to removing and measuring a considerable number of bars showing high and low joint deflection. The results of these measurements indicated a need for better mill inspection to control vertical camber and led to a more thorough control of camber ranges during manufacture. Also the initial use of the "Toeless" type of bar such as applied in this test indicated a pronounced tendency to "cocking" the bars during first application and led to development of the present yoke gauge now in general use for applying the "F" types of bars to prevent "cocking". The 152 lb. and 131 lb. "F" type bars in this test were badly cocked when first applied. In the joint deflection comparison a good showing is made by the 131 lb. rail (untreated) with the B-1 type bar (Plan 66194-B) both on tangent and sharp curves. As to rail end batter the 131 lb. (untreated) rail with B-1 bars also gives the least amount of batter on tangent and sharp curves after eliminating the 131 lb. (heat treated) rail from which it would be expected less batter would occur. For the various weights of rail (untreated) on curves the 152 lb. rail had an additional service of one year over 130 lb. rail and three-fourths year over 131 lb. rail before it was necessary to transpose the rail. Measurements of rail abrasion during the period of test shows a marked decrease in abrasion on both tangents and curves for the 152 lb. and 131 lb. rails over the 130 lb. rails all untreated. Maintenance costs have been largely affected by local conditions, particularly differences in drainage and in the new tie territory of 130 lb. rail previously mentioned.

ROLLER AND DROP TESTS OF POTENTIALLY DEFECTIVE RAIL

Roller tests and drop tests were conducted on a batch of rail suspected of having interior defects. A Sperry hand testing device had been used to indicate the defects. A total of 25 rails were subjected to the roller test. A camber of 13/16" on rolls spaced 90 in. apart was used. All 25 rails endured the test with out fracture. Next, the rails were submitted for drop testing. This was carried out with the rail placed on a 48" span with a drop of 22 feet and the blow of the tap was directed at the location marked by the Sperry hand check. Results indicated that interior defects were not present.

BATTER TEST OF 151 LB. R.E. RAIL

This report covers a test of 151 lb. R.E. rail in which the base and lower portion of the web at the rail ends is cut square while the head and upper portion of the web is mitred, the change in angle of out taking place about the center of height of web. The mitre makes an angle of 60 degrees with the line of track. For the purpose of test the above rails were laid on the Pittsburgh Division in No. 1 Eastward Freight Track east and west of Ardara on April 27, 1935. For comparison, 67, 131 lb. X-Rails with ordinary square ends were laid at same time adjacent and west of the mitred rails on the same track. After one night's traffic had passed over the rail initial measurements of rail and batter were taken. It was concluded that insofar as rail end batter there is no advantage in the use of mitred end rails over ordinary square cut end rails as determined by batter measurements over a period of one year and-1/2 months service in heavy tonnage freight track.

RAIL ABRASION AND END BATTER OF CONTROL COOLED 131 LB. R.E. RAILS

This is a progress report showing results of rail abrasion and end batter of control cooled 131 lb. R.E. rails rolled and treated by various manufacturers and laid during 1935. The Illinois and Bethlehem rails were laid on the Middle division No. 4 westbound passenger tracks on tangent and 4 degrees 0" curve east and west of Lewistown, Pa. The Carnegie and Inland rails were laid on the Panhandle Division No. 1 eastbound passenger and freight track on tangents and curves ranging from 3 degrees 14' to 7 degrees o" west of Carnegie, Pa. It was found that for the tangent track the differences in both abrasion and batter as between thermal treated and ordinary hot bed cooled rails are hardness of the rail has resulted from the thremal treatment. The information for curve is not directly comparable on account of wide variations in curvature where measurements were obtained. There have been no transverse fissures or other failures in either the test or comparative rails during the three year period between measurements.

STRESS CORROSION OF RAIL WEB STEEL (STATIC)

The test included six rail joint segments containing one bolt hole with a bolt inserted to make the joint. It also included twenty steel specimens taken from rail steel which were subjected to static bending stresses. The twenty corrosion test specimens were tested after nearly twelve and one half years of exposure to the elements. The joint segments were tested approximately one month later. All of the test specimens were cleaned throughly and examined in the laboratory by Magnaflux and Magnaglow methods for the presence of corrosion cracks. While there was considerable pitting to be found, the laboratory examination disclosed no cracks in any of the specimens. This test shows that static stress combined with corrosion has little or no effect upon the development of cracks in rail web steel.

ARRANGEMENT OF RAIL ANCHORS ON TRACK HAVING MAJOR TRAFFIC IN ONE DIRECTION BUT SIGNALLED FOR MOVEMENT IN BOTH DIRECTIONS

The test consisted of two stretches, one at Metuchen on the New York Division and one at Edgewood on the Maryland Division. Each stretch was signalled for movement in both directions. Application of rail anchors in five different arrangements was made on new 155# rail. From experience gained in this test it may be concluded that six anchors with traffic are seldom sufficient on a main line track. With regard to reverse anchoring it may be concluded that two reverse anchors are sometimes, but not usually sufficient. Four reverse anchors appear to be sufficient in all cases. For track having major traffic in one direction but signalled for use in both directions, a minimum of 8 normal and 4 reverse anchors be used and that they be applied in the present conventional arrangement with reverse anchors being applied to the opposite side of normally anchored ties.

140-LB. RAILS TO FINE GRAIN STEEL (ALUMINUM ADDED TO THE INGOT)
The purpose of this test was to determine if inherently fine-grain steel will resist shelling better than rails of ordinary steel. Frequent inspections of the test installation were made, and it was observed that the fine-grain and ordinary rails performed nearly alike. In 18 months' time the flaking and head checks were much in evidence, and after two years of service, head checking and flaking were well advanced. A derailment in November 1956 damaged three of the fine-grain rails. A previous laboratory examination of the rails had revealed that the fine grain steel had practically the same mechanical properties as the coarse grain steel as measured by tensile tests and Brinnel hardness. It was concluded that fine grain steel produced by addition of aluminum to the ingot as used in this test, offers no advantage for use in rails.

DETERMINATION OF PLASTIC FLOW IN RAIL HEAD
The purpose of the test was to determine the amount of plastic flow which takes place in the gauge corner of a rail on the high side of a curve under conditions which produce shelling. The rails were laid on the Bolivar Curve. At this location the track was laid with 140-lb., 1948 rail, which in August 1953, was showing flaking and light shelling. This is a 4-degree curve with 4-inches superelevation, authorized speed 45-mph, and carries moderate to heavy eastward freight traffic. Records kept in connection with another test indicate a tonnage of approximately 29,000,000 gross tons annually. The three test rails were installed August 17, 1953. Inspection September 12, 1955, showed light flaking on all three rails. On the high rail of curves there is a flow of metal at the top gauge corner of the rail toward the gauge side. This flow of metal extends to a depth of 1/4-inch to 3/8-inch below the rail surface. The magnitude of deformation is positive evidence of shear stresses well beyond the yield point of the steel.

A1 040279
RAIL WEB STRESSES IN HIGH SPEED TERRITORY
The purpose of the present test was to determine if possible the cause of frequent split web failures in the joint on 131-lb. RE rail on the Fort Wayne Division, and in 152-lb. PS rail on the New York Division. Web failures in 131-lb. and 152-lb. rail on the Fort Wayne and New York Divisions are adequately explained by the corrosion fatigue theory. The ocassional bolt hole failures in 133, 140, and 155-lb. rail are not readily explained. A 50% allowance for impact is justifiable based on measured wheel loads. Application of reformed bars changes stress distribution in the rail web and in many cases increases web stresses, accelerating rail web failure. Loose bolts and increase in rail end gaps increase rail web stress. The results of this test emphasize the need for protection of rail steel against corrosion, for maintaining standard bolt tension, a good fit between bars and rail, and good surface through joints.

ALLOY STEEL RAIL (CHROME-VANADIUM OR "CV")
The CV rail was laid in October 1953, in connection with regular rail renewals. The location was selected because it was one where moderate shelling had developed in the previous 131-lb. rail over a period of about 11 years. A total of 47 CV rails were laid--16 on the low side and 31 on the high side of the curve. Measurements of gauge superelevation, ordinates and rail head wear were made. A final inspection of CV rail was made on October 29, 1959, at which time 30 CV rails remained in track. There was no indication of shelling, although, some flaking was noted on the CV rail, and there was no indication of rail and defects. The results of this test have shown the CV alloy steel of the composition used to be unreliable. Its good wearing qualities and superior resistance to shelling are over-shadowed by its poor resistance to impact.

FLAME HARDENED AND HEAT TREATED STOCK RAILS
Flame hardened and heat treated stock rails were installed at locations where the open hearth stock rail had shown short life due to excessive wear, primarily flange wear. Flame hardening and heat treating produced a Brinell hardness on the rail head of approximately 350. Both the flame hardened and heat treated stock rails gave better performance than the open hearth stock rail; however, the flame hardening process resulted in considerable vertical distortion of the stock rail, as much as five feet in 60-ft. As a result, this type of hardening was discontinued. While this test was installed initially to investigate the reduction in flange wear, the use of heat treated stock rails to date and the results of heat treated rails used for other purposes indicate that they provide greatly increased life and reduced maintenance as compared with ordinary stock rails where crushing and plastic flow cause frequent renewal.

A1 040283
FLAME HARDENED VS HEAT TREATED AND MANGANESE CROSSINGS
The purpose of this test was to determine the relative value from a service point of view of flame hardened crossings, as compared with heat treated and manganese crossings. Two flame hardened, one heat treated and one maganese crossings were installed on new timber supports in a two over two track crossings, making an angle of 71 degrees 38'. All crossings were interchangeable. These crossings were installed on May 2, 1953. On the September 8, 1954, inspection it was found that excessive batter on one of the flame hardened crossings made renewal necessary. Initial cost, maintenance required, as well as service life indicate a preference for the heat treated crossing over the flame hardened.

RAIL ANCHOR RESISTANCE IN TRACK
Six panels of track were tested at two locations. Resistance to rail anchors was developed by applying a longitudinal load to the end of each rail in a panel of track; this load was transmitted through rail anchors and ties to ballast. The load was applied by means of two hydraulic jacks and manually operated hydraulic pump. The panels at Lewistown having every tie anchored failed at a total load of 32,000 pounds while the panel having alternative ties anchored failed at 29,000 poinds. Panels at Parkersburg having every tie anchored failed at an average total load of 20,000 pounds while the panels having alternate ties anchored failed at an average total load of 18,000 pounds. Actual resistance to longitudinal movement, per panel, depends on type and quality of track structure.

RELATIVE HAZARD INVOLVED IN WEB CRACKS OF VARYING LENGTH DETECTED BY AUDIGAGE
For testing, eight rails having web cracks from 0.25 to 9 inches in length along the centerline of the web were prepared by joining them with a pair of reformed joint bars, to a sound rail end of the same section, making a combined specimen somewhat over six feet in length with a joint at the center. These specimens were placed under the million pound machine with supports 60-inches apart, the joint at the center, and the load applied at the extreme end of the sound rail at the center of the joint. The loading was increased until ultimate failure in the rail end was obvious. Two rails with cracks through the bolt hole were also tested. On the first series of tests, except for one rail which had a nine inch crack, the load had to be carried beyond that which gives a bending moment corresponding to what can be expected in track. In the second set of tests rail loading caused the cracks to lengthen. It is still recommended that rails with cracks over 5 inch in length be removed as is required by Audigage testing procedure.

REPORT TESTS OF STABILITY OF 100 TON CAPACITY HOPPER CARS UNDER VARIOUS TRACK CONDITIONS HOLLIDAYBURG, PA.
Tests were started in June 1966 and completed in January 1967. No. 14 track, approximately 3600 feet in length, including 1000 feet of two degree curve, was selected as a suitable test site. Tangent track test runs were made with the track warped successively at intervals of 19'-6", which is normal joint stagger for 39 foot rails, and intervals of 31 and 39 feet. Curve track tests were made with the track warped at 19'06" and 15'-6" intervals. The modified H43 loaded hopper car and the H46 loaded covered hopper car should satisfactorily negotiate an indefinite succession of cross level changes in opposing directions of 1-1/2 inches in tangent track, 1 inch on curves with no more than 5 inches of superelevation and 1/2 inch where the superelevation exceeds 5 inches, regardless of speed. Continuous succession of cross level changes limits speed to 15 mph. The unmodified H43 loaded hopper car should satisfactorily negotiate an indefinite succession of cross level changes in opposing directions of 1 inch in tangent track, but not more than 1/2 inch on superelevated curve track regardless of speed. Continuous succession of cross level changes limits speed to 10 mph.

WEAR LIFE OF HEAT TREATED 131 LB., 18 FT. SWITCHES
This brief letter correspondence records the fact that an in-service test of heat treated switches progressed to the point where the first switch was removed because of excessive wear after 27 months of service. This was considered about seven times the life of an ordinary switch. The cost of this 130 lb., 18', heat-treated switch was $161 which was thought to be the cost of untreated switches at the date of purchase.

A COMPUTER STUDY OF DYNAMIC LOADS CAUSED BY VEHICLE-TRACK INTERACTION
Computer analyses of vehicle and track are producing enlightening results regarding actual dynamic loads and the manner in which various parameters of vehicle and track structure affect these loads. Using this information, it is possible to decide more intelligently how to alleviate the high wheel-rail stresses caused by today's unique traffic and track conditions. Possible solutions range from better track maintenance to different wheel rail geometries to changes in stiffness and damping of trucks and the track structure itself.

THE RELATION BETWEEN THE SWAYING OF HOPPER CARS AND THE STAGGER OF RAIL JOINTS IN TRACK
Freight cars with high-center-of-gravity loads sway considerably, especially on tracks with low joints. To produce synchronism, the time of swaying must have a definite relation to the speed of the train. A principle that maybe used to destroy cumulative swaying is that the stagger of rail joints must be such that a car must hit, simultaneously, a pair of joints, the joints being in opposite lines of rails. A second principle is that the stagger should be unequal in such a way that enough joints occur at suitable phases of swaying to neutralize the effects of the other joints. Frictional resistance helps in this principle. The amplitude of swaying may be increased by a series of low joints, provided that the swaying of cars synchronizes with the impulses given by the joints.

REPORT ON A STUDY OF TANK CARS INVOLVED IN A COLLISION AT CRETE, NEBRASKA
On February 18, 1969, a Chicago, Burlington & Quincy eastbound freight train derailed cars and freight cars standing on an adjacent double-end

siding. The group of standing cars included three tank cars loaded with anhydrous ammonia. The center car of this standing group of tank cars was a stub-sill, non-insulated tank with a nominal capacity of 33,500 gal. In the collision, the tank ruptured, permitting contents to escape. Temperature-impact energy transition curves from the Charpy tests are shown. The fracture of the Crete tank car was almost entirely of a brittle nature. The metallurgical processing of the tank led to a microstructure conducive to low toughness and a high NDTT.

QUALITY OF RAILS AND MEANS OF GUARANTEEING IT--FALLING WEIGHT TESTS AND DEFINITION TESTS (1ST AND 2ND SERIES OF TESTS)
The main object of these tests--was to define and to standardize the conditions of use of the falling weight tests laid-down in UIC Leaflets 860-1-0 and 860-2-0, for the acceptance of rails of current quality and rails of nontreated steel of a quality resistant to wear. It was concluded that a falling weight test, irrespective of its type, is not representative of the fatigue behavior of rails in the track, but it was considered advisable to retain for the time being, such a test on complete pieces of rail, to make it possible to detect and eliminate brittle rails with a large degree of probable success and to maintain each rail production within a truly characteristic and correct scatter range.

A1 040414
QUALITY OF RAILS AND MEANS OF GUARANTEEING IT--CONDITIONS OF USE FOR TECHNICAL SPECIFICATION UIC 860-1 CONCERNING: DIMENSIONAL TOLERANCES, FALLING WEIGHT TEST, TENSILS TEST-PIECE, DETECTION OF PIPING
The conditions of application of UIC Specification No. 860-1 were investigated relative to dimensional tolerance, falling weight test, tensile test piece, and detection of piping. Initially, rail tolerance measurements indicated that the majority of mill-produced rails were not acceptable, but if specified tolerances were strictly adhered to, it was felt the price of rail would increase greatly. Since users were reasonably satisfied with currently produced rail, the tolerance applicable to web thickness, inclination, and openings of the fishing angles were relaxed. When UIC Specification No 860-1 was initiated in 1954, it constituted the first step towards the standardization of the falling weight test. The Committee now offers a choice between two methods of carrying out the falling weight test; one method involves two successive blows applied to the test pieces rolled from a certain number of ingots, the other involves one blow and is applied to test pieces rolled from every ingot. Because of the nature of the steel used for wear-resisting rails, the corresponding UIC Specification 860-2 has been drafted to include a tensile test piece of 10 mm diameter. The Committee to propose the standardization of the 10 mm diameter test piece. One result of this decision is that the minimum elongation will have to be raised from 12 to 14% in the case of ordinary rails. This test has been found to be not very accurate and of limited interest, since in reality it only permitted the revelation of piping in the rail without offering the possibility of its true appreciation. The Committee therefore sought another test for inspection purposes which would reveal piping in an indisputable manner. After considerable research, they have decided on a test which consists of the examination of the polished slice of rail intended for the macrographic (sulpher print) test.

BEHAVIOUR OF THE METAL OF RAILS AND WHEELS IN THE CONTACT ZONE-RESIDUAL STRESSES IN THE RAIL (CONTINUED) STUDY OF THE WORK-HARDENED ZONE
This report contains the results of measurements taken to study the work-hardening caused by traffic, and more especially the changes in the residual stresses in the rails near the running tread which constitute an important factor in the study of rail fatigue phenomena. About 5 mm below the surface the work-hardening is very large, and the rail is the center of a hydrostatic pressure zone extending down to a depth of approximately 10 mm, this then changing into a tensile one with a maximum at about 15 mm. This may explain why the fatigue cracks (of the kidney-shaped flaw type) tend to originate at a depth of 10 to 20 mm but do not develop in the upper highly compressed zone. Furthermore, the residual-stress fields vary from one section of the rail to another, probably as a result of the oscillations of the wheel-loads due to short-wave rail corrugations.

A1 040417
BEHAVIOUR OF THE STEEL AT THE POINT OF RAIL-WHEEL CONTACT- INTRODUCTORY STUDY ON THE CAUSES OF SHELLING CRACKS IN RAILS
This report reviews pertinent literature on the subject of shelling cracks in rail head. From the research conducted at the University of Illinois it is concluded that shelling cracks in rail heads are primarily due to fatigue under repeated rolling action. Obvious methods of reducing the development of shelling cracks would be to reduce wheel loads on the rails, to use larger diameter wheels or to use stronger rail steels. Future research should be directed towards the closing of the gap between standard fatigue data and the fatigue phenomenon as it occurs under contact stresses due to rolling action. At the moment, the prime difficulty in correlating tensile or torsion and rolling contact fatigue data stems from insufficient knowledge of stress distributions modified with respect to elastic theory by plastic deformation.

Question C53. Restrictions on the use of this document are contained in the explanatory material.

SERVICE AND DETECTED FAILURES OF BUTT-WELDED RAIL JOINTS
During the period 14 service and detected failures of butt-welded rail joints were submitted for examination to the AAR Research Center. Macrographic and Microscopic examinations of the welds and of both rails adjacent to the joint were made. Since the majority of the butt welding rail in the United States is done by means of the electric flash process, the failures reported in Table 1 are predominantly in the welds produced by this process. Because of the thermal shock produced by this process in the relatively short heated portions at the ends of the rail, failures occur in rails with heavy segregation or fish tail which, before welding were in a homogeneous state, but opened into a discontinuity during the welding.

INVESTIGATION OF SERVICE AND DETECTED BUTT-WELDED RAIL JOINT FAILURES
In the period between October 1, 1965, and October 1, 1966, sixteen failures, service and detected, in butt-welded rail joints were submitted to the Association of American Railroads Research Center for a metallurgical examination. To date, the investigation has been completed on 9 of these 16 failures, in two oxyacetylene pressure butt weld: It is believed that a result of improper welding practice. Failure in an electric-flash butt weld was attributed to the presence of an electrode burn introduced during the welding process. In other electric-flash butt welds it was disclosed that the rail ends were cropped with a petrogen torch and that the time between cutting and welding ranged from a few days to several weeks. This time lapse is of concern because of the incipient cracks that may form and further develop on subsequent heating operations. A second possible cause for these failures is that the amount of rail cropped from the ends of these secondhand rails was insufficient to remove existing bolt-hole cracks that extend back into the web. In still other electric-flash butt welds, heavy segregation patterns were found.

ROLLING-LOAD AND SLOW-BEND TEST RESULTS OF BUTT-WELDED RAIL JOINTS
In the period from October 1, 1965, to October 1,1966, sixteen rolling load tests and six slow bend tests were conducted on butt-welded rail joints at the Association of American Railroads Research Center. The joints were made by the thermite (Thermex Metallurgical, Exomet and Orgotherm), submerged-arc and oxyacetylene pressure-butt-welding process. The rolling-load tests were made on a 12-in-stroke rolling-load machine. Welded specimens were tested for various reasons including: (1) to determine the quality of the submerged-arc-welded rail joints, (2) to evaluate 115-lb thermite welded rail joints made by the Exomet process, (3) to determine the seriousness of making butt welds from rails with hairline cracks of (pipe) in the web. (4) to investigate the possible detrimental effects of a collar that was not removed from an Orgotherm thermite welded rail joint. The slow bend tests were made with the rail resting on supports 4 ft. apart and loaded at 2 points, one on each side of and 6 in. from the weld. These tests were made with the rail base down, thereby subjecting the head to a compressive stress and the base to a tension stress. For satisfactory service performance a minimum of 1.5 in. of deflection and 140,000 psi modulus of rupture are being used as tentative criteria for oxyacetylene and electric-flash pressure butt welds. A summary of the slow bend test results is provided.

BUTT WELD FAILURES
A record of failures in various types of butt-welded rail is presented and briefly analyzed. On the basis of failures per 100 weld years, the failure rates for the oxyacetylene pressure butt welds and electric flash pressure butt welds are low, and about the same, for new rail. It should be noted, however, that the average service period of the oxyacetylene pressure butt welds is 68 percent longer than that of the electric-flash pressure butt welds. For relay rail, the performance of the oxyacetylene pressure weld is somewhat better than that of the electric-flash pressure weld. The failure rate in thermite welds is substantially higher than that for either of the two pressure processes.

EVALUATION OF LINDE'S EXPERIMENTAL 936-89 WIRE FOR BATTERED RAIL END BUILD UP USE
An investigation to evaluate Linde's experimental 936-89 cored wire for rail end build up was conducted based on rolling-load test results, hardness survey results and a metallurgical examination to determine the quality of the weld. Information supplied by Linde relating to the welding procedure indicates that prior to welding, all joints were preheated to 700 F. A Tempil stick was used to determine the preheat temperature. Immediately following the preheat the joints were welded using 425 amperes, 27 volts. Sample rail joint were resurfaced at the butt edge to bring the deposit closer to the edge. These welded, battered rail end sample joints were subjected to rolling-load testing in the 12-in-stroke rolling-load machine. Testing of one sample was discontinued after the joint had been subjected to 4,002,200 cycles in the rolling-load machine because of excessive batter. Testing specimen 154 C was subjected to 2,000,000 cycles in the rolling-load machine. This test was discontinued because of a failure, originally starting as a progressive-type failure from a bolt hole, and later resulting in a head and web separation when the bolts were tightened to a desired tension. Speciments cut from joint 154 A show a normal heat pattern and good weld-metal deposit penetration. A good weld-metal deposit penetration was noted.

METALLURGICAL EXAMINATION OF FOUR ELECTRIC-FLASH BUTT WELD SERVICE FAILURES SUBMITTED BY THE FLORIDA EAST COAST RAILWAY
An investigation was made to determine the cause of four electric-flash butt welded rail joint service failures. These four failures are representative of a group of 13 or more failures that occurred in a short period after laying. From the results of this investigation it is believed that these failures are not related to the quality of the rails or the soundness of the welds. It was later disclosed that the rail ends were cropped with a petrogen torch prior to welding. Information was also received that the time between cutting and welding could range from a few days to several weeks. It is possible that incipient cracks formed during cropping of rail ends. Once these incipient cracks have formed, further development of the crack can occur on

reheating, such as during the welding operation. A second possible cause for these failures is that the amount of rail cropped from the ends of these secondhand rails was insufficient to remove bolt-hole cracks that extend back into the web. From this investigation it is believed that these failures can be attributed to (1) cutting the rail ends with a petrogen torch, (2) incomplete removal of existing bolt-hole cracks, or a combination of both these factors.

SHELLY RAIL INVESTIGATION, ROLLING-LOAD AND SLOW-BEND TEST RESULTS

Two methods presently employed for improving shelling resistance is the addition of alloying elements and the heat treating of rail. The rolling-load tests in a cradle-type machine are designed to evaluate these methods of improving the resistance to shelling. Rolling-load test results obtained from these cradle-type machines for the period between October 1, 1965, and October 1, 1966, are shown. The S-13 series were initiated to compare the effects of welding prior to flame hardening and flame hardening prior to welding. The electric-flash butt welds were made from secondhand 132-lb HF rail and flame hardened by the Hammon process. Specimens S-13A and S-13C failed after being subjected to 389,800 and 656,900 cycles, respectively. As a result of this performance, rolling-load tests were conducted on welded joints made from 132-lb HF secondhand rail having no flame hardening applied. These joints, S-13E and S-13J, shelled after being subjected to 1,088,000 and 1,163,000 cycles, respectively. Rails flame hardened by the Linde process developed shells after being subjected to 1,254,400 and 844,900 cycles in the cradle-type rolling-load machine. During this period there were no slow-bend tests.

BEHAVIOUR OF THE METAL OF THE RAILS AND WHEELS IN THE CONTACT ZONE--ENQUIRY INTO THE PROBLEM OF SMALL DIAMETER WHEELS APPENDIX 3

The observations made at the Mairy mine concerning the wheel-rail dynamics are discussed. The width of the rolling band is wider than on the SNCF and can be explained by wear of the wheel and rail. It could also be due to transverse elastic deformation of the wheel. The calculations and measurements are summarized which were carried out in the laboratory of the SNCF to investigate the influence of the load, the curvature of the rail and the tire, and more particularly of wheel diameter on the stresses to which these components are subjected.

DERAILMENT OF A PASSENGER TRAIN CONSISTING OF A DIESEL LOCOMOTIVE WITH SIX-WHEEL TRUCKS, A BAGGAGE CAR, AND A COACH

Three letters discuss the derailment of June 7, 1968. A sketch of the derailment area and photographs of sections of the track involved are included. This derailment is characteristic of a number of derailments that have occurred on curves at or near permissible speed of passenger trains having locomotives with six-wheel trucks, derailment apparently occurring first of the rear truck of the locomotive unit or the lead truck of the baggage car following. In each case the high rail of the curve was overturned. A high ratio of L/V is required to overtrun a rail and it is unlikely that this high a L/V ratio would be developed in track unless there is some unusual condition such as a jack-knifing of couplers between cars, an unloading of the lead wheel of the truck on the high rail, or some severe wedging action of the truck between rails due to a malfunction of the truck components.

TEST TO DETERMINE VERTICAL AND LATERAL FORCES IMPARTED TO THE RAIL BY A TYPE U28CG GENERAL ELECTRIC LOCOMOTIVE, SANTA FE CLASS 350

The test runs were made using a train consisting of two lightweight chair cars and three baggage cars and a locomotive of two units, one having the instrumented truck. Tests were run at speeds up to 90 mph on dry rail and moderate temperature. The test results show lateral forces of substantial magnitude being exerted on the rails, an occasional one having a finite duration of ten feet. They also show vertical wheel loads of low value in some locations. The test results indicate it is possible for these two conditions to occur simultaneously on two or three adjacent wheels of a truck and produce an effective L/V ratio of sufficient magnitude to overturn the rail.

MEMORANDA ON CONFERENCES HELD TO DISCUSS THE DERAILMENT PROBLEM WITH 6-AXLE TRUCK LOCOMOTIVES

Two memoranda discuss derailments involving 6-wheel truck locomotives in which the high rail of a curve has been rolled over. An itemization is made of 20 derailments involving six railroads during the time period 1964 to 1970. The memoranda discuss the deliberations of a meeting between representatives of each of the railroads involved and the AAR.

DERAILMENT DATA

A series of derailments are discussed. The majority of the derailments involve a loaded car connected at one or both ends with a cushion underframe car. A test plan is suggested to simulate the derailments by using a loaded hopper car and an adjoining box car with cushioned underframe containing instruments trucks. The instruments would measure lateral and vertical forces exerted on curves similar to the derailment sites.

Derailments described in BCL-1914, Letter Correspondence.

DERAILMENTS OF TWO PASSENGER TRAINS

The pertinent facts are given for the two derailment sites and the train consist. In both cases derailment occurred at the rear truck of the last locomotive unit or front of the following car. A drawing of the wide gage is shown of the actual worn wheel and rail contour of the derailed axle involved in the first derailment. Both derailments are not satisfactorily explained.

DERAILMENT ON REVERSE CURVE

Four data sheets concern derailments on reverse curves and turnouts. The derailment on the reverse curve involved a hopper car, loaded with bulk clay, which climbed the high rail at 15 mph. The Santa Fe rules for laying and maintaining turnouts are given. One derailment at a No. 8 turnout involved splitting a switch by entering the turnout at 18 mph, proscribed speed was 10 mph. Crosslevel information is given for a derailment at the point of a frog.

ANALYSIS OF COVERED HOPPER CAR DERAILMENTS ON THE BALTIMORE AND OHIO RAILROAD
Covered hopper car derailments on the B&O system during 1967 were analyzed to update previous work. The analysis confirmed and strengthened the conclusions found earlier. The conclusions reached were that (1) in-service life has a significant effect on rock-off derailments, and (2) the April 1964 speed restriction was effective in reducing early age derailments of the cars covered. For the year 1967, it was found that derailments of C&O-B&O covered hopper cars that generated L&D claims were nonexistent. The B&O series 602000 cars have made it through their critical first-year period with only two minor derailments, neither of which generated L&D claims. This fact tends to indicate that the increased snubbing in the trucks under this series of cars has reduced their early life derailment susceptibility. Based on these results as well as on the fact that all new 100-ton covered hopper cars in AAR interchange service must now have increased snubbing, it is recommended that the April 1964 speed restrictions be expanded to cover all covered hopper cars built in 1967 which have not been modified to control the roll problem. The restriction could be withdrawn in January 1969, when all cars of this type either will have completed their "wear-in" period or will have been equipped with additional snubbing.

BUTT WELD FAILURES
A summary of the butt weld failures accumulated up to December 1967 is tabulated. On the basis of failures per 100 weld years, the failure rate for the oxyacetylene pressure butt welds is slightly higher than for the electric flash pressure butt welds for new rail (0.0072 to 0.0046). The average service period of the oxyacetylene pressure butt welds is 48 percent longer than that of the electric flash pressure butt weld. For relay rail, the performance of the electric flash pressure weld is somewhat better than that of the oxyacetylene pressure weld.

INVESTIGATION OF SERVICE AND DETECTED BUTT WELDED RAIL JOINT FAILURES
In the period between October 1, 1966, and October 1, 1967, there were seven service and no detected failures in butt welded rail joints investigated by the metallurgical laboratory of the AAR. A summary of these service failures is tabulated. Investigation 136-22 involved an electric flash butt welded joint that failed in service. The rails used in the fabrication of this joint were 112-lb RE sections rolled July 1942. This failure could be attributed to an entrapment introduced during the welding process. Investigation 136-25 involved a rail, part of a continuous welded string, that failed in service. This rail was identified as a 140-lb PS section rolled in 1959. This failure can be attributed to these electrode burns which were introduced during the welding process. Investigation 136-27A, B, and C involved three electric flash butt welded joints that failed in service. The rails used in the fabrication of these joints were 132-lb RE sections rolled in August 1965. These electric flash butt weld failures can be attributed to pipe and heavy segregration. Investigation 136-31 involved an Orgotherm thermite welded rail joint that failed in service. The rails used in the fabrication of this joint were 115-lb RE sections rolled in June 1966. This failure could be attributed to the presence of a martensite formation that resulted from a heavy grinding of the thermite weld collar after the weld metal had cooled. Investigation 136-34 involved an electric flash butt welded joint that failed in service. The rails used in the fabrication of this joint were 136-lb RE sections rolled in 1967. This failure could be attributed to the presence of this cementite.

A1 040472
RESULTS OF ROLLING-LOAD AND SLOW-BEND TESTS OF BUTT WELDED RAIL JOINTS
In the period between October 1, 1966 and October 1, 1967, 22 rolling-load tests were conducted on butt welded rail joints but no slow-bend tests were conducted. These butt welded rail joints were made by the oxyacetylene and electric flash butt welding process. The rolling-load tests were made on a 12-in-stroke rolling-load machine. Investigation 214 (samples A through F) was conducted to determine the seriousness of hairline cracks (segregation and pipe) on oxyacetylene pressure butt weld quality. Five of the six joints with stood 2,000,000 cycles of repeated loadings without failure, which is considered a run-out, and one joint (214E) failed after 897,100 cycles. A macroscopic examination made on transverse sections cut from the end of each rail prior to welding indicates that this failure originated from a fishtail. Investigation 220 (samples A through F) is a continuation of the problem presented in investigation 214 but was conducted to determine the effects of hairline cracks on joints from rails of heavier sections. It was found that fatigue of the failed specimens originated in the fillet between the head and web and can be attributed to a shear drag introduced while removing the weld upset. Investigation 226 (samples A and B) was conducted to evaluate two electric flash butt welded joints from which the upset metal had been ground from the top and sides of the head and bottom and sides of the base but not removed from the web. An examination of the fracture surface to determine the fracture mechanics indicates that this failure originated in the fillets between the web and upset metal. Investigation 230 (samples A and B) was conduced to evaluate oxyacetylene pressure butt welded joints made with a new type of welding head. Joint 230A failed after 33,500 cycles of repeated loading and joint 230B withstood the 2,000,000 cycle minimum requirement without failure. This failure can be attributed to the lack of fusion at the weld interface.

PROGRESS REPORT ON ANCHORAGE OF CONTINUOUS WELDED RAIL
Measurements were made on a test installation for the study of rail anchorage for continuous welded rail. The purpose was to obtain data on (1) the effect of train movements on rail anchorage forces (static before and after) and (2) the relation between rail anchorage force and tie movement. This installation was on tangent track with 115 RE continuous welded rail. All weight bars were loosened for the first train to obtain zero readings and a 100-lb force was applied to eastbound anchors (anchors to restrain easterly rail movement). All westbound anchors had the bolts adjusted to just be in contact. The joint gap and rail temperature were measured periodically. Also, the rail position lengthwise of the track was measured at each of 7 test locations. These measurements were then repeated after each of four trains had passed to show the change that had been effected by the train passage. Tests were also made to determine the resistance or force required to move the ties in the ballast. Specific results from the various tests are presented

in several tables. Truck housing dynamic recording equipment was driven to the test site and information was recorded under all trains during a two-day period. The recording equipment consisted of 12-carrier amplifiers and a direct writing oscillograph. Ten channels recorded the longitudinal rail forces exerted through rail anchors to the weigh bars on the ties. The remaining two channels, connected to extensometers, were used to measure the longitudinal movement of the rail and tie with respect to the reference pipe.

A1 040474
INVESTIGATION OF FAILURES IN CONTROL-COOLED RAIL
In the period between October 1, 1966 and October 1, 1967 there were seven failures in control-cooled rail, three service and four detected, investigated by the metallurgical laboratory of the AAR. Investigations 132-10A and B involved two rail specimens both having a detected transverse discontinuity in the head. These transverse discontinuities were detected by a detector car. Rail specimen 132-10A was identified as a 100-lb RE. This failure should be classified as a transverse fissure from hot torn steel. Rail specimen 132-10B was identified as a 132-lb RE. This failure should be classified as a detailed fracture from a shell. Investigations 132-12A and B involved two rail specimens both having a detected internal imperfection in the web. These internal imperfections were detected by a detector car and a hand test. Both rail specimens were identified as 132-lb RE. It was noted that both these rails have a pipe, and a non-metallic entrapment (slag) commonly associated with pipe, in the web. Investigation 135-16 involved a rail that failed in service. This rail was identified as a 112-lb RE. A photograph of the fractured faces showed a fatigue ring development. This fatigue ring development (detail fracture) started from a longitudinal separation close to the running surface of the rail head, then turned downward to form a transverse separation at a right angle to the running surface. This failure should be classified as a detail fracture from a shell. Investigation 135-28 involved a service failure that resulted from a derailment. This rail was identified as a 112-lb RE. This failure was caused by an impact force of unusually high magnitude that is believed to have been the result of a derailment. Investigation 135-29 involved a rail that failed in service. This rail was identified as a 115-lb RE. This failure was attributed to the presence of a base seam in conjunction with a high impact loading at subzero temperatures.

ULTRASONIC TESTING OF RAILWAY COMPONENTS
Ultrasonic testing has expanded to the stage where it is a vitally important inspection method for two major railway components, axles and rails. It is likely that the use of the method will extend in many other fields. The success with which ultrasonic testing is now practiced is dependent upon three factors. They are: a thorough understanding of the type and position of flaws likely to occur in the component and the significance of flaw size; a sound knowledge of the principles underlying the use of ultrasonics for this purpose; and, a testing organization which can put sound techniques, well-trained men, and well-maintained instruments of the right type to work.

TWO-VIBRATOR TYPE SEARCHING UNIT AND ITS APPLICATION TO ULTRASONIC FLAW DETECTOR
In order to detect flaws located closely near surface in a metal material using a ultrasonic flaw detector, a two-vibrator type searching unit was invented. One of the two vibrators is a transmitter and the other a receiver. This unit can be used to inspect Thermit welded part of rails. Two-vibrator type searching unit is applied to an audigauge type flaw detector for use in rails. The unit can detect big flaws if they exist more than 1 to 5 mm apart from surface. In case of small flaws, they can be detected if their distances from surface are more than 5 mm.

REPEATED SHOCK TEST OF RAILWAY TRACK
By means of a repeated shock tester for track, the dynamic properties are studied of the test track. Test tracks were selected one on a wooden tie section and the other on a concrete tie section. There were laid 50 kg PS rails, wooden ties without tie-plates or pre-stressed concrete ties with a spacing of 60 cm. Ballast was crushed stone with a depth of 25 cm and a shoulder width of 35 cm. Before every test the ballast was tamped. To know the pressure on rails, bending stress was measured. Displacement of rail depression was calculated on the data of measurements by the velocity vibrometer. Dynamic force upon rails was calculated on the data of rail bending stress. This force exceeds the centrifugal force under 1400 to 1900 rpm and this is considered to be caused through resonance.

THIRTEENTH PROGRESS REPORT ON SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS
One specimen of a chromium-vanadium rail, heat treated to 490 Brinell hardness gave a rolling-load test of 21 million cycles. Ten specimens of high-silicon rails gave rolling-land tests that averaged 2,307,000 cycles. Two specimens of 140-lb. chrome-vanadium alloy rail, gave rolling-load tests that averaged 3,625,000 cycles. One shelling crack started at a segregation streak in the rail. Rolling-load tests to produce detail fractures from shelling indicate that both chrome-vanadium alloy rails and heat-treated carbon-steel rails resist the production of detail fractures better than standard carbon-steel rails. All rolling-load tests to produce shelling indicate that rails with higher hardness, with corresponding increase in mechanical strength, give longer laboratory rolling-load tests.

A1 040516
THE EFFECT OF STRESS RAISERS AROUND A BOLT HOLE ON THE FATIGUE LIFE OF A RAIL
A universal fatigue testing machine was obtained and a bending fixture was designed. The function of the machine is to apply a vertical vibratory force to any specimen. The alternating force is applied 1800 times a minute to an elastic test specimen, and can be adjusted between zero and 5000 lb. The 132-lb. RE section was used because it represents the heaviest of AREA sections, and the 140-lb. PS section was used because it had a bolt hole location in the heavier web area. The severity of the defects varied from light to heavy drill gouges, and from light to heavy burrs, as well as the location of the brand one the edge of the hole. The effect of the stress raisers on the fatigue life of the rail sections is very pronounced. All these stress raisers around the bolt hole were produced in the manufacturing process. The statistical data indicates that a bolt hole drilled with a dull or improperly sharpened drill through a brand reduces the fatigue life of the rail by 50 percent.

INVESTIGATION OF FAILURES OF WELDED RAILS
Six failed welds were sent to this laboratory for evaluation. One electric-flash butt weld failed after about two years in service because of a fatigue fracture starting at near midheight of the rail web at a small ball of the molted sparks which ordinarily fly away as the rails are being heated but which in this case became trapped in the weld. Another electric-flash butt weld had also been in service about two years when it failed because of a fatigue fracture starting in the rail web about 3/4 in above the rail base. These two failures can be attributed to a combination of three circumstances: High tensile stresses due to cold weather. Stress concentration at the small imperfections in the welds. Stress concentration due to the flash under the rail bases. Four additional failures are described. Eleven bend test results are reported.

RAIL FAILURE STATISTICS COVERING (A) ALL FAILURES, (B) TRANSVERSE FISSURES, (C) PERFORMANCE OF CONTROL-COOLED RAIL
These statistics are based on the rail failures reported to December 31, 1961, and are submitted as information. They include the service and detected failures reported by 50 railroads on all of their main-track mileage which constitute approximately 90 percent of the main track in the United States and Canada. The accompanying tables and diagrams indicate the extent of control of the transverse fissure problem that has been obtained by the use of control-cooled rail and detector car testing, give data on the quality of each year's rollings for the various mills, and show the types of failures that are occurring on the various railroads as related to the mill producing the rail.

SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS
Rolling-load tests are reported for the following types of rail: (1) German abrasion-resistant rails; (2) basic-oxygen standard carbon-steel rails; (3) basic-oxygen high-silicon steel rails; (4) 115-lb. standard carbon-steel rails; and (5) flame-hardened rails. Mechanical tests are presented for Japanese induction-hardened 119-lb. rails.

LATERAL BALLAST RESISTANCE AND STABILITY OF TRACK IN EARTHQUAKE
The behavior of the railway track in earthquake was studied through experiment and theoretical analysis. The experiment was performed with real tracks in the RC-box placed on the vibrational table of 5 times 5 sq m in dimensions. The conclusions are as follows: against the earthquake acceleration with which railway structures are designed, 83% of the static lateral ballast resistance of track is maintained in the track on the Shin Kansen and 78% in the track with PC-ties and crushed stone ballast on the narrow gauge lines. The long weld rail track holds the safety factor at least 1.15 for the buckling due to temperature rise in the earthquake with the same acceleration mentioned above.

WHEN AND WHERE DID TRAIN ACCIDENTS OCCUR? (REPORT 4)--STATISTICAL ANALYSES OF DERAILMENT ACCIDENTS OF FREIGHT TRAINS
Thirty freight train derailment accidents, which occurred from 1953 to 1967, were analyzed by regression analysis using 15 variables describing track

conditions, train consists and driving technics. The variables included: the view of the tracks at the derailed position, the radius of the curve at the same position, the vertical view of the tracks, the slope of the tracks, the weight of the rail per unit length set at derailed position, the direction of derailment, the interval of the derailed car wheel shafts, the shock absorbing equipments in the coupler of the derailed car, the suspension mechanism for wheels, the running condition of the train when it derailed, the weight of loaded goods, the location of the derailed car in the train, the total number of cars in the train, the scheduled velocity of the derailed train, and the year when the derailment happened.

PREVENTING RAIL FAILURES IN TRACK
U.S. and German rail inspection cars are briefly described and illustrated. Rail head defects are determined by a combination of induction and ultrasonic examination. A separate examination for web defects is conducted at joint bars by ultrasonic inspection. Some 20,000 defective rails are replaced each year with sound rails before service failure occurs. It is estimated that these replacements avoid derailment expense of 200 million dollars at an inspection cost of 6 million dollars.

TESTS TO DETERMINE THE EFFECT OF REMOVING THE BULGE FROM THE BOTTOM OF THE RAIL BASE ON THE STRENGTH OF ACETYLENE PRESSURE BUTT WELDS
Eight specimens were welded from 3-ft lengths sawed from two 115 RE Inland rails, and welded in the normal fashion. On four of the specimens the bulge was left on the base and on four of the specimens the bulge was ground off. A ninth specimen was cut from a 78-ft length from a previous welding run leaving the bulge on the base. Slow bend tests were made. There was considerable variation in the maximum load before fracture and especially in the energy for fracture. Observation of the fractured surfaces showed smooth areas predominately in the base and web indicating that full fusion had not been obtained in the welding process. The results obtained in the drop tests showed the same lack of complete fusion in the appearance of the fractured area. It is concluded that there is no significant difference in the strength of the weld whether or not the bulge on the base of acetylene pressure welds is removed by grinding or left on as has been the past practice.

PHYSICAL TESTS OF NORMALIZED AND NOT-NORMALIZED OXYACETYLENE PRESSURE-BUTT-WELDED 115 RE RAIL
The welds were made using three 39-ft rails, according to the normal procedure with the exception of not normalizing eight of the welds. The rolling-load tests were made using 48,000-lb and 60,000-lb wheel loads. The data indicate that all the failures produced in the rolling-load tests were from causes other than the effects of normalizing or not normalizing. The slow bend test of two normalized and two not-normalized oxyacetylene pressure butt-welded rails made. The results indicate a trend toward greater load, energy absorption and deflection in favor of the not-normalized tests. The drop tests of two normalized and two not-normalized oxyacetylene pressure but-welded rails were conducted. Again no significant difference can be found in the data for the normalized compared with the not-normalized welds.

SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS
Four rolling load tests of high silicon-vanadium rails averaged 1,850,000 cycles. Two similar tests of high silicon-chromium-vanadium rails ran 1,682,000 and 5,805,400 cycles. One more test of standard carbon rails flame hardened by the Union Pacific Railroad ran 11,501,100 cycles. Two rails containing 0.047 percent columbium ran 2,051,000 and 2,304,800 cycles, and the rails developed excessive flow at the gauge corner. Pictures are shown of induction-hardened rails from service. This method of treatment did not prevent early shelling failures. Five specimens were tested to develop detail fractures from shelling.

SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS
Two rolling load tests were made on a high-silicon rail which ran 1,944,400 and 1,480,000 cycles. A standard carbon-steel rail gave unusually long tests of 4,371,000 cycles. These specimens deformed considerably before the shelling cracks were visible on the side of the rail head. Two induction-hardened 50-kg rails from Japan gave rolling-load tests of 517,400 and 718,300 cycles. One double-flame hardened specimen ran 4,185,000 cycles in the rolling-load test. This is a much higher test than previous flame-hardened specimens. Single flame-hardened rails ran from 1,490,000 cycles to 3,403,800 cycles, which are also very high rolling-load tests for flame-hardened rails. Two rails with high manganese and high silicon were tested. The rolling load tests varied from 1,792,400 cycles to 3,260,500 cycles. Three specimens were tested to develop detail fractures from shelling. They developed failures at 2,007,400; 5,204,900 and 4,492,200.

ROLLING-LOAD-TEST RESULTS OF WELDED ENGINE-WHEEL BURNS ON RAIL SUPPLIED BY THE SEABOARD AIR LINE RAILROAD
The oxyacetylene-welding method is the standard procedure for repairing wheel burns. Two welds of this type were prepared as controls. Eight engine-wheel burns were then welded by means of the electric-arc method. The first six welds were made on 115-lb RE rail and the last four welds were made on 132-lb RE rail. In this type of test 2,000,000 cycles without failure are considered a run-out. All of the welds were checked ultrasonically for defects. The oxyacetylene welds had the best results, in that one ran to 2,000,000 cycles without a failure and the other ran to 589,000 cycles, failing from a detected inclusion. The electric-arc welds failed prematurely at 49,000 to 159,000 cycles. The microscipic examination of fractures revealed taht a sharp line of demarcation between the weld metal and rail metal existed as well as very fine porosity on the interface. This porosity in all of the electric-arc welds was the cause of the failure. The microsocpic porosity in the interface could not be detected ultrasonically whereas the indication of the inclusion was very definite.

SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS
Laboratory tests of chrome-vanadium rails give high cycles for failure but with considerable scatter in results. Rolling-load tests are reported on six extremely high-silicon rails with 1.63 percent silicon. These specimens did not give as good results as previous tests on rails with less than 1 percent silicon content. Rolling-load tests are reported on six induction-hardened rails. These rails resist flow or abrasion on the gauge corner but develop shelling cracks in the laboratory tests sooner than standard carbon-steel rails. Two detail fractures from shelling were produced in laboratory rolling-load tests of 136-lb chrome-vanadium rails with Brinell hardness of 368 and 373. These two rails ran 2,837,900 and 9,258,500 cycles.

FINAL REPORT ON A THREE-DIMENSIONAL PHOTOELASTIC INVESTIGATION OF THE STRESS DISTRIBUTION IN THE HEAD OF A RAILROAD RAIL ALONG LINES PARALLEL TO THE AXIS OF THE RAIL
The complete state of interior principal stresses along critical lines parallel to the axis of the rail have been determined photoleastically in the head of a model of a railroad rail. The curves of the stress distributions revealed several dangerous states of stress which may contribute to, or produce, the shelly failure. The normal stress components alternate between large compressions and relatively small tensions; there exist oblique planes, which are subjected to completely reversed large normal stresses; the range of the alternating shears is plus or minus 35,000 psi approximately, and the endurance limit for completely reversed shear is 37,000 psi; and the planes on which the maximum shears during each loading cycle act, are subjected to fluctuating shears and normal stresses. The range of the variable shear on these planes is at least from 0 to 54,000 psi, which comes dangerously close to the endurance limit of 59,000 psi.

SIXTEENTH PROGRESS REPORT ON THE ROLLING-LOAD TESTS OF JOINT BARS
Seven tests using 115 RE bars with easements on the top bar surfaces to depths of approximately 0.220 and 0.110 in were completed. The shallow easements were effective in eliminating gouging of the bars by the rail ends. Six joints with shallow easements averaged 349,080 cycles. Twelve tests of joints using 132 RE bars with the same type of milled easement were completed. Two bars with deep easements failed. The shallow easements were effective in preventing gouging of the bars. Average cycles for failure for 6 joints with deep easements were 611,630 and average cycles for failrue for 6 joints with shallow easements were 583,530 cycles.

REPORT ON PENNSYLVANIA RAILROAD M. OF W. TEST NO. 591, DETERMINATION OF PLASTIC FLOW IN RAIL HEAD
On the high rail of curves there is a flow of metal at the top gauge corner of the rail toward the gauge side. This flow of metal extends to a depth of 1/4 in. to 3/8 in. below the rail surface. The flow of metal toward the gate side extends back to the edge of the center arc and beyond, probably to the center of the rail head. The magnitude of deformation is positive evidence of shear stresses well beyond the yield point of the steel. This condition was demonstrated on the high rail of a 4-deg curve under moderately heavy freight traffic after 75,000,000 gross tons. This was at a location of moderate shelling on previous rail. Only light flaking had developed in the test rail at the time of removal.

FATIGUE TESTS OF RAIL WEBS
This report covers corrosion fatigue tests using a corroding agent of tap water mixed with sufficient sulfuric acid. Specimens were stressed at a rate of 150 cycles per minute for the first 1,000,000 cycles or until a crack had been detected. After 1,000,000 cycles, the speed of testing was increased to 800 cycles per minute and maintained at that rate until the specimen cracked, or until 10,000,000 cycles had been reached. From these tests it may be concluded: that the stresses in the upper rail fillets on tangent track outside of the joint bar limits at the rail end and at the first bolt hole with the new 115 RE rail section and new AREA bolt spacing are well within limits that can be tolerated, provided no unusual corrosion conditions exist that substantially reduce the fatigue strength of the rail steel.

TESTS OF ELECTRIC FLASH BUTT-WELDED RAILS
This paper describes rolling-load tests and physical tests of specimens of 131 and 130-lb electric flash butt-welded rails which were undertaken to determine if stress relief treatment would be necessary. The 131-lb. rail was set up for rolling-load tests of weld 73 in. in a 33-in. stroke rolling-load machine. The second rolling-load test was made on weld 52 in the 131-lb. rail, which was supplied with all the flash metal ground off except under the rail base. 1. The first two-rolling load tests that failed at a bolt hole and stress raiser on the rail webs emphasize the damaging effects of such conditions. 2. The rolling-load tests which ran over 2,000,000 cycles with 60,000-lb. wheel load without failure, are considered very satisfactory for welded rails. 3. The bend tests of 132-lb rails gave higher tests than unwelded 131-lb. rails, and as high as any previously tested rail welds. 4. Some of the physical tests indicate that the welds which were not stress relieved were slightly stronger than the stress relieved welds. However, the difference is negligible and no conclusions on this subject should be based on tests of only two welds.

DETERMINATION OF THE SNAKING EFFORT IN TRACK LAID WITH LONG WELDED RAILS BY MEANS OF A NON-LINEAR CALCULATION
The author describes a method to ascertain, with the assistance of an electronic computer, the axial effort due to snaking in a track laid with long welded rails. In these calculations, the influence of the lateral resistance and that of the angular rigidity can be introduced in their true nonlinear form, so accurately that the stress under which snaking occurs can be determined exactly. It is necessary to establish by measurements the lateral resistance and the angular rigidity. After this has been done, the admissible value of the preliminary deformation, free of stress, of a track with long welded rails can be calculated fairly rapidly. Provisionally we can affirm that the critical wave length will be considerably shorter than that obtained by the methods of calculation previously suggested.
Translated from De Ingenieur, No. 39, Sept. 1964.

PANEL DISCUSSION--C&NW WAGES WAR AGAINST TRAIN ACCIDENTS
This paper surveys the creation and current operation of the C&NW, Accident and Loss Prevention Department. Topics include procedures for analysis of derailments, review of hot box and dragging equipment detector systems and implementation and rules education. The first year after creation of this department, the costs of our train accidents were down over 30% from the previous year of 1966. Even more encouraging was the fact that losses resulting from human failures decreased over 90%.

INVESTIGATION OF FAILURES IN RAILROAD RAILS
Twenty-four failed control cooled rails were evaluated. The causes of failure are described. Preliminary tests were conducted to determine possible damage to rails by welding bond wires. A free held acetylene torch and the thermit welding methods were used to produce the bonds. The metallographic hardness tests and Charpy tests indicate that some martensite was produced in the rails which is hard and brittle. However, this did not seem to produce early failure in the rolling-load tests.

RAIL FRACTURES RESULTING FROM ENGINE WHEEL BURNS, INCLUDING EFFECT OF REPAIRING SUCH BURNS BY OXYACETYLENE OR ELECTRIC WELDING
Twenty-one specimens were artificially burned with the wheel rotating at a speed of 15 mph, the rails being applied to the moving surface of the wheel for 3-sec. intervals. The burns produced by this method were approximately 1-1/2 in. wide by 2-1/2 in. long and appeared to be quite uniform in nature. A tabulation of the rolling-load tests completed on these specimens up to the present time is shown. Up to the present time no explanation can be offered for the difference in fatigue life due to the location of the built-up metal on the engine burn. Tests have not progressed far enough to lead to any conclusions.

EIGHTH PROGRESS REPORT OF THE SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS
Two rails were selected from the high side of a 4-deg curve. These rails had carried 63,385,600 tons of traffic at average speeds of 35 mph. One rail showed flaking along the gauge corner over its entire length and had also developed 6 or 7 small black shelly spots. The second rail contained 30 black shelly spots. During the past year, 23 specimens have been tested in the cradle type rolling load machine. The chemical analysis, physical properties and results of rolling-load tests of these specimens are shown. The laboratory rolling-load tests produce shelling failures similar to the deeper type of shelling which develops in service. It is also believed that the laboratory tests give a quick method of determining the relative length of service which can be expected in track as compared with standard carbon steel rails. Preliminary results of service tests of rails tested in the rolling-load machines last year give indications of this correlation but the service tests are not as yet completed.

SUMMARY REPORT ON THE EXAMINATION OF RAILS WHICH CONTAIN DETAIL FRACTURES
This study examined detail fractures from shelling which had been found in rail by detector cars and determined if the chemistry, mechanical properties or structures of detail fracture rails varied from those of random rails. Examination of 54 detail fractures showed that such fractures may assume a wide range of size and shape. Of the fractures examined, 28 percent had bright, unoxidized surfaces; indicating no contact with the surface of the rail. About 70 percent of the rails containing detail fractures were taken from the high side of curves. The average chemical analyses and mechanical properties of 44 rails having detail fractures and 26 random rails were so nearly the same that no distinction between the two groups was possible. The mechanical tests included hardness, tensile properties, and impact properties.

MEASUREMENTS OF STRESSES IN 132 RE RAIL ON TANGENT TRACK--SANTA FE RAILWAY
Three test sections are as follows: new AREA design, headfree 36 in. joint bar for 132 RE rail, with bolt spacing of a 3-1/2--6--6 in.; same joint bar design with bolt spacing of 4-1/2--9 in.; and same joint bar design with bolt spacing of 2-1/2--6-1/2--6-1/2 in. This installation offered an opportunity to obtain measurements of stresses developed under regular traffic in the new 132 RE section. On tangent track under conditions typical of main line operation, it may be concluded: that the stresses in the upper rail fillets on tangent track outside of the joint bar limits have been reduced with the new 132 RE section to well within the fatigue strength of rail, steel, and that the concentrated rail web stresses within joint bar limits at the rail end and at the first bolt hole with the new 132 RE rail section and the new AREA bolt spacing are well within limits that can be tolerated, provided no unusual corrosion conditions exist that substantially reduce the fatigue strength of the rail steel.

FATIGUE TESTS OF RAIL WEBS
Two sets of tensile specimens were cut from the webs of the rails; one set parallel to direction of rolling, and the second set transverse to direction of rolling. Physical properties of the rail web steel as determined by these tensile tests are listed. Only slight differences in the physical properties of the two groups of specimens were disclosed. Previous studies of the fatigue of rail webs in the laboratory indicated a fatigue life several times greater than was actually obtained in service at some locations. Since corrosion of the rail web was quite heavy at the locations where early service failures occurred, it was thought that the discrepancy was due to corrosion. The S-N diagrams are shown for the tests completed to date with no corrosion on the specimens. The S-N diagram is shown for specimens under completely reversed stress, with tap water corrosion, have not revealed as great a reduction in fatigue corrosion, hav not revealed as great a reduction in fatigue life of rail webs as service failures indicate.

A1 040809
FATIGUE TESTS OF MANGANESE STEEL
All specimens were tested under a range of stress from a maximum compressive stress to a tensile stress 50 percent as great. Endurance limits at 10 million cycles were indicated as follows: As-cast surface 38,000 psi; ground surface 42,000 psi; shot peened surface 48,000 psi. Corrosion fatigue tests using a 5-percent solution of sulfuric acid were made on unprotected

specimens with as-cast, ground, and shot peened surfaces, and the S-N diagrams approached a vertical line at approximately one million cycles for all specimens. The protective paint coating applied to three groups of specimens proved to be beneficial, although not totally effective in increasing their fatigue life under 5-percent acid corrosion. A few hardness tests on unstressed specimens indicated little difference in hardness for as-cast and ground surfaces and a much greater hardness for shot peened specimens.

A1 040810
EFFECT OF BOLT SPACING ON RAIL WEB STRESSES WITHIN THE RAIL JOINT

Tests were conducted to study the effect of bolt tension, applied wheel loads and bolt hole spacing, upon rail web stresses within the limits of the joint bar. Tests were made with bolt tensions of 10,000 lb., 20,000 lb. and 30,000 lb. Three bolt spacings from the rail end were used as follows: 2-1/2 in., 6-1/2 in.,6-1/2 in.; 3-1/2 in., 6 in., 6 in., and 4-1/2 in., 5-1/2 in., 5-1/2 in. The rail used was the new 115-lb RE section with 36-in. headfree joint bars and 1-in. diameter bolts. Similar stress measurements were also made on two 131-lb RE rail joints in tangent track during the passage of regular trains. Vertical tensile stresses in the rail web that would be expected to be in the range of 15,000 to 20,000 psi, with 30,000 lb. bolt tension were found to be as high as 50,000 to 70,000 psi at the bolt holes. Moving the first bolt hole farther away from the high stress area near the rail end not only lowered the tension stress at the bolt hole, but also reduced the stress in the upper and lower fillets and web area at the rail end. It is recommended that the present spacing of bolt holes at the rail ends of 2-1/2 in., 6-1/2 in., 6-1/2 in. be revised to 3-1/2 in., 6 in., 6 in. for six hole joint bars and from 2-1/2 in., 6-1/2 in., to 3-1/2 in., 6 in. for four-hole joint bars.

FATIGUE TESTS OF RAIL WEBS

Corrosion fatigue tests were made on T-shaped specimens cut from the web of a 112 lb-RE rail under bending stresses ranging from a maximum compressive stress to a tensile stress 20 percent as great. A solution of 36 percent sulfuric acid was used as a corroding agent and was allowed to drip at the rate of 10 drops per min. on the specimens. in addition, corrosion fatigue tests were made on three groups of painted specimens in order to test the practicability of different types of paint as protective coatings for rails in tunnels, highway crossings, and other places where corrosion fatigue failures are likely to occur.

INVESTIGATION OF FAILURES IN RAILRAOD RAILS

During the year, 52 failed control-cooled rails were evaluated. The causes of failures follow: 17 failed due to transverse fissures, four from shatter cracks, seven from hot torn steel, one from inclusion, one from welded engine burn and four from hand gas butt welds; 16 failed due to detail fractures from shelling; seven from head and web separation cracks; three from crushed head and web; five fractured from base break at seam; 1 contained black shelly spots; and three had bolt hole cracks.

RAIL FAILURES RESULTING FROM ENGINE WHEEL BURNS, INCLUDING EFFECT OF REPAIRING SUCH BURNS BY OXYACETYLENE OR ELECTRIC WELDING

Service failures of repaired burns have been negligible. One railroad reports that of 500,000 burns repaired in the last 8 years only 6 service or detected failures of welded engine burns have occurred. Benefits derived from welding repair are: elimination of undesirable microstructure and quench cracks; which serve as potential stress raisers or reduce the fatigue strength of the rail steel elimination of low spots on the rail surface; and building up of engine burns permits recovery of much rail for main line use which would otherwise be scrapped or consigned to secondary service.

TENTH PROGRESS REPORT OF THE SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS

Repeat cradle type rolling-load tests on two specimens of manganese chrome, vanadium alloy rails gave high cycles for failure 8,117,000 and 9,635,000 indicating that these alloy rails may be several times as good as standard carbon steel rails. A 115-lb. heat-treated standard carbon rail gave 9,625,000 cycles in the cradle rolling machine, which indicates that this type of rail is as good as the manganese, chrome, vanadium alloy rails. Rolling-load tests are reported on high silicon rails, nickel alloy bars and rails, and flame-hardened rails, but none of these particular specimens gave tests comparable with the maganese, chrome, vanadium alloy steel or the heat-treated standard carbon steel rails. Metallographic examination of 14 failed rails which had developed detail fractures in service located rather large inclusions in the steel near the fractures in half of these rails.

SUMMARY OF PROGRESS OF INVESTIGATION OF STRESS RELAXATION IN RAIL STEEL

Relaxation of stresses in small bar specimens is being studied as a function of time and temperature, and rolling-load fatigue tests are being run on small specimens. These specimens were cut from a 152-lb rail rolled in 1939. The rail had shelly spots throughout its length. Measurements are made before bending after bending and before heating and after heating and removal from the jig. A summary of test results is shown in a plot of percent stress relaxation versus time at temperature. For temperatures lower than 900 deg F., the amount of relation is quite small. After an initial period, the amount of relaxation at a given temperature increases only slightly as time at temperature increases.

TWELFTH PROGRESS REPORT ON SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS
This paper summarized the past year's progress on shelly rail studies at the University of Illinois: 1. Stress relieving of specimens during laboratory rolling-load tests at either 1000 or 800 deg F have not appreciably increased the life of the rails. 2. Rolling-load tests of commercially flame-hardened rails gave tests about 50 percent above the average for standard carbon steel rails. 3. Rolling-load tests of high silicon steel rails gave tests almost double the average for standard carbon steel rails. 4. An electric furnace 60-lb steel rail with European chemistry gave very low tests in the rolling-load machine--94,400 cycles. 5. Metallographic examination of 17 shelly rails from service found only 1 rail which contained extra large non-metallic inclusions, which could explain why it had developed shelling in service. 6. Using a special rolling-load machine, detail fractures from shelling were produced in five standard steel rails and one alloy rail. 6. The cause of shelling in service appears to be that present wheel loads are too heavy for the small area of contact between wheel and rail, so that as a result of the flow of the steel, internal stresses are produced that exceed the capacity of the steel to withstand such stresses. 7. Laboratory rolling-load tests indicate that stronger rail steel, such as high silicon steel rails, intermediate manganese chrome-vanadium alloy rails, or heat-treated rails should give longer life before shelling develops in service.

FINAL REPORT ON THE STUDY OF SIMULATED RAILS UNDER REPEATED ROLLING LOAD
This investigation has studied some of the factors which might contribute to shelly failure formation. The investigation has been directed particularly toward a study of the effects of progressive plastic deformation resulting from repeated rolling-wheel loads. Some variables introduced were wheel load, wheel radius, and cycles of repeated rolling load. Experimental evidence suggests that plastic deformation occurs in a rail with early successive load repetition. Further, the tests show that, although deformation is inelastic, many of the effects of the variables studied would be qualitatively predictable by elastic equations such as the Herz equations and this work suggest that smaller wheel loads or larger diameter wheels would be quite helpful. It is also interesting to note that the Herz equations would suggest the use of higher strength rails for longer rail life. This is also in agreement with general observations from actual service and from laboratory tests of rail.

FINAL REPORT ON A THREE-DIMENSIONAL PHOTOELASTIC INVESTIGATION OF THE PRINCIPAL STRESSES AND MAXIMUM SHEARS IN THE HEAD OF A MODEL OF A RAILROAD RAIL
This report deals with a photoelastic study of the stresses in a model of the head of a railroad rail, utilizing for this purpose the most recent developments in three-dimensional photoelasticity. The study was undertaken in the expectation that the results would lead to a better understanding of the phenomenon of shelling in rails. It is concluded that: 1. Near the region of contact the principal stresses in the model are all compressive both for the vertical load and for the combined loads used. 2. Below the region of contact the longitudinal stresses become tensile for both types of loading. 3. The maximum shear lies in the transverse section of symmetry for both types of loading. 4. The effect of the horizontal thrust is primarily to increase the shear in the immediate vicinity of the area of contact by 30 percent. 5. On the side of the rail away from the load the stresses are predominantly tensile and are much smaller than on the loaded side for both types of loading.

A1 040829
DISCUSSION ON "THE ENGINEERING ASPECTS OF HIGH-SPEED TRAINS" (1) MOTIVE POWER; (2) PASSENGER ROLLING STOCK; (3) BRAKING AND SIGNALLING; (4) PERMANENT WAY
This paper surveys the engineering aspects of high-speed trains in terms of motive power, passenger rolling stock, braking and signaling, and permanent way. In developing high-speed trains there is clearly a need to examine all aspects of vehicle performance on the track, and also a need to subject every item of traction equipment to the closest secrutiny to ensure that it is suitable for onerous high-speed duties. The car of the future will probably be lower and smoother, and with smaller windows than present-day cars. It will be pressurized and adjacent body ends will be closer to incorporate peripheral coupling and improve passenger access. It will also cost more. A basic consideration in obtaining the best brake performance of high-speed trains is the maximum braking retardation. When high retardations are used and as the maximum speed of trains increases from about 100 mph to 120 mph (or even 150 mph) two problems of braking which become increasingly important are adhesion and heat dissipation. Both necessitate modifications to present braking practice when higher speed stops are to be made. It is generally agreed that at high speeds some form of cab signaling is essential, and systems in use vary from the relatively simple A.W.S. as used in this country to apparatus which starts, controls, and stops the train automatically. There is every justification to believe that, from the point of construction, modern track would be quite suitable for speeds up to 160 mph--possibly more--where it is straight or flat-curved.

A1 040833
FATIGUE TESTS OF RAIL WEBS
Two specially designed vibratory machines were used to determine the fatigue of less-than-full-size rails because rolling-load machines were unable to break the web of full-sized sections. In all tests a constant ratio of compressive to tensile stress was maintained, the bending stress on the top side ranging from a maximum compressive stress to a tensile stress 20 percent as great. The specimens were cut from two sections of 112-lb. RE rail. The fatigue curves show that reduced fatigue strength results from stamping. These data would indicate an endurance limit of approximately

59,000 psi, for unstamped specimens, and 51,000 psi for stamped specimens at 40 million cycles. At one million cycles, the reduction in fatigue strength for the stamped specimens is slightly over 20 percent. Although these tests were made on specimens instead of a complete rail section, the stresses were of the same order of magnitude as the web stresses which occur in the field, thus affording a measure of the reduction in fatigue strength of a full-sized web which may be ascribed to the presence of stamped numbers.

A1 040870
RAIL DESIGN AND SERVICE MEASUREMENT OF RAIL WEB STRESSES OUTSIDE OF JOINT

The report on rail design deals primarily with the revisions of design to improve the strength in the upper web fillet of the rail to better resist the high range of stress that occurs on curved track on the gauge side at this location. The work described on rail design in the report was occasioned by the occurrence of web failures in the 131 lb. RE rail section on the low rail of curves after considerable traffic had been carried and there had been a reduction in height of section because of rail wear. The cause of split web failures (head and web separations) in 131 RE rail has been found to be corrosion fatigue. Laboratory and service stress measurements have demonstrated that this section develops high stresses in the upper web fillet gauge side, on the low rail of sharp curves. Based on practical experience, mathematical theory, and laboratory and service tests using modern strain measuring equipment, the 140 PS rail section has been developed to retain all the desirable characteristics of the 131 RE section and eliminate its weaknesses. The report contains a detailed drawing of the 140 PS rail section developed from this research and which is now known as the 140 RE rail section, having been adopted by the American Railway Engineering Association as a standard standard section. A detailed drawing of the 133 PS section and of the 155 PS section which were developed from this research are also included in the report.

THERMIT WELDED RAILS, FULL FUSION PROCESS

The purpose of the test was to determine the strength and safety of Thermit welded rails (Full Fusion Process). Eight specimens of 131 lb. RE rail 8 ft. long, including a Thermit weld at the center, were provided for laboratory tests. For comparative purposes, eight similar specimens, including an Oxweld pressure weld, were furnished for test. All specimens were 131 lb. RE rail. Three specimens of each kind of weld were tested head down, and three specimens, head up, under the drop test machine. One specimen of each type of weld was tested head up and one head down, under static load, under the million pound testing machine. Results of the drop tests and static tests and of the hardness survey are shown on attached tabulated statements. Every Thermit welded rail broke with the first drop under the drop test machine, even though in one case with the rail tested head up the drop was reduced from 59" to 6" and the energy from 44,000 ft. pounds to 4500 ft. pounds. The Oxweld specimens each withstood the first and second blows with the full 44,000 ft. pounds energy. On the static test the Thermit rail tested head up broke at 262,000 pounds load on a 48" span, and the Thermit rail tested head down broke at 251,000 pounds load. The Oxweld specimen tested head down broke at 375,000 pounds with a square break directly through the weld. The Oxweld specimen tested head up did not break with a load of 375,000 pounds. The strength of the Thermit full fusion weld as determined by these tests does not approach the strength of a full section rail or that of a bolted joint. The grain structure is coarse, the fractures are brittle, indicating the probability that failures in service might be sudden and without warning.

NUMERICAL CALCULATION AND APPROXIMATE FORMULA OF BUCKLING STRENGTH OF TRACK

In 1967, the adoption of 60 kg rail in the track of the Sanyo Shin Kansen was determined. For this determination, it was considered that the temperature difference corresponding to the buckling strength of the track with this rail would not be different so far from that of the track with 50 T rail. To confirm this, the authors made the calculation program of the buckling strength of track and computed this for every rail in Japan including the new 60 kg rail. Through the investigation of calculated results, it was found that there would be simple approximate formula to calculate the buckling strength of track. This paper contains the calculating method of the buckling strength, calculated results, the composition of the approximate formula and its application.

RETAINING GAUGE ON CURVES: THE L&N APPROACH
Louisville and Nashville has found that powerful diesel units with three axle trucks cause problems with holding gauge on curves. L&N launched three point plan: a laboratory study, use of gauge-measuring devices, and new standards for tie-plate sizes and spiking patterns for curves. Use of a common tie-plate for 100 lb and 132 lb rail meant that the 132 lb rail base covered one of the spike holes on the gauge side. To help prevent rail overturning under those conditions, a compression clip anchor was used in place of the spike on curves. L&N has adopted a new 18 inch tie-plate for problem curves. Diesel locomotive truck side thrust was suspected as a source of wide gauge on curves, so a gauge sensing device was mounted on a locomotive truck. Tests confirmed the rail moved outward under dynamic loading. Measuring devices attached to the rails also confirmed movement. A pickup truck equipped for rail/highway operation was also equipped with gauge recording instruments. On heavy-tonnage routes, curves of 5 degrees or more or troublesome curves get the new 18 inch tie-plate. Three line spikes are now used on the outer rail of the curve, with one screw spike in the hold down holes on either side of the rail. Still another technique being tried is the use of washer head screw spikes which are driven as line spikes.

A similar article on the L&N approach to curve problems appeared in Railway Track and Structures, V69, N1, January 1973.

MEASUREMENT AND ANALYSIS OF WHEEL-RAIL FORCES
Described is a method used to continuously measure, record, and analyze the lateral and vertical forces between wheels and rails of several types of railroad freight cars under a variety of car and track conditions. The method, using analog-to-digital conversion and computerized data handling, has produced results relating to a multitude of car and track behavior subject areas. Especially important is the definition, development, and verification of performance "signatures" which are generated in a unique and characteristic manner by each car in negotiating a given curve. The finding of such "signatures" to be completely reproducible and yet sensitive enough to change with relatively minor track or car component variations, i.e., modifications, supports the belief that these techniques can be applied beyond pure experimental scopes into routine (a) trackside inspection of cars in passing trains; (b) mechanized track inspection; and (c) truck design evaluation.

This paper was presented at the ASME Winter Annual Meeting, November 28-December 2, 1971. The notification of this paper appeared in Mechanical Engineering.

TECHNICAL STUDIES TO EVALUATE THE INFLUENCE OF OPERATIONAL FACTORS ON TRACK LOADING
This paper describes briefly theoretical and physical investigations which have recently been performed by Canadian National Railways. The objective of investigations has been to establish means of reducing the probability of train derailment. While the scope of the derailment study is indicated, two efforts have been singled out for more detailed description. The first effort was directed to determine through computer simulation and analysis programs the lateral loading on curved track which can result from longitudinal train action forces. The second effort to be reviewed was directed to determine, through field measurement, actual lateral tieplate loads on curved track imposed by various vehicle types.

THE INFLUENCE OF WHEEL-RAIL CONTACT FORCES ON THE FORMATION OF RAIL SHELLS
This paper describes an analytical and experimental investigation of the problem of rail shelling; in particular the influence of the stresses resulting from wheel-rail contact forces is studied. These contact forces are due to the weight of the car, and the tracking of the wheel on the rail. An analytical analysis includes the yielding of the rail material, the subsequent development of residual stresses, and plastic flow due to a moving load. Explanations are given for the mechanics of shelling and other associated behavior that is found in rail.

FRA GEARING UP TO ENFORCE TRACK SAFETY STANDARDS
The Federal Railroad Administration's Bureau of Railroad Safety has been enlarged and reorganized under the name of Office of Safety. The result of the reorganization which became effective November 13, 1972, was to establish the activities of the Office of Safety under two groupings, one called the Compliance Division and the other the Standard and Procedures Division. Activities of the Compliance Division will include the training of personnel involved in administration of safety programs, the monitoring of programs in states that have been certified to participate in administration of the Safety Act, the evaluation of field performance, the development of guidelines for field programs, and the coordination of field safety activities. Under the Standards and Procedures Division will come such activities as the development of rules and standards, the provision of technical advice and counsel to the headquarters and field forces, the analysis of reports and data and the development of enforcement procedures and policies. Inspection and surveillance activities of the Office of Safety will be handled through the same regional setup as prevailed under the Bureau of Railroad Safety. Personnel are being recruited and trained, regulations are being prepared for the certification of states, and a track manual of uniform practices is being readied.

RAILROAD ACCIDENT REPORT: DERAILMENT OF MISSOURI PACIFIC RAILROAD COMPANY'S TRAIN 94 AT HOUSTON, TEXAS, OCTOBER 19, 1971
The Missouri Pacific Railroad's freight train 94 was traveling north on track which belongs to the Atchison, Topeka and Santa Fe Railway when 20 of its cars derailed in Houston, Texas, on October 19, 1971, at 1:44 p.m. There were four diesel-electric locomotive units and 82 cars in the train. Derailed cars included six tank cars containing vinyl chloride monomer and two cars containing other hazardous materials. Two tank cars were punctured in the derailment. The vinyl chloride monomer escaped and ignited. The Houston Fire Department attempted to control the fire. Approximately 45 minutes after the initial derailment, one tank car ruptured violently and another tank car 'rocketed' approximately 300 feet from its initial resting place. This sequence of events caused the death of a fireman. Fifty people were injured and there was considerable property damage. Most of the injured were firemen. The Safety Board determines that the probable cause of this accident was an unexplained emergency brake application which induced lateral forces exceeding the holding capacity of the track fasteners.

DETECTING THE PROPAGATION OF KIDNEY-SHAPED FATIGUE FLAWS IN RAIL HEADS ON THE LINES OF THE HUNGARIAN STATE RAILWAYS
The author discusses the cause and propagation of kidney-shaped fatigue flaws in the rail head as well as the measures designed to prevent fractures. The main purpose is the description of the functional relationship between the propagation of the fatigue flaw and the traffic load. The formation of flakes in the rail material, the hardness of the rail head and the notch effect set up in the rail head by internal flaws are discussed. It is found that the propagation of the flaws is jointly caused by a number of processes such as microinclusions, oscillatory movements of dislocations, high stresses in the rail head, etc. The positions of the initial centres have been investigated by examining and measuring several fractures. Methods for calculating the height of the fissure and its inclination towards the vertical are developed. An analysis is made of the development of fatigue flaws as a function of the traffic load, and the existing relationship is established by an equation. In determining the effective cross-sectional area of the rail, the wear of the rail is also taken into account and added to the area of the fatigue flaw. After an analysis of the permissible threshold values, certain specifications are suggested, and the size of the flaw area in percent of the total cross-sectional area of the rail head is indicated with the aid of nomographs. In addition to the manual examinations, the introduction of ultrasonic high-speed testing vehicles is urgently recommended. In modern railway operation, ultrasonic testing is the most suitable method of detecting dangerous flaws; but the influence of human subjectivity in evaluating the results must be eliminated by using modern computers.

CONTINUOUSLY SUPPORTED RAIL SUBJECTED TO AN AXIAL FORCE AND A MOVING LOAD
The recent practice of welding railroad rails to each other suggests that considerable axial compression forces may be induced in the rails because of a rise in temperature. This in turn may reduce the critical velocity for the track to the range of operational velocities of modern high-speed trains. The purpose of the paper is to demonstrate that this is indeed a possibility.

EFFECT OF BALLAST CONDITIONS ON TRACK STABILITY
It is shown how installation of long-welded rail on Europe's principal trunk routes has created problems of track stability caused by the presence of thermal stresses in the track, affected by local climatic conditions. The measurements obtained by the tests conducted at the Technical University in Munich, West Germany showed that the lateral resistance is greatest when the track has settled under traffic. After tamping combined with a rise of 2 to 3 cm, the lateral resistance decreases by approximately 70%.

THE EFFECT OF SURFACE FILMS ON FATIGUE CRACK INITIATION
The suppression of fatigue crack initiation by surface films can be viewed in terms of two mechanisms: (1) protection against environmental attack, and (2) suppression of surface plasticity. These two mechanisms are described in detail. Environmental protection requires a flawless coating which is impermeable to the active component of the environment and resistant to fracture under repeated cyclic strain. Suppression of plasticity requires a film with an elastic modulus greater than the substrate metal. The stiffer coating repels dislocations from the surface and suppresses the development of slip bands and crack initiation. (Author)

TECHNICAL STUDIES TO EVALUATE THE INFLUENCE OF OPERATIONAL FACTORS ON TRACK LOADING
This paper describes briefly theoretical and physical investigations which have recently been performed by Canadian National Railways. The objective of investigations has been to establish means of reducing the probability of train derailment. While the scope of the derailment study is indicated, two efforts have been singled out for more detailed description. The first effort was directed to determine through computer simulation and analysis programs the lateral loading on curved track which can result from longitudinal train action forces. The second effort to be reviewed was directed to determine, through field measurement, actual lateral tieplate loads on curved track imposed by various vehicle types.

EVALUATION OF THE BRITTLE FRACTURE OF RAILS [SPRODBRUCHABSCHATZUNG AN SCHIENEN]
The testing of rails provided for in the technical specifications of the railways (and particularly the UIC) gives incomplete information concerning the behaviour of rails subjected to certain frequent stresses in service, such as the effect of impacts caused by flats on the wheel treads. The author's purpose is to establish more satisfactory criteria for evaluation purposes, taking into account the triaxial character of the pressure in the rails by making use of the Schnadt diagram covering the index of the capacity of plastic deformation of the steel in relation to the pressures to which it is subjected. The above article contains an account of the work carried out by the author in order to establish characteristic parameters of the risk of brittle fractures of the rails in relation to a coefficient covering eventual cracks, or grooves, in the rail surface, as well as the temperature, the load, and the speed, and numerical formulae are provided covering the German State Railway's S 49 rails. WHAT THE DESIGNER MUST KNOW ABOUT FRACTURE MECHANICS
Traditional design criteria make no attempt to account for the failure mode which is characteristic of a flawed, frangible structure. A design rationale is outlined for brittle and brittle-ductile transition materials which contain flaws caused, for example, by metallurgical inclusions; fabrication and erection overloads, and fatigue cracking. Linear elastic fracture mechanics can be employed successfully for high strength-low toughness materials design. Laboratory test results for critical values of Kc, the stress intensity factor, may be applied to combined load problems by use of the strain-energy-density factor Sc. Design with materials of higher toughness-/yield strengh ratios follows essentially the same procedure with a slight modification in interpretation of the fracture toughness parameter. A number of example problems are solved and the results compared with those obtained using the traditional failure criterion.

ON THE STABILITY OF THE RAILROAD TRACK IN THE VERTICAL PLANE

The report reviews and discusses various aspects of railroad track buckling in the vertical plane. Buckling tests of straight tracks are reviewed first. A review of the published analyses on vertical track buckling reveals that they may be grouped into two main categories. In one category, the authors assume that the track is an elastic beam which is continuously supported by a Winkler base, before as well as during buckling. In the other group, the authors assume that the track is a beam of uniform weight, which rests on a 'rigid' base and that the buckling load is reached when part of the track lifts itself off the base. To clarify the validity of some of the assumptions made, two simple models which represent the assumptions made are studied first. This is followed by a review of the literature. A1 051536
APPLICATION OF GUIDEWAY ROUGHNESS POWER SPECTRAL DENSITY AS A MANAGEMENT TOOL

Ground surface vehicles such as trucks or railway cars can be considered as mechanical systems suspended on vibrating wheels. The source of vibrational energy is the roughness in the roadway or the guideway. A portion of the vibrational energy is transmitted through the vehicle suspension system and to the passengers or lading inside the vehicle. The magnitude of the transmitted energy and its frequency content depend on the roughness of the surface, the speed of the vehicle, and the mechanical characteristics of the suspension system. If the roads and guideways are categorized by the Power Spectral Density (PSD) of their surface roughness, the amount of vibrational energy can be predicted if the speed and the characteristics of the vehicle suspension system are known. Conversely, if a safe limit of the vibration has been established for a particular lading, management can render a cost effective decision on guideway maintenance, speed practices, and vehicle design from knowledge of the PSD characteristics of a proposed route.

FORMATION OF FATIGUE CRACKS IN RAILS [ERMUEDUNGSBRUCHBILDUNG IN SCHIENEN]

The rates of unlimited fatigue strength resisting flexion, traction-compression, and shearing, are, in the case of a perfect steel, linear functions of the resistance to fracture caused by traction, in the author's view. He provides diagrams showing these rates, as well as their variation in relation to the rail surface. He makes brief reference to the distribution of pressures in the rail, and explains the manner in which the rates of unlimited fatigue strength can be exceeded when the rail contains inclusions of slag, segregations, or concentrations of ferrite. He explains, in detail, the mechanism of the propagation of the oval flaw and concludes with a number of observations concerning the means of improving the resistance of rails. [German]

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Part one of this report discusses a laboratory investigation of 132-pound rail made from vacuum degassed steel. The purpose of this investigation is to determine whether rails made from vacuum degassed steel and air cooled are comparable in properties with rail steel produced by currently common practices. The manufacturing process and test specimens are described. Rolling load tests, drop tests, slow bend tests, Charpy impact tests, hardness tests, and chemical analysis are performed. Macroscopic and microscopic examinations and physical property determinations are examined. The properties of vacuum degassed steel rails without controlled cooling were comparable to those manufactured by conventional techniques. Part two is a report on a field inspection of vacuum degassed steel rail on the Norfolk & Western Railway. Slight curve wear was noted in the high side rails, and slight rail wear was noted on the low side rails. No shelling or head checking was noted.

RAIL FAILURE STATISTICS COVERING (A) ALL FAILURES (B) TRANSVERSE FISSURES (C) PERFORMANCE OF CONTROL-COOLED RAIL
This report of rail failure statistics covers all failures, transverse fissures, and performance of control-cooled rail. Mill performance with regard to service failures is discussed. Statistics for both accumulated service failures and detected number of defects are given. No additional transverse fissure failures in control-cooled rail were reported in 1971 indicating that good quality control and mill practices have been followed in the manufacture of this rail to avoid shatter cracks. The low incidence of rail failure from welded engine burns indicates that practice of welding these burns is showing good service performance. Butt weld failures are tabulated.

WHEEL AND RAIL LOADINGS FROM DIESEL LOCOMOTIVES
A review of wheel and rail loadings from diesel locomotives is presented in six areas: 1) sample derailment data, 2) basic curve negotiation mechanics, 3) experimentally determined wheel-to-rail forces, 4) rail profile data, 5) the effect of dynamic brake levels, and 6) mechanical considerations. In summarizing all of these factors the following areas deserve the most attention: 1) locomotive braking practice with regard to delay in power to brake transfer, gradual buildup of braking level and control of braking level over crossovers, turnouts, and curves; 2) track in relation to gage widening, level of rail irregularities, and possible thermal strain investigations; and 3) mechanical factors including proper alignment control in draft gears, and proper bolster stops on units without alignment control.

SOME ASPECTS OF SERVICE DEVELOPMENTS IN RAIL-HEAD METAL
Service developments in rail-head metal characterized by the presence of white etching regions have been studied. After the development of microstructural white-etching regions resulting from traction and adhesion conditions, spalling begins as a result of trains passing repeatedly over these hard and increasingly brittle areas. White-etching regions on a car-dumper hoop rail resulted from impact during loading and unloading of the dumper, because these areas were in contact with mating guide wheels in the normal load and unload positions of the car dumper. White-etching also results from the effects of repeated loads on the vertical face of non-end-hardened bolted rail. A rolling-contact fatigue test concludes that rail steels have longer life at lower maximum static contact stress levels than at higher stress levels.

STRESS DISTRIBUTION IN THE PERMANENT WAY DUE TO HEAVY AXLE LOADS AND HIGH SPEEDS
The stress distribution in the rail head near the contact surface between rail and wheel with heavy axle loads at high speeds is discussed. An experimental investigation of the stress distribution was performed. Tensile bending stresses in the rail head and rail foot, and lateral forces are discussed. In Germany a test track of prefabricated concrete slab was constructed, and the measurements taken showed that scattering of stresses in the rail foot were small and did not vary with the driving speed.

A1 052265
THE THERMAL ELONGATION OF RAILS ON ELASTIC MOUNTINGS
Elongation and contraction of rails due to temperature changes is a primary factor affecting the variation in length of rails and their associated strains and stresses. This report considers thermal elongation in conjunction with the longitudinal elasticity of rail fastenings. The sequence of longitudinal loads on elastic rail mountings and the thermal elongation involving rail creep are mathematically presented. Numerical values worked out on a study of the Delft Viaduct show that the assumption of continuous distribution of rail mounting resistance provides a workable theory by which thermal elongation of rail systems can be effectively analyzed.

AAR STUDIES OF BUTT WELDED RAIL JOINTS
The purpose of this study was to obtain a correlation between defects shown by radiographs of thermit butt welds in track and results obtained in rolling-load tests in the laboratory. Thermit welds in the Canadian National

Railway and the Denver & Rio Grande Western Railroad were evaluated. The Research Center's repeated load tests did not correspond exactly to service conditions. More study is needed on the effectiveness of the radiographic examination technique in determining if thermit welds contain defects that would seriously impair their serviceability in track.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL METHODS FOR THEIR PREVENTION
This report is in two parts. Part one presents the causes of shelly spots and head checks in rail. Samples of these service defects were analyzed and then duplicated at the Association of American Railroads Research Center. Results showed that they were stress induced microstructural changes, not foreign material attributable to manufacturing practice. Part two presents a summary of the test using fully heat-treated rails and alloy rails installed on curves with shelly histories. Changes in rail design were included in this test. For fully heat-treated rails wear on the low side rails was relatively less than on the high side rails. Use of high silicon rails was also tested. Chipping was noted in both the high-silicon and regular rails where bond wires had been attached by welding.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail are discussed and methods for their prevention are presented. Two phases of the project include the inspection of heat-treated rail and alloy-rail service test installation on curves with a history of shelling, and the laboratory investigation of shelling rail involving rolling-load and slow-bend tests. Field inspections are made at test installations on the Norfolk and Western, Cheseapeake and Ohio, Great Northern, and Pennsylvania Railroads. Results of the inspections are presented for each respective railway. It is concluded that the heat-treated rails show generally good results and promise considerably more service.

EFFECT OF LUBRICATION IN PREVENTING FROZEN RAIL JOINTS AND RETARDING CORROSION OF RAIL AND FASTENINGS
The effect of lubrication is investigated in preventing frozen rail joints and retarding corrosion of rail and fastenings on a five-mile service test of North Western's eastward main track, relaid with 78-ft butt-welded 115 RE rail in 1957. Four of the five miles were sprayed out-of-face; the other mile, the control, had no protection until July, 1962, when special compounds or paints were applied to some of the welds after flame cleaning and wire brushing. Applications of metal preservatives are described for each mile of test track, indicating where corrosion was minimized. It is concluded that the spray and brush coats of Texaco 55 and NO-OX-ID provide the best protection against corrosion of rail and fastenings.

A1 052287
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail are explored and methods for their prevention are presented. Heat-treated-rail and alloy rail service test installations are inspected on curves with shelly histories, and laboratory investigations of shelly rail involving rolling-load and slow-bend tests are also made. Service test installations on the Great Northern Railway of rails rolled from continuously cast blooms, fully heat-treated rails, Columbium-treated rail, and Curve-master rail, were inspected, and contour tracings of the rail inspected were made. Service test installations on curves are designed to study both resistance to wear and flow and resistance to shelling. Two methods presently employed in improving these properties are the addition of alloying elements and heat treating. The addition of certain alloying elements improves resistance to wear and flow but does not necessarily improve resistance to shelling. The use of other alloying elements may improve both of these properties. It is shown that rail if properly heat treated, will be improved in both of these properties. If improperly heat treated, the results are detrimental rather than beneficial.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail are determined, and methods for their prevention are discussed. Two phases of the investigation include the inspection of heat treated and alloy rail service test installations on curves with shelly histories and the laboratory investigations of shelly rail involving rolling-load and slow-bend tests. The usual service test inspections are made of the fully heat-treated and alloy rail installations to corroborate the observations of previous years. Investigations featured include the service test installation of induction-hardened rail on the Great Northern Railway and on the Norfolk and Western Railway and the test installation to compare high-carbon rail with blue-end rail on the Pennsylvania Railroad. New developments in induction and flame hardening of rails to increase their resistance to shelling are also reported.

RESULTS OF ROLLING-LOAD AND SLOW-BEND TEST OF BUTT-WELDED RAIL JOINTS
Results of rolling-load and slow-bend tests of butt-welded rail joints are reported. Welding methods include submerged arc, thermit process, and oxyacetylene pressure process with abrasive-wheel-cut weld faces and with variations in upset pressure and Btu input. Welds with magnaflux and ultrasonic indications of defects are also included in tests. It is noted that results, particularly results of submerged arc process, represent initial work on developments needing considerable further refinement. Results on thermit welds are representative of the results obtained in previous test of such welds, except those made by the Southern Railway, which show results meeting the standards established by tests of oxyacetylene pressure butt welds and flash butt welds for the first time. Investigations of welds with magnaflux and ultrasonic indications indicate a lack of uniformity existing in judging these indications at the inspection stations.

RAIL WEAR TESTS ON THE ST. LOUIS-SAN FRANCISCO RAILWAY
Two curves on the St. Louis-San Francisco Railway were selected for rail wear tests. The section having a slightly lower rate of wear in past service was not lubricated. The other curve had a "Meco" single rail lubrication using graphite grease at the far end of its two curves. The effectiveness of the lubrication was gaged by taking rail profiles at various intervals of time. These profiles show the amount of steel worn from the heads of the rail gage. Elevation and curvature of the high rail were measured at each point where a profile was taken. Seven sets of profiles were taken of the rails undergoing the tests. The profiles show significantly less wear on the curve with the track lubricator than on the curve with no lubrication. The effectiveness of molybdenum-disulphide was tested as a rail lubricant. Its application showed less wear rate. These service tests definitely show that track lubricators are effective and can double the life of the outer rail in the presence of heavy sanding.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL: METHODS FOR THEIR PREVENTION
This report is presented in two appendices. Appendix 8-a covers the inspection of service tests of fully heat-treated and alloy rail installations. There are five tests of fully heat-treated rail, three of high-silicon rail, one of chrome-vanadium, and one of columbium-treated rail. The heat treatment in some locations has shown considerable value in extending rail life under shelly conditions and in resisting head flow on the low side of curves. The high silicon and low-alloy rails show a resistance to wear and shelling. The chrome-vanadium rail shows excellent performance. Appendix 8-b covers 1) rolling-load tests to produce shelling in high-silicon chrome-vanadium rail, columbium-treated rails, basic-oxygen standard carbon rails and flame-hardened rails; and 2) end-quench hardenability curves determining the quenching characteristics of some of the low-alloy rail steels. High-silicon chrome-vanadium rails rated high in rolling-load tests. End-quench hardenability curves are given for four rail steels to furnish information on the quenching characteristics of low-alloy rail steels.

A1 052327
ENGINEERING ASPECTS OF CURRENT RAIL SECTIONS
This investigation of the engineering aspects of current rail sections falls into four phases. 1) Flexural Stiffness and Strength--The additional stiffness as indicated by the moment of inertia and strength as indicated by the section modulus of the 106 CF&I, 119 CF&I and 136 CF&I sections are increased approximately in proportion to the additional amount of metal provided in these sections. 2) Shape of Head Contour--Measurements indicate the rolled contour of the 115 RE and 132 RE sections fit the worn wheel contour better than the 119 CR&I and 136 CF&I sections. Better service performance as to the development of shelling is concerned can be expected from them. Narrowing of the rail head decreases the radius of hollowing of worn car wheels with resultant increase in wheel contact pressures and internal direct stresses and shearing stresses within the rail head. 3) Depth of Rail Head--Increased depth of rail head in the CF&I sections provides additional metal for vertical head wear. Measurements of actual vertical head wear as related to traffic and traffic densities indicate the present RE sections have adequate depth of head to provide a full usable life of the rail. 4) Localized Web and Fillet Stresses--Measurements indicate that upper fillet stresses in the web are reduced with the CF&I sections as compared to corresponding RE sections.

This article is an abstract of Report No. ER-15.

A1 052333
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
This informational progress report is contained in two appendices. Appendix 8-a covers inspections of service tests of heat-treated and alloy-rail installations at 11 locations. There were five tests of heat-treated rail, three of high-silicon rail, and three of chrome-vanadium alloy rail. Heat-treated rail continues to show decided increased life over standard rail. Use of heat-treated rail on the low side of curves has increased life of rail 5 to 8 times, and on high sides 1 1/2 to 4 times. High-silicon rails have shown greater resistance to the detrimental effects of heavy wheel loads on the low side of curves than standard rails. Chrome-vanadium alloy rails show greater resistance to wear than standard rails. However, in this test the chrome-vanadium alloy steel of the composition used was unreliable. Appendix 8-b covers rolling-load tests to produce shelling in 136-lb high-silicon vanadium rails, failed shelly rails from service, and rolling-load tests to produce detail fractures from shelling. Results of tests of 115-lb columbian rail and tests of 133-lb rail single flame hardened by the Union Pacific Railroad are also reported.

A1 052352
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Most of the information in this report on causes of shelly spots and head checks in rail is contained in the two appendices. Appendix 8a covers inspections of service test of heat-treated and alloy steel rail installations at five locations. There are three tests of heat-treated rail and two of high-silicon rail. Heat-treated rail in tests on the Norfolk & Western Railway continues to show increased life over standard rail. High-silicon have shown greater resistance to the detrimental effects of heavy wheel loads in the low

side of curves than standard rails. Appendix 8b contains studies done at the University of Illinois. Three rolling-load tests to produce shelling in high-silicon rails, standard carbon-steel rails and 50-kg rails induction hardened in Japan are presented and discussed. Two rolling-load tests on a high-silicon rail ran 1,944,400 and 1,480,000 cycles. A standard-carbon-steel rail gave unusually long tests of 4,347,000 and 4,371,000 cycles. These specimens deformed considerably before the shelling cracks were visible on the side of the headrail. Two induction-hardened 50-kg rails from Japan gave rolling-load tests of 577,400 and 718,300 cycles.

A1 052361
WHEEL LOAD, WHEEL DIAMETER AND RAIL DAMAGE
The dual study of wheel load, wheel diameter and rail damage is presented. It is concluded that formulas derived from earlier studies should be applied to today's situations for worn wheel on worn rail. A report on shelly rail reviews previously gathered information before discussing a recommendation that a limitation be placed on wheel loads for diesel and turbine locomotives. The recommended limit for wheel loads is 800-lb per inch of diameter. The study concludes that shelly rail stress increases in proportion to the cube root of the load; the life of the rail up until the time failure occurs decreases very sharply for any small increase in stress.

STATIC AND FATIGUE TESTS ON PRESTRESSED CONCRETE RAILWAY SLABS
The fatigue properties of prestressed pretensioned concrete railway slabs are discussed. A theoretical study of the fatigue resistance of such members is first presented, followed by a description of laboratory tests on six beams. Test results are discussed and interpreted. The theory of fatigue failure is based on three diagrams including a failure envelope based on a limited amount of fatigue test data on prestressing strands and a diagram of the fatigue characteristics of plain concrete. The two failure envelopes are combined with curves expressing the moment-stress relationship for a given beam. The investigator is able to predict the critical loading. It is concluded that the test results check reasonably well with the critical fatigue loads predicted on the basis of the stated theory of fatigue failure.

A1 052398
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS OF THEIR PREVENTION
Causes of shelly spots and head checks in rail are discussed, and methods for their prevention are recommended. Research conducted by the research staff of the Engineering Division of AAR and by the University of Illinois is reported. Inspections of service tests of heat-treated and alloy rail are made at nine locations, including five tests of heat-treated rail, two of chrome vanadium alloy, and two of high-silicon rail. The final report of heat-treated rails on the Norfolk & Western Railway reveals a very definite advantage of heat-treated rail over standard control-cooled rail, with rail life increased by 2 1/2 times in the case of shelling. Economic advantage of heat-treated rail involves a rail life 4 1/2 times that of standard rail. University of Illinois reports results of mechanical and rolling-load tests to produce shelling failure and details fractures and tests of six rails which developed detail fractures in service.

INVESTIGATION OF FAILURES IN CONTROL COOLED RAILROAD RAILS
Failures in 43 control cooled rails were investigated and tabulated. There were no transverse fissures from shatter cracks and no rails which contained shatter cracks. Five fractures from welded engine burns were examined. Three appeared to have failed from porosity at the bottom of the weld deposited metal and two apparently developed from cracks not removed before making the welds. One head and web separation failure representing 432 track failures in insulated joints was examined. It was determined that the cracks were the results of corrosion fatigue.

A1 052403
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL METHODS FOR THEIR PREVENTION
Continuing investigations confirmed that heat-treated or alloy rails were effective in extending the service interval before gage corner shelling occurs in track. A description and summary of eight test installations of heat-treated and alloy rails in areas of high shelling was presented. Appendix 8-a presented the progress of shelly rail studies. Rolling-load tests of high-silicon rails and one chrome-vanadium rail were performed. Shelly rail failures from service were examined and rolling-load tests to produce detail fractures in the laboratory were performed. Detail fractures from shelling in European rails were discussed. High-silicon rails gave rolling-load tests 50 to 100 percent better than standard carbon-steel rails before developing shelling failures. Three tests of a chrome-vanadium alloy rail gave two tests over 5,000,000 cycles and one test of 1,846,000 cycles. Rolling-load tests of high-silicon rails to develop detail fractures from shelling produce failures similar to those produced in track.

A1 052406
CURVE WEAR WITH DIESEL LOCOMOTIVES ON THE BESSEMER AND LAKE ERIE RAILROAD
A series of test runs were made to obtain definite information on the amount of rail curve wear produced by diesel locomotives relative to that produced by the remainder of the train. A second series of tests was made for the purpose of relating the effectiveness of flange oilers on the locomotive and rail lubricators in the track in controlling the amount of curve wear. Instrumentation consisted of a box to catch metal abraided by diesel units from the track and a motion picture camera to photograph the passing wheel flange on the high rail. The tests show that although the rate of rail and wheel wear with a diesel unit is greater than for a heavily loaded freight car, the greater amount of rail wear is due to the train rather than the diesel units. Rail and wheel flange wear on curved track can be practically eliminated by lubrication with either flange oilers on the diesel units or rail lubricators in track, or a combination of the two.

A1 052410
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Progress in the continuing study of the causes of shelly spots and head checks was reported. The performances of various installations of heat-treated and alloy-steel rail have been tabulated. Appendix 8-a presented rolling-load tests of heat-treated chrome-vanadium rail, high-silicon rails, and 140-lb. chrome-vanadium alloy rail. Examination of shelly rails from service and rolling-load tests to produce detail fractures in the laboratory were discussed. One specimen of chrome-vanadium rail, heat-treated to 490 Brinell hardness, ran 21 million cycles in a rolling-load test. Ten specimens of high-silicon rails averaged 2,307,000 cycles in rolling-load tests. Two specimens of 140-lb. chrome-vanadium alloy rail averaged 3,625,000 rolling-load cycles. Photographs of one shelling crack in a service rail indicate the crack started at a segregation streak in the rail. All rolling-load tests to produce shelling indicate that rails with higher hardness, with corresponding increase in mechanical strength, give longer laboratory rolling-load tests.

A1 052418
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Five service tests of rail are discussed. There are four of heat-treated rail and one of alloy rail. In the progressive study of shelly rail rolling-load tests of flame-hardened rails, high-silicon rails, and electric furnace steel rails were performed. Examination of shelly rails from service was performed. Rolling-load tests to produce detail fractures were done. The rolling-load tests indicate that stronger rail steel should give longer life before shelling develops in service. Study and testing on simulated rails indicated that plastic deformation is the major factor in shelly failure. Design changes and metallurgical changes to limit plastic deformation would improve rail life. Use of lower wheel loads, larger wheels and higher strength material is indicated. A photoelastic study of the stresses in a model of a railhead utilizing developments in three dimensional photoelasticity for a better understanding of rail shelling was presented. Plastic models of the prototype were thinly sliced and the data obtained were subjected to a field of polarized light. Processing the data was done by the shear difference method. Principal stresses and maximum shears were studied through loading tests. Principal stresses and maximum shears were found in the transverse section of the rail under the center of the wheel.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
A summary of the performance of heat-treated rail at five installations is presented. Results of rolling-load tests for each installation was presented. The progress on shelly rail studies was presented. Rolling-load rests on heat-treated rail, three experimentally flame-hardened rails and commercially flame-hardened rails were performed. Rolling-load tests to develop detail fractures and stress relaxation tests were made. The tests of the experimentally flame-hardened rails did not compare favorably with tests of heat-treated or alloy rail. Progress in the studies of stress relaxation in rail steel and deformational behavior of rails is reported. Bending fatigue tests of rail steel specimens were run to investigate whether a subcritical thermal treatment might heal progressive fatigue damage. No beneficial effect was noted. The mechanisms involved in rolling-load failures were then studied by work with low-carbon steels sensitive to the Fry "strain-etch" technique and with silver chloride which has optical properties and metal-like mechanical behavior. More work will be done with these two materials.

STRESS CONCENTRATION IN BUILT-UP STRUCTURAL MEMBERS
This report covers a description and analysis of tests made to determine stress concentrations in plates in the vicinity of rivet or bolt holes under varying conditions of pitch, gage, edge distance, bearing and clamping force. Measurements of strains with SR-4 strain gages and the methods of photoelasicity were the two test procedures employed in the investigation. The items investigated by each of these methods and the results are as follows. Stress concentrations at the sides of open holes in plates will vary within relatively small limits if the conventional spacing of 3 hole diameters and edge distances of 1 1/2 diameters is maintained. Stress concentrations at the sides of holes with pins in bearing in double shear will be higher than for open holes. Plates connected by pins bearing in double shear will be higher than for open holes. Plates connected by pins bearing in single shear have stresses at the sides of the holes 20 to 40 or more times the average stress on the gross section of the plate when load is applied centrally with respect to width of plate. In joints connected by high clamping bolts, the stresses inside the hole produced by clamping applied through washer only are compressive. In correlating the magnitudes of stress concentrations with the results of fatigue tests on typical specimens it can be concluded that elastic stress concentration is a valid criterion for establishing the fatigue strength of fabricated structural members. Appendix I presents a qualitative explanation of stress concentration and change of direction of stress path or trajectory.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
A summary of the performance of five test installations of heat-treated rail was presented. Appendix 9-a presented the progress of shelly rail studies at the University of Illinois. Repeat cradle type rolling-load tests on two specimens of manganese chrome, vanadium alloy rail indicated that these rails may be several times as good as standard carbon steel rails. A test of 115-lb heat-treated standard carbon rail indicated that this type was as good as the manganese, chrome, vanadium alloy steel of the heat-treated standard carbon steel rails. An electron micrograph of nickel alloy steel showed detail in fine pearlite structure which was not revealed by a light microscope. Appendix 9-b presented a summary of progress on the investigation of stress relaxation in rail steel. The work was in two areas: 1) Relaxation of stresses in small bar specimens was studied as a function of time and temperature, and 2) rolling-load fatigue tests on small systems. Specimens cut from the

top section of the rail were tested and results indicated possibly larger values of relaxation in percent of applied stress than for other specimens. Rolling-load fatigue tests produced failures that require further investigation of the effect of alleviation of damage by stress relaxing heat-treatment.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
A summary of the performance of heat-treated rail in two test installations was presented. Progress on shelly rail studies at the University of Illinois was presented in appendix 10-a. Rolling-load tests of heat-treated rails, flame-hardened rails, alloy rails and headfree rails were performed. Laboratory examination of detail fractures from shelling was performed. Design and construction of a new cradle-type rolling machine was discussed. A description of the technique used to produce electron micrographs at 35,000X magnification was given. Rolling load tests continued on 132-lb heat-treated rail revealed that yield strength was increased 65 percent, tensile strength 31 percent, elongation 18 percent, reduction of area 100 percent, and endurance limit 40 percent. Results of rolling-load tests on seven rails flame-hardened different amounts on the rail treads showed four specimens failed by head and web separation cracks, and three failed by shelling. Rolling-load and physical tests on two specimens of alloy rail steel showed that these rails have physical properties which compare closely with those of heat-treated rails. Examinations of seven detail fractures from shelling revealed that the shelling cracks started longitudinally in the steel and then turned into transverse detailed fractures.

A1 052447
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Progress on the continuous study of shelly spots and head checks in rail was presented. Heat-treated rail tests indicate that its use extended the life of a rail before gage corner shelling occured. Appendix 10-a described studies at the University of Illinois where examinations of shelly rails from service and laboratory tests to produce shelling were performed. It was observed that the black shelly spots developed by two processes. Two rolling-load test on an alloy rail were high. Examination of the failed specimen revealed non-metallic inclusions. Rolling-load tests on heat-treated rail specimens of standard chemical analysis compared with non-heat-treated companions revealed that heat-treated specimens gave 3 to 4 times the performance of the non-heat-treated specimens. Appendix 10-b presented a summary report on the examination of rails containing detail fractures found by detector cars. The purpose was to determine if the chemistry, mechanical properties, or structures of detail fracture rails varied from those of random rails. The average chemical analyses and mechanical properties of 44 rails having detail fractures and 26 random rails were so nearly the same that no distinction between the two groups was possible. The mechanical tests included hardness, tensile properties, and impact properties. Examination of deep etched structures and microstructures of detail fracture rails indicated that the steel used was of relatively good quality.

TEST RESULTS ON RELATION OF IMPACT TO SPEED
Test results on relation of impact to speed are reported to support the proposed Article 107 of the Rules for Rating Existing Iron and Steel Bridges. It is noted that a study of short span steel bridges 20 to 40 ft. long and deck plate girder spans 40 to 130 ft. long subjected to live loads with or without hammer blow indicates that the reduction of impact as a result of speed should occur at 40 mph or less, rather than synchronous speed or less as was proposed in 1947 for spans longer than 50 ft. The value of 40 mph was selected as the maximum practical speed where allowable reduction in impact might be permitted since rolling equipment without hammer blow has no synchronous speed. It is noted that some values of total impact on truss spans approximately 120-150 ft. long, subjected to equipment with hammer blow, receive more impact than is provided by Article 206 of the Specifications for Steel Railway Bridges. The character of the reduction equation for truss spans subjected to rolling equipment with hammer blow is consistent with the data.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-MEASURES FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail are reported and measures for their prevention are recommended. Reports of four study groups are presented. It is noted that no definite relationships or trends exist in the relationship between chemistry and shelling, or curvature, elevations, speeds, and grades. It is found that transposing shelly high rails to the low rail, if done in time, is worthwhile. Rail slow-cold worked under traffic in nonshelling locations and relaid in shelling locations possesses very little, if any, greater resistance to shelling than ordinary rail. Studies of high carbon rail indicate that it will retard but not eliminate shelling and that it has a tendency to head check and this in turn causes gage corner flaking or minute shelling. A seven-year summary report of shelly rail investigation at the University of Illinois is presented. Also presented is a summary report on the examination of 300 shelled spots selected from the track of 11 major roads, indicating that the shelled spots were predominantly of surface origin.

COMPARISON OF WEB STRESSES IN 131-LB RE AND 140 PS -(PENNSYLVANIA) SECTIONS
Report is made of field measurement of stresses made by the Pennsylvania Railroad in 131-lb. RE and 140 PS sections of rail. The 140 rail section is designed to compensate for the inadequacy of the 131 section, and the two sections are compared. Stresses reported include the maximum stress in the web in a vertical plane occurring under a concentrated load. It is noted that in the service tests, made under conditions where rails were failing, the maximum stress is always found on the gage side of the low rail and that is where fatigue cracks develop. It is concluded from these service measurements that the laboratory basis of design of the new section is sound and that the laboratory stress measurements forecast the reduction in service stress with satisfactory accuracy.

REPORT ON SERVICE TEST OF SOLID MANGANESE CROSSINGS FROGS AT MCCOOK, ILLINOIS
Service tests of solid manganese crossing frogs at McCook, Illinois, are reported. Stress measurements are covered in the flangeways and at other significant stress areas of five different designs of manganese castings placed in the crossings of the Baltimore & Ohio Chicago Terminal Railroad and the Atchinson, Topeka & Santa Fe Railway. Service tests include tests of the original design of casting by Taylor-Wharton and the Carnegie-Illinois casting. It is concluded that some of the designs included in the tests are more resistant to the development of fatigue cracks than others, but in none were the developed stresses low enough relative to the fatigue strength of the manganese steel to give the service life under heavy traffic that should be expected, and efforts to further reduce these stresses are recommended.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL SURFACES-DEVELOP MEASURES FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail surfaces are investigated, and preventative measures are recommended. It is found that no definite relationship exists between chemistry and shelling, and no definite trend regarding curvature, elevations, speeds and grades. Transposing shelly high rails to the low rail, if done in time, is worthwhile. Rail slow-cold worked under traffic in non-shelling locations and relaid in shelling locations possesses little resistance to shelling compared to ordinary rail. It is also found that high carbon rail does not eliminate shelling but retards it more than ordinary carbon rail; however, the high carbon rail tends to head check and in turn cause gage corner flaking or minute shelling. Reports are submitted by the Norfolk & Western, Pennsylvania, Duluth, Missabe & Iron Range, and Chesapeake & Ohio Railroads.

A1 052472
INVESTIGATE CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL SURFACES FOR THE PURPOSE OF DEVELOPING MEASURES FOR THEIR PREVENTION
The investigation into the causes of shelly spots and head checks in rail surfaces was presented. A definition and description of shelly spots, the most serious type of rail damage, was presented. The division of the work of this subcommittee was described. Appendix A presented the shelly rail studies conducted at the University of Illinois. Laboratory studies of failed shelly rails concluded that shelling appears to be the result of cold working of the rail steel by "line contact" with car wheels. The presence of imperfections accelerated the formation of cracks. Laboratory rolling-load tests to produce shelling were performed. Different rail steel compositions were studied through rolling-load tests. The Brinell hardness of the wheel path after rolling was measured. Full sections specimens of heat-treated carbon rail were tested under rolling-load. No conclusions were reached.

A1 052473
NINTH PROGRESS REPORT OF THE JOINT INVESTIGATION OF FISSURES IN RAILROAD RAILS
The information in this report of the joint investigation of fissures in rails was contained in five sections. Field tests for batter of end-hardened rails in service on the Chesapeake and Ohio Railway were performed. The summary of the batter values was tabulated. Rail ends with large cracks had approximately three times the batter of uncracked ends. Examination of end-hardened rails from the C and O test track in Carey, Ohio revealed that most damage, weeping cracks and flow of the metal over the ends and sideways, produced batter and drooping of the rail ends. Tests of mill cooling containers for rails were discussed. Examination of control-cooled and Brunorized rails which failed in service revealed that none of the control-cooled rails contained shatter cracks, but did have transverse fissures from blow holes and welded spots, horizontal split heads, detailed fractures from engine wheel burn, fatigue failures starting in the web, and detailed fractures from shelly spots. The Brunorized rails had developed transverse fissures from shatter cracks as nuclei. A comparison of drop and bend tests was summarized.

Conducted by the Engineering Experiment Station, University of Illinois in cooperation with the Association of American Railroads and the Rail Manufacturers' Technical Committee.

A1 052474
EIGHTH PROGRESS REPORT OF THE JOINT INVESTIGATION OF FISSURES IN RAILROAD RAILS
Field tests for batter of end-hardened rails in service on the Chesapeake and Ohio Railroad were presented. Batter values for the leaving rails increase with the amount of traffic, whereas the values for receiving rails decrease. Laboratory tests of cracked end-hardened rails from test track revealed that a large number of the rails developed weeping cracks which will require building up by welding. The proposed recommended practive for the control cooling of railroad rails for consideration by the mills and railroads was presented. Mill tests of control cooling and mill tests to determine the temperature and manner of the growth of shatter cracks in steel rails were performed. It was concluded that shatter cracks develop gradually in size and number in shatter sensitive carbon steel rails as they are allowed to cool between the ranges of 400 and 70 degrees F. Control-cooled and Brunorized

rails in service were discussed. A comparison of drop tests and bend tests on "A" rails was tabulated. A study of the drop test for rails was presented in the appendix. The force of a blow, its measurement by deflection and its measurement by measurement of the permanent elongation in the bottom fiber of the rail at mid-span were discussed.

A1 052477
DISCUSSION ON STRESSES IN RAILROAD TRACK. PART 1
A discussion of the comparison of tests on stretches of welded track under observation was presented. The purpose was to learn of the magnitude and distribution of the anchorage given between the ties and ballast at the ends of the welded stretch and along its length to resist the forces set up by chance changes in the temperature of the rail, and to learn how the influences tending to change the length and alignment are met in the track. Stress measurements were made on the web of the rail, and the temperature of the rail was taken with the open ended thermocouple and portable potentiometer. The observations were reduced by temperature corrections of gage readings and made comparable for both strains and stresses. Throughout the intermediate part of the welded stretch very little change occurred throughout the variations in summer and winter temperatures. The rails changed length through an average distance of seven rail lengths for the end portions of the rails for both the summer and winter tests. For the higher summer temperatures and lower winter temperatures the stresses may be expected to increase in proportion to the increase in change of temperature from the 63 F base. Lateral deflection of angle bars occurred when bolts were tightened. Tightening of the inner bolts in worn bars also developed lateral bending stresses in the bars. The stresses were generally compressive and the bars bend about an axis appproaching the vertical and high tensile stresses occurred on the inner flanges of the bar. These will add to the tensile bending stresses produced by wheel loads.

A1 052478
DISCUSSION ON STRESSES IN RAILROAD TRACK. PART 2
Observations and tests made on the stretches of welded rail of the Delaware and Hudson Railroad, one section at Albany, and two at Schenectady, were presented. The purpose of the tests was to find changes in length in rail at any place along the stretch, anchorage or restraint at any place along the length and temperature stresses set up in the rail at any place. Readings were taken with strain gages. Temperature of the rail was taken with a thermocouple and potentiometer. Summer and winter measurements were taken. All the welded stretches kept their alignment well even on curves. The longitudinal movement at the ends of the welded stretches and at points along the length due to temperature changes was small. No noticeable movement of the ties in a direction longitudinal of the track was seen. At the end of a welded stretch a tensile or compressive force of considerable magnitude may be transmitted to the adjoining rail. Variable anchorage forces developed in the summer at points due to the presence of under-crossings and viaducts. The flexural stresses developed in the rail by the loads of traffic will be superimposed on the temperature stresses and the two sets of stresses at any point in the height of the rail must be added or subtracted according to their nature.

OPTIMUM ADAPTATION OF THE CONVENTIONAL TRACK TO FUTURE TRAFFIC. STUDY OF THE CHANGE IN THE TRACK LEVEL AS A FUNCTION OF THE TRAFFIC AND OF THE TRACK COMPONENTS (FIRST RESULTS OF LABORATORY AND SITE TESTS)
The report deals with the change in the longitudinal level of conventional tracks under the effect of operating loads. Tests have been carried out in the laboratory and on actual sites on differently equipped tracks, with a view to defining the influence of the various track component parameters. The discovered evolution law of defects has shown that the reduction in sleeper spacing and of crib and shoulder consolidation exert a rather clear influence. It has also become apparent that the quality of the maintenance operations exerts a very large influence. These findings should however be treated with caution. The influence of the inertia of the rail, the thickness of the rail pads, the types of sleepers and the conditions of the formation and of the ballast, will be accurately defined later.

BEHAVIOUR OF THE METAL OF RAILS AND WHEELS IN THE CONTACT ZONE. CALCULATION OF THE COMPLEX STRESS CYCLES IN THE RAIL SUBJECTED TO ROLLING LOADS. ASSESSEMENT OF THE DANGER OF DAMAGE (CONTINUED)
This study deals with new calculations of the composition of the residual stresses and the stresses induced in the rail during the passage of wheels, for different loading values, wheel diameters and wheel-tyre transverse curvatures. One thermal stress and three residual stresses have been considered. The latter have been calcuated and then measured with the help of an original strain-gauge method. The danger of rail damage has then been evaluated by means of the damage line criterion proposed by Mr. Dang Van (see C 53/RP 7 and C 53/RP 8). It has been possible in this way to define the danger factor for each loading case. It has been shown that two types of danger exist, namely, fatigue and plastic deformation.

Restrictions on the use of this document are contained in the explanatory material.

CONSTRUCTIONAL ARRANGEMENTS FOR IMPROVING THE RIDING STABILITY AND THE GUIDING QUALITY OF ELECTRIC AND DIESEL LOCOMOTIVES AND VEHICLES. COMPARISON OF THREE MEASURING METHODS FOR DETERMINING THE FORCES EXERTED BY THE WHEELS OF A MOTIVE POWER UNIT ON THE RAILS IN A CURVE OF 300M RADIUS (GIORNICO 1957)
In order to make a comparison between the measuring methods developed by the NS and the SJ for determining the forces occurring between wheel

and rail, comparative tests were carried out on a curve of 300 m radius on the Gothardline in October 1957. For these tests the following measuring apparatuses were used: one measuring rail of the CFF; six measuring base plates of the NS; six measuring base plates of the SJ. For an initial series of tests, the measuring rail was laid on six adjacent sleepers fitted with the measuring base plates of the NS and, for a second series of tests, on six adjacent sleepers fitted with the measuring base plates of the SJ. The measuring rail was secured to the other sleepers by means of the usual CFF fastenings. The forces indicated by the CFF measuring rail on the one hand and by the NS measuring baseplates and the SJ measuring baseplates on the other hand, were determined at various speeds and compared with each other. Considerable differences were shown by the lateral forces determined in this way, by means of the measuring rail and the measuring baseplates of the NS and the measuring rail and the measuring baseplates of the Sj, respectively. Better agreement was displayed by the vertical forces, though, in this case, comparison was only possible between the measuring rail and the measuring baseplates of the NS (the measuring baseplates of the SJ not being designed for the measurement of the vertical forces). The considerable differences between the measured values were considered to have been caused chiefly by the mutual influence of the measuring rail and the measuring baseplates of the NS and the measuring rail and the measuring baseplate s of the SJ respectively, on each other. Since the test arrangement used at Giornico-measuring rail laid on measuring baseplates-did not prove satisfactory, it is suggested, when making comparative tests in the future, to have the three methods of rail measuring equipment arranged at adjacent sites on a curve. The relationship between the values supplied by the three measuring methods should be established with the aid of a fourth measuring method, e.g. by means of directly measuring on the wheel of the vehicle under test the forces exerted on the rails (as already developed by the SJ to a certain degree of perfection).

Restrictions on the use of this document are contained in the explanatory material.

A1 052683
CONSTRUCTIONAL ARRANGEMENTS FOR IMPROVING THE RIDING STABILITY AND THE GUIDING QUALITY OF ELECTRIC AND DIESEL LOCOMOTIVES AND VEHICLES. MEASUREMENTS OF THE FORCES EXERTED ON THE RAILS BY VARIOUS TYPES OF MOTIVE POWER UINTS (MEASURED IN A CURVE OF 300M RADIUS AT GIORNICO)

In 1955 the CFF decided to intitiate investigations in order to determine by means of experiments the extent of the wear to which the track would be subjected in a curve of 300 m radius by the then newly developed locomtive types of the series Ac 4/4 (BoBo) and Ac 6/6 (CoCo). The measuring rail working according to the Schlumpf system was used as measuring apparatus. The results of these measurements have shown that the modern bogie locomotives subject the track to less wear at the same speed (BoBo) or to hardly any heavier wear (CoCo) than the rigid frame locomotives of not so recent date. Following the tests which had been made at the suggestion of the Working Group "Measurements on the track" of the B 10 Specialists Committee, for the comparison between three different measuring methods (see B 10 RP 4), arose the possibility of repeating the tests made in 1955. The measuring rail was again used as measuring apparatus, as it had been done for the tests made in 1957, but the tests included a larger number of locomotive types and a considerable versine error was intentionally arranged in the test track. The tests made in 1957 have confirmed the fundamental results of 1955, moreover they have shown that 1) a transverse coupling between the bogies and 2) the lateral movement of the rubber cushioned leading axles of the CoCo locomotives considerably reduce the forces exerted on the track.

Restrictions on the use of this document are contained in the explanatory material.

STATISTICAL CHARACTERIZATIONS OF RAILWAY TRACK BEHAVIOR

Absolute space curve data of railway track, representing the vertical and lateral perturbations of both running rails, was collected and analyzed. A variety of track is studied, including high speed versus yard, bolted versus continuous welded rail (CWR), and old versus new construction. Analytical techniques include Signal Averaging, Analysis of Variances, and Correlation analysis. As a result, it is concluded that railway track is characterized by a pure Markovian process, a periodic process, and a periodically modulated random process.

SPECIAL STUDY. BROKEN RAILS: A MAJOR CAUSE OF TRAIN ACCIDENTS

The report identifies broken rails as the largest single cause (in 1972) of train accidents and suggests that the problem will magnify. The study analyzes the current means for controlling rail failures, such as rail manufacture, use, inspection, research, and regulation. Recommendations are directed to the Federal Railroad Administration to revise accident reporting methods, to determine the reason for the drastic increase in train accidents resulting from broken rails, to promulgate additional regulations prescribing rail use and maintenance, to develop criteria for rail inspection, and to initiate research of rail and rail flaw detection methods. Recommendations also are directed to the railroad industry to initiate rail research, to accumulate rail failure statistics, and to institute track maintenance policies that will reduce the number of train accidents resulting from broken rails.

IMPROVEMENTS OF MAINTENANCE CRITERIA COVERING THE RUNNING GEAR OF SHIN-KANSEN RAILCARS BY MEASURING THE TRANSVERSAL ACCELERATIONS OF THE BODY [SHIN-KANSEN DENSHA SOKO KANRI SHIRYO SEIDO UO KOJO NI KANSURU KENKYU]

Osaka engine shed officials measure, under 200 km/h on line conditions, the body accelerations of Shin-Kansen railcars each time the wheels are re-profiled (every 70,000 km). Following these measurements, an index is calculated in accordance with an empirical formula that is a linear combination of the acceleration occurrence frequencies classified by section (linear combination of the values of the acceleration distribution analysis). Bogie overhaul is scheduled in accordance with the value of this index. In applying this method, the JNR encountered difficulties due to the effect of 3 factors on transversal accelerations: the state of the track, the speed (the index is very sensitive to speed variations of only a few km/h), weather conditions (transversal stability is distinctly improved in rainy weather). The article describes how corrective laws were worked out to eliminate the effect of the first 2 factors. For the 3rd factor, it was decided to limit measurements to periods of wet weather. THE BEHAVIOUR OF RAILS IN RELATION TO THEIR CONDITIONS OF USE
The principal rail failure statistics of 5 Administrations have been analysed with a view to determining the respective influence of the different features involved in the behaviour of rails in service. Some recommendations are proposed concerning the choice of rail-section as a function of the traffic, the grade and quality of the rail steel and the construction of rail joints. The problems raised by welds in continuously welded rails, by the substructure and by the environment are also mentioned. It seems that the rail withdrawals for fatigue defects increase proportionally with the total traffic load on the one hand with the cube of the average axle-load on the other.
Restrictions on the use of this document are contained in the explanatory material.

ELASTIC DEFORMATIONS IN TRACKS WITH S 60 RAILS [Zroznicowanie Odksztatcen Sprezystych Nawierzchni S 60]
The author looks back over studies carried out by the PKP over a four-year period into the behavioural pattern of tracks with S 60 rails on wooden or concrete sleepers, on main intercity routes. The article gives the results obtained for elastic depression of rails, their side-slip and stress, for rail deflection (including its height) or the coefficient of rigidity of track formation and rail, the effect of ballast grain size on depression, etc. He also gives forecasts for increases in track irregularities in relation to the loads carried in practice according to mathematical models and analysis of the measurements. The conclusions drawn underline the considerable advantages provided by the S 60 rail tracks which could be increased still more by perfecting the technology and quality of laying and maintenance work. PERFORMANCE OF WELDED JOINTS IN RAILS
It is shown that high-carbon and chromium alloy steel joints, produced by butt welding, possess reduced resistance to impact loading in comparison with the base metal although they have otherwise excellent mechanical properties. Gas-pressure welding insures greater resistance of the joints to impact loading in comparison with resistance flash welding.

MODEL STUDY FOR VERTICAL TRACK BUCKLING
A study is presented of two models which represent the mechanism of vertical buckling of a track when subjected to a mechanical or to a thermal compression force, respectively. The postbuckling equilibrium curves and their stability are discussed and a stability criterion is defined. The effect of various track model parameters, upon the buckling load or buckling temperature, is shown. Graphs reveal that the range of safe compression forces for the mechanically compressed structure is much smaller than the range of the safe forces due to constrained thermal expansions; indicating a possible explanation why in the tests in which the compression forces are induced by jacks the track buckles predominantly in the vertical plane, whereas when the track is compressed by constrained thermal expansions it exhibits mainly horizontal buckling modes. It was found that the buckling loads, or temperatures, obtained from a linearized analysis have no relevance to the actual values obtained from a nonlinear analysis; the difference in results being substantial for buckling temperatures.

SPECIAL STUDY OF PROPOSED TRACK SAFETY STANDARDS
The report reviews the initial track safety standards proposed by the Federal Railroad Administration in response to the mandate of the Federal Railroad Safety Act of 1970. The report discusses the risks involved in promulgating nonobjective, incompatible, or nonadaptable standards and suggests alternate approaches that may promote effective and enforceable track safety standards. The report recommends that standards not be advanced unless they are objective, compatible with the system, and adaptable to circumstances, including changes in technology. Additional recommendations are directed at methods of strengthening the standards including such items as definitions, and the inclusion of standards for the promotion of safety at grade crossings and reducing the incidence of rail failure.

RAILROAD ACCIDENT REPORT: CHICAGO, BURLINGTON AND QUINCY RAILROAD COMPANY TRAIN 64 AND TRAIN 824 DERAILMENT AND COLLISION WITH TANK CAR EXPLOSION CRETE, NEBRASKA, FEBRUARY 18, 1969
At about 6:30 a.m., on February 18, 1969, Chicago, Burlington, and Quincy Train No. 64 derailed the 72nd to the 90th cars, inclusive, at a turnout located on the spiral of a 2 degree curve as the train was entering Crete, Nebraska, at a speed of about 52 miles per hour. The derailed cars struck standing cars on a siding south of the main track and the cars of train 824

A1 072593
RAILROAD ACCIDENT REPORT: PENN CENTRAL COMPANY TRAIN SECOND 115 (SILVER STAR) DERAILMENT AT GLENN DALE, MARYLAND, JUNE 28, 1969
The "Silver Star" operating as Penn Central Train 2nd 115, derailed on Penn Central tracks at Glenn Dale, Md. about 1:23 p.m. June 28, 1969. Among the 541 passengers in the 18 cars, 144 persons were transported to area hospitals, 12 of whom were admitted. Total estimated damage, excluding personal injuries, were in excess of $300,000. The derailment was caused by lateral movement of the track under the train. The lateral movement was caused by buckling of the track because of high compressive forces caused by heat expansion and the tendency of rail to creep in the direction of the predominant flow of traffic and descending grade. A number of injuries to passengers were caused by their being thrown from the seats and striking interior parts of the cars, and by luggage being thrown about inside the cars.

THE STRESS AND STABILITY ANALYSES OF RAILROAD TRACKS
The paper presents a survey of the state of knowledge in the fields of stress and stability determination of a railroad track. At first, the evolution of the railroad track structure is briefly summarized. This is followed by sections which discuss the development of the methods for the determination of stresses in the rails and ties, and the stability of the railroad track due to constrained thermal expansions.

This paper was contributed by the ASME Applied Mechanics Division for presentation at the Winter Annual Meeting, 17-21 November 1974. The research was sponsored by the Department of Transportation, Federal Railroad Administration, Rails Systems Division, Washington, D.C.

RAILROAD ACCIDENTS AND NONDESTRUCTIVE INSPECTION
Railroad accident data published annually by the Office of Safety in the Federal Railroad Administration are analyzed to indicate the most severe causes of railroad accidents. The severity is judged by viewing both the frequency of accidents and the dollar damage per accident. Most of the components or conditions in the groups found to be severe accident causes are amenable to non-destructive inspection. An analysis shows the maximum benefits of an extensive non-destructive inspection program to appear in the wheel and axle category followed in order by track geometric and dynamic conditions and rails and joints. A review is provided for non-destructive inspection methods in current railroad use and potentially useful for the future.

CONTRIBUTION TO THE THEORETICAL EXAMINATION AND EXPERIMENTAL TESTING OF RAILS [Ein Beitrag zur Theoretischen Untersuchung und Experimentallen Pruefung von Eisenbahnschienen]
The forces acting on rails under different conditions of service stress were calculated. Calculations were compared with results of fatigue tests on S49 and UIC60 rails. The variables investigated for their specific effects included locomotives vs freight cars and fast succession of trains. Fracture formation and propagation are discussed. It is concluded that high axle loads require a large rail section, and small wheel diameters also require a high tensile rail steel. The UIC60 rail of steel with 900 N/mm2 minimum tensile strength meets the two requirements and offers ample reserves. [German]

FAILURES OF RAILS AND TRACK SWITCHES [Schadensfaelle an Eisenbahnschienen und Weichen]
Statistics of failures and investigation of the rail material point out to the specific kind of failure of rails. In particular there occur fractures in the form of the running edge peeling off as well as of cross fractures. Even the rails manufactured of high-strength steels cannot cope with heavy loading, occurring in curves with a narrow radius. This led to the development of rails with a yield point exceeding 600 N/sq mm that are being successfully used. A method for analysis of failures is suggested. [German]

ULTRASONIC 'EYES' ABOARD BRITISH TESTING TRAIN LOCATE RAIL DEFECTS
Ultrasonic "eyes" capable of detecting and recording hidden flaws in railroad tracks have been placed in use in Great Britain aboard a new rail testing train which travels as it works at speeds up to 25 mph. This paper reports the technique.

This abstract is also contained in "A Bibliography on the Design and Performance of Rail Track Structures", September 1974, RRIS #072794, which was prepared for the Urban Mass Transportation Administration.

standing on a track north of the main track. A tank car in train 824 was completely fractured on impact with the derailed cars which released the lading of 29,200 gallons of anhydrous ammonia into the atmosphere. A gas cloud was formed which blanketed the surrounding area for a considerable time due to the weather conditions. Three trespassers riding on train 64 were killed as a result of the derailment and six people were killed and 53 were injured as a result of exposure to the cloud of ammonia. The Safety Board determined that the derailment was caused by the movement of a rail of the turnout due to lateral forces produced by the locomotive as it moved over track alignment and surface deficiencies of the track. The complete fracture of the tank car on impact was contributed to by the brittleness of the steel of the car caused by the low ambient temperature.

RAILROAD ACCIDENT REPORT: RICHMOND, FREDERICKSBURG AND POTOMAC RAILROAD COMPANY TRAIN NO. 10/76 DERAILMENT WITH THREE FATALITIES AND NUMEROUS PERSONAL INJURIES, FRANCONIA, VIRGINIA, JANUARY 27, 1970
Train No. 10/76 derailed on Richmond, Fredericksburg and Potomac (RF&P) 1970. The train consisted of one express car, one postal car, two baggage cars, four coaches, two sleeping cars, and three diesel-electric locomotive units. The train proceeded northbound on No. 2 track and at Possum Point, 80 miles north of Richmond, crossed over to No. 3 track to avoid conflict with a local freight. On approaching Franconia, speed was reduced from 80 miles per hour to 70 miles per hour; at Franconia, speed was further reduced to 65 miles per hour, and as the train traversed the north end of a curve, the locomotive lurched severely to the left. Immediately thereafter, the derailment occurred. The accident resulted in the derailment of the eight rear cars of the train. The third, fourth, and fifth cars remained upright and coupled to the head end of the train. A separation occurred between the fifth and sixth cars, and between each of the following cars. The sixth through 10th car veered to the left down a bank, and either partially or completely overturned. Of the 101 passengers in the 10 cars, three were killed, five incurred injuries requiring hospitalization and 45 persons were treated for less serious injuries. The National Transportation Safety Board determines that the probable cause of the derailment was the lateral movement of the track immediately ahead of the locomotive, due to conditions resulting from inadequate track maintenance procedures.

MEAN STRESS EFFECTS ON FATIGUE CRACK GROWTH AND FAILURE IN A RAIL STEEL
Over a limited range, the effect of mean stress has been studied on fatigue crack propagation and on the critical fatigue crack size associated with sudden fast fracture in center-notched plate specimens of a rail steel under pulsating loading. The results have been presented in terms of the stress intensity factor range K and the ratio R of the minimum to maximum stress. Increasing R was found to both accelerate cracking and reduce the critical crack size at instability. The data have been correlated with three crack growth equations currently used in the literature and it was found that the equation of Forman et al. relating crack growth rate to K and R gave the best fit. This equation was used to predict life in the finite range of the S-N curve. Fractographic examination revealed that the fracture surfaces were complex and a number of fracture modes contributed to cracking.

RAILROAD ACCIDENT REPORT: PENNSYLVANIA RAILROAD TRAIN PR-11A, EXTRA 2210 WEST AND TRAIN SW-6, EXTRA 2217 EAST DERAILMENT AND COLLISION DUNREITH, INDIANA, JANUARY 1, 1968
About 9:30 p.m., January 1, 1968, Pennsylvania Westbound freight train PR-11A, consisting of 98 cars and five-unit diesel-electric locomotive, was passing Dunreith, Indiana, at 42 miles per hour when the trailing wheels of the 88th car, an empty tank car, AESX 850, derailed at a broken rail near the eastern edge of the town. At the same time, eastbound freight train SW-6 consisting of a five-unit diesel-electric locomotive and 106 cars, was moving eastward at 32 miles per hour on the adjacent track. The derailed car in train PR-11A continued westward until it became disengaged from its trailing truck when it struck the crossing board at a grade crossing about 723 feet west of the point of original derailment. One or more cars collided with cars of hazardous materials moving in the opposite direction in SW-6's train, causing a general derailment and puncturing several tank cars of flammable materials. A large-scale fire ensued, followed by a violent explosion of a tank car of ethylene oxide forty-five minutes later. Immediately after the derailment and outbreak of fire the population of Dunreith was evacuated without injury. A cannery and several residences and businesses were destroyed. Three firemen and two police- men were slightly injured in the fire and explosion. The probable cause of the initial derailment in train PR-11A was the broken rail within the compromise joint where two different sizes of rail were joined. A contributing causal factor was the inadequate track maintenance which left the joint unsupported and allowed the development of the break in the rail. This initial derailment and the design of the lift-off type of center-pin connection between the truck and body of AESX car 850 which allowed the truck to separate from the car under impacts of a simple derailment, led to the secondary collision and general derailment.

RAIL RESEARCH-PROBLEM DEFINITION
A program was initiated to determine and define the problems associated with rail. The purpose was to collect and analyze facts regarding national and international experience on rail behavior, in order to focus attention on the major unresolved problems in rail. These are (1) Joint area problems, both bolted and welded, (2) Plastic deformation of rail head causing shelling, (3) Rail defects and premature removal of rail from track, and (4) Appropriate selection of rail based upon service requirements-use criterion. This report presents a background study of rail design, chemical composition and heat treatment of rail, manufacturing and rolling of rail-reviewing problem areas of each. A discussion of rail defects and the background and techniques of rail defect (flaw) detection is also presented. Recommendations are made for further research and study on bolt hole drilling, rail straightness, new rail steel process and manufacturing techniques, wheel/rail interaction, fracture properties and defect propagation of present and proposed rail steels, rail flaw detection technology, and economic use criterion of rail.

ANALYSIS OF NAD CRANE MAINTENANCE OF WAY
The report represents an in-depth comprehensive analysis of NAD Crane's railroad maintenance of way (M/W) program. Quantitative tools have been developed to provide a rational framework for decision making for M/W. This analysis was prompted by the occurrence of numerous derailments attributed to poor track conditions. The safety aspects of derailments of hazardous material including high explosives required a thorough analysis of causes related to operations of the Ordnance Department and the Public Works Transportation, Maintenance, and Maintenance Control Division. The report presents several recommendations for the establishment of annual levels of maintenance, recommendations on the equipment required, and recommendations on the priority use of maintenance resources. TRAIN HANDLING AND OVERTURNED RAIL
The Canadian Pacific Railway recently used the EMD's dynamometer car to explore the problem of harmonic roll and over-turned rail. The problem is particularly bad in the Rockies. The tests indicated several methods by which train handling procedures could be improved to reduce the chance of a derailment.

MEANS AND METHODS TO INCREASE TRACK STABILITY
The stability of track is a serious problem for every railroad, especially since the introduction of welded rail. The primary concern of this paper is the behavior of track after trackwork has been carried out with particular regard to its geometry. Such work affects the resistance of track to all types of movement, both under traffic and induced by climatic conditions. The attention is directed at conventional track structures because too little is so far known about other types. It is concluded that a high standard of track geometry can only be maintained by lining machines; modern equipment can efficiently increase the lateral resistance of the ballast bed; and track stiffness can be increased with appropriate fasteners and new types of ties.

TESTING LATERAL SLIPPING OF THE TRACK WITH A NEW DESIGN OF SLEEPER IN THE AUSTRIAN FEDERAL RAILWAYS [Gleisverwerfungsversuche der Oesterreichischen Bundesbahnen mit neuen Schwellenformen]
Tests on the lateral slipping of the track on a curve with a radius of 189 m have shown that the track's resistance to lateral displacement was considerably improved by modifying the shape of the sleepers, and that the welding of the rails was also possible with smaller radii. The resistance to lateral displacement of the Be 14 d sleeper with lugs is twice that of the B 14 sleeper without lugs, and 50% higher than the resistance of the Be 17 sleeper, which has about the same basic surface as the Be 14 d sleeper. TRACK TRAIN DYNAMICS. ACCIDENT INVESTIGATION
This manual, a report marking the completion of one assignment of the International Government-Industry Research Program on Track-Train Dynamics, is a guide to systematic investigation of any derailment in order to establish a cause, or combination of causes. It presents information stressing the close relationships between track, train and vehicle characteristics, train handling, and track-train dynamics. Stressed is the need to recognize that a derailment may be combination-caused, rather than mandating the investigators to report a single cause. This is necessary if information from the accident investigation is to accurately reflect the true situation. The manual concludes with six recommendations for individual railroad users.

This project was sponsored by the Association of American Railroads, the Federal Railroad Administration, the Railway Progress Institute and the Transportation Development Agency of Canada.

THE TRIBOLOGY OF WHEEL ON RAIL
The functioning of wheels and rails as a supporting and guiding system depends on a Hertzian contact of 1.2 x 10 to minus 4th power sq m (0.2 in sq) area. In addition to its supporting function, this area must withstand tangential forces to enable the functions of traction, braking and guidance to be fulfilled. Such traction forces are accompanied by a deflection known as 'creep' and classical estimates of this quantity are compared with measurements made on the track. Modes of wear of wheel and rail are described and alternative systems which avoid contact are discussed.

A METHODOLOGY FOR EVALUATING THE ECONOMIC IMPACTS OF APPLYING RAILROAD SAFETY STANDARDS. VOLUME I
The report presents a methodology for evaluating the economic impacts of applying railroad safety standards. The scope is considered broad enough to permit evaluation of all the safety standards thus far proposed by the Federal Railroad Administration and to allow for detailed analysis of individual equipment, track, and human factors standards. At the same time, the details and examples are fairly specific in order to present insight into the techniques and problems which might be encountered. Volume 2 of this report is the manual whose step-by-step procedures are intended for the implementation of economic impact analysis. Portions of this document are not fully legible.

A METHODOLOGY FOR EVALUATING THE ECONOMIC IMPACTS OF APPLYING RAILROAD SAFETY STANDARDS. VOLUME II
This manual is intended as a working document for Federal Railroad Administration personnel, and provides step-by-step procedures which are intended for use in determining the economic impact of proposed railroad safety standards. It is a companion piece to Volume I, the Final Report. The procedural framework described is broad enough to encompass safety standards in equipment, track, and human factors standards. At the same time, the details and examples are fairly specific in order to present insight into the techniques and problems which might be encountered. In developing this manual, high priority was placed on presenting workable procedures that can be used immediately for economic impact evaluation. Special attention is given to accidents and accident prediction, discounting, quantification problems and the role of sensitivity analysis. A completely worked example is presented in the appendix. Portions of this document are not fully legible.

SOAC: STATE-OF-THE-ART CAR ENGINEERING TESTS AT DEPARTMENT OF TRANSPORTATION HIGH SPEED GROUND TEST CENTER. FINAL TEST REPORT. VOLUME I. PROGRAM DESCRIPTION AND TEST SUMMARY
The six-volume report presents the technical methodology, data samples, and results of tests conducted on the SOAC on the Rail Transit Test Track at the High Speed Ground Test Center in Pueblo, Colorado during the period April to July 1973. The Test program comprises three areas: Vehicle testing, ways and structures testing and track geometry measurement. The objective of the SOAC program is to demonstrate the current state-of-the-art in rail rapid transit vehicle technology, with passenger convenience and operating efficiency as primary goals. In this series, Vol. I contains a description of the SOAC test program and vehicle, and a summary of the test results; Vol. II, Performance Test data; Vol. III, Ride Quality Test data; Vol. IV, Noise Test data; Vol. V, Structural, Voltage, and Radio Frequency Interference Test data; and Vol. VI a description of the Instrumentation system used for performance, ride quality and structural testing.

DEVELOPMENT OF A NEW SYSTEM FOR DETECTING FATIGUE CRACKS IN STEEL BRIDGES
The nondestructive detection and characterization of fatigue cracks during field inspection of steel bridge structures are put in perspective in terms of the magnitude of the problem and viable nondestructive methods. The results of nondestructive method assessment, selection, evaluation, and experimental confirmation are presented in detail. Developed as a useful and effective solution to the problem, the inspection system consists of two independent, complementary, lightweight, battery-powered electronic instruments-an acoustic crack detector (ACD), which uses ultrasonic principles, automatic signal analysis, and a simple digital data display for rapid survey, and a magnetic crack definer (MCD), which uses magnetic principles and a simple ON-OFF light data display for defining the precise location and crack length. The features and functioning of the equipment are briefly described, and laboratory and field demonstrations, presentations, and field inspections are reviewed. The technical basis for equipment development, including equipment concepts, is summarized.

TEST TRAIN PROGRAM SIXTH PROGRESS REPORT
The report describes the progress of the Rail Research Program involving operation of the FRA test cars and the performance of other rail research efforts during the period 1 July 1973 to 30 June 1974. High-lights of the work reported include operation of the FRA test cars to perform track surveys and other rail research activities; test car upgrading; expansion of the Rail Research Program; and data management and data analysis tasks which have been undertaken to benefit railroad technology. The Rail Research Program primarily involves the operation and instrumentation of the FRA test cars. This research program is designed to provide high-speed measurement of railroad track characteristics, development of comprehensive track measurement techniques, development of special testing instrumentation, and data evaluation through analysis and electronic processing.

A1 095213
THE EFFECTS OF VARIATIONS IN HEAT TREATMENT ON THE STRENGTH AND TOUGHNESS OF RAIL STREEL
Because of the growing number of incidents due to rail failures, research is being made into possible improvements. The AAR and Carnegie-Mellon University have jointly sponsored a research programme into the possiblity of improving rail strength (which determines what axle load can be supported without any permanent rail deformation), and toughness (defined as the measure of the steel's resistance to brittle fracture or the slowness with which a defect spreads) by simply altering the heat treatment conditions (rolling or austenization temperature, isothermal transformation temperature or cooling rate). The general tendencies of the phenomenon have been determined. Strength and hardness are unaffected by austenization temperatures between 1470 degrees F and 1830 degrees F but toughness decreases. Resistance increases as isothermal transformation temperature rises (between 1010 degrees F and 1155 degrees F and toughness would reach its maximum at about the lowest temperatures tested). This unfinished study should make it possible to decide whether the improvements that can thus be obtained are adequate for justifying a transformation of the heat treatment process or whether this line of research is pointless.

MEANS AND METHODS TO INCREASE TRACK STABILITY
The author deals with the means and methods of preventing the decreases in track stability following maintenance operations. Above all, he refers to the so-called Plasser-all-side-system RS-System and gives an account of some tests to determine the best conditions for its use. He goes on to provide graphs showing: the results of a large number of measurements of track resistance to lateral deformation; the conditions of buckling stability deduced from theoretical and relative formulae either in the case of simple buckling of a perfectly straight track or that of deformation of a track with a slight flaw at the outset. He comes to the familiar conclusions as far as conditions for good stability are concerned: high standard of track geometry; increased lateral resistance of the ballast bed by use of modern equipment; increased track stiffness with wing-ties, used so successfully by the Austrian Federal Railways.

STEADY-STATE VIBRATIONS OF RAIL ON AN ELASTIC DAMPED FOUNDATION SUBJECTED TO AN AXIAL FORCE AND A MOVING LOAD
The recent practice of continuously welded railroad rails suggests that considerable axial forces may be induced in the rails due to a change in temperature. This paper presents an analytical solution for the effect of an axial force on the steady-state vibrations of a rail continuously supported on an elastic damped (viscoelastic of the Kelvin type) foundation and subjected to a moving load. The presence of damping is shown to result in an unsymmetric dynamic deflection of the rail. Due to phase shift the largest deflection occurs slightly behind the point of application of the moving load, and the deflection ahead is always larger than the deflection behind the point

of maximum deflection. The results are relevant to present studies of the temperature buckling of continuously welded railway rails. If the rail is near to the point of buckling due to thermal strains, additional longitudinal strain in the rail due to a moving load may result in buckling of the rail ahead of the moving load.

A NON-DESTRUCTIVE METHOD OF MEASURING INTERNAL RAIL FORCE

Stability of continuously welded rail (cwr) can be monitored by determining the longitudinal force that exists at all times in the rail. British Rail Scientists have developed a rail-force transducer which permits rapid simple accurate measurements to be made of stress changes unaccompanied by changes of length. Using the results, the stress-free temperature of the rail is easily calculated. Transducers are cylindrical in shape and are installed by gluing in holes of the standard fishbolt size drilled in the rail's neutral axis. Readings from the transducers are taken at any time by using a portable measuring instrument.

A1 095414
ANALYSIS OF TRACK PARAMETER HETEROGENEITY AS A COMPLEMENT TO GEOMETRICAL METHODS OF TRACK CONDITION RATING

The condition of a track may be defined by track rating indices (W indices at the PKP) taken from recordings by a track inspection car, or obtained by geometrical measurements (longitudinal dip and cross-sectional irregularities, without load or with a moving load, lateral displacement, etc.). By track heterogeneity, the writer means the differences that such indices reveal on lengths of line with identical make-up, similar age, and used by the same traffic. These heterogeneities, which may be caused by the laying or maintenance of the track, or by constructional features with different characteristics, are also likely to result in great differences in the rapidity with which these lengths of line deteriorate, necessitating earlier continuous track renewal. The article proposes methods of assessing these heterogeneities by tests based on classic statistics laws. Numerical examples thus deal with: heterogeneities in the W index, by the X to the 2nd power test; heterogeneities in the track gauge by a method called the "ZM test" taken from an American book referred to in the bibliography; correlations between rail dip and lateral displacement under a moving load, by an analysis of sequential correlation. These complex analyses are not used as a basis of routine maintenance decisions, but in investigations for the purpose of explaining abnormal phenomena.

VERTICAL ACTION OF FORCES BETWEEN WHEEL AND RAIL WHEN CROSSING A RAIL JOINT

An example serves to determine the maximum dynamic vertical wheel force when a modern coach crosses a rail joint. The problem is described mathematically by a system of ordinary differential equations and is solved by means of an analog computer. The high dynamic vertical wheel forces obtained linearly increase with the travelling speed. As a result, the demand of more elastic wheels is made for railway vehicles travelling at high speed, besides that of a high quality of the permanent way. [German]

RAIL STUDY BESSEMER AND LAKE ERIE RAILROAD

Because of the ever increasing concern with shelling of rail and its possible connection with wheel loads and the present day trend to still heavier wheel loads, a study was conducted on the Bessemer and Lake Erie Railroad to analyze their rail conditions in conjunction with their use of 90-ton cars for transporting of ore. This railroad has been using these 90-ton capacity hopper cars since 1931, with practice being to load ore for southbound movement to capacity, thus creating loads averaging 32,300 lbs. per wheel. It has been noted over the years that even with these wheel loads and rather high annual tonnages, the Bessemer has had little or not shelling of their rail. This study was prompted to see if an answer could be derived as to why no shelling problem exists here. In particular, two locations on the railroad were checked where the present rail in track is 131 lb., laid in 1938, and has had over 400,000,000 gross tons of traffic, most of which consisted of are carried in these 90-ton hopper cars. The northmost location is at Springboro, Pennsylvania, where there is a length of one mile of the 131 lb. rail in track (north and south of Mile Post 116). The other location is through and to the south of Grove City, Pennsylvania, Mile Post 60-63, where there is a 3-mile section of 131 lb. rail in track. Both of these sections of 131 lb. rail now carry both northbound and southbound tonnage, but prior to single tracking and installation of C.T.C. in 1957, this trackage was the southbound main track in both instances and carried the predominant southbound ore traffic. At both locations of 131 lb. rail, rail profiles were taken, degree and superelevation of curves were noted, predominant speeds of tonnage trains in both directions were noted, condition of the entire track structure and, in particular, condition of the rail both on tangent and curves were noted. Photographs were taken to show the rail condition. Because of curvature in the locations not exceeding 3 degrees, other locations on the railroad were chosen to make like studies, these locations having the same or less annual tonnages, and having different weights of rail of shorter service life, but having greater degree of curvature. Rail profiles and photographs were taken at these locations also. Along with the study of the rail and track conditions, a study of the 90-ton B & LE hopper cars was conducted, obtaining all pertinent data, prints, and photographs having to do with their construction and maintenance. The Bessemer's rail replacement policy is guided by the formula--T = .703xWxD.565 where T = Life of rail in million gross tons. W = Weight of rail in lbs. per yard. D = Traffic density in million gross tons per year.

Conducted under sponsorship of AAR Joint Committee on Relation Between Track and Equipment.

METALLURIGICAL, PHYSICAL AND ROLLING LOAD TEST RESULTS OF RAIL ROLLED FROM CONTINUOUSLY CAST BLOOMS

The development of information relative to any new process applicable to producing rail more economically is of interest to the industry. The opportunity of investigating the application of continuous casting in rolling rail presented itself when the M.W. Kellog Company became interested in investigating this process on behalf of a Mexican client. The AAR Research Center cooperated in developing the metallurgical, physical and rolling load test results of rail rolled to the S49 section from continuously cast blooms. The results on the same type of of tests as described above tested in the 12 in stroke rolling load machine are shown on Table 4. The S49 rails and the oxyacetylene pressure butt welded rail joints did not fail. The flash butt welded rail joints failed prematurely due to grinding cracks away from the weld caused by heavy cold grinding as shown in Figs. 8 and 9. The drop test results of the rail as shown on Table 5 indicate that the rail met the AREA specification. Fig. 10 illustrates the effect of the drop test. As mentioned before, very few butt welded rail joints have withstood the standard drop test for rail. The structure of these fractures were noted to be fiberous. The results of the investigation of the S49 rail rolled from continuously cast blooms at the AAR Research Center and comparable results of the investigation by Dr. Janiche indicate that rail produced by this process is of equal quality to rail produced by the standard process. The results are surprising in this first attempt of producing rail in this manner. As the art of of continuous casting in reference to rail is advanced, all of the defects such as segregations will undoubtedly be eliminated. The economy of the process is predicated on the elimination of mold and teeming practices as well as soaking pits and primary mill installations. It is of interest to call attention to the last paragraph of the attached report which states that the UIC specification for rolling rail calling for a bloom cross section of at least 20 times larger than the rail cross section was not met in this case. In the above rolling, the ratio amounted to 15 to 1 in the case of the 30 d rail and 9 to 1 in the case of the S49 rail.

FIELD INVESTIGATION OF LONGITUDINAL FORCES IN A SANTA FE RAILWAY CONCRETE TRESTLE

This report contains a description and analysis of data obtained on a 660 ft long concrete trestle. The trestle contains 20 spans of 33 ft prestressed concrete box beams on reinforced concrete caps and columns. The height, base of rail to ground line, was uniform throughout at 26 ft. The purpose of this investigation was to determine the effect on the trestle of braking and traction as developed by a 278 ft long test train. Direct and bending stresses were obtained in the bents and axial stresses obtained in the rails at each abutment. Runs were made with both tight and loosened rail joints. In addition to the braking and traction runs, normal speed runs were made to determine stresses in the box beams and columns. On the basis of tests on this structure it may be concluded that: 1) The maximum longitudinal bent force measured was from braking and was 23 percent of the force computed on the basis of 15 percent of the test train bent reaction. 2) With tight rail joints the percentage range of total longitudinal braking force resisted by the bents was 41 to 56 percent, by the rails was 20 to 46 percent and by the backwalls apparently was 5 to 30 percent. 3) That portion of the longitudinal braking force transmitted to the bents was resisted by all bents of the bridge, acting as cantilevers, including those which carried no vertical live load. The distribution of longitudinal force was not uniform throughout the length of the bridge, but was highest for bents under the test train and gradually decreased with increase in distance from the test train. Loosening the rail joints at the ends of the bridge increased the longitudinal force resisted by the bents. 4) The maximum longitudinal force resulting from braking was 158 kips, which was 12 percent of the weight of the train. 5) The maximum longitudinal force resulting from traction of the locomotives was 76 kips, which was 15 percent of the weight on drivers. 6) Bending stresses were lower than those resulting from longitudinal forces. Also, bending stresses due to eccentricity were highest near the tops of the bents, while the stresses due to longitudinal forces were highest near the ground line. 7) For the test span, the arrangement of transverse tie rods, and the shear keys used was effective in producing a very nearly uniform distribution of the live load to each of the box beams comprising the span. 8) For the test span, the ratio of recorded to calculated strains due to bending, ranged from 0.83 to 0.94.

THE EFFECT OF UNIT TRAINS ON STRESS OCCURRENCES IN A CHICAGO AND NORTH WESTERN RAILWAY BRIDGE

This report contains a description and analysis of data obtained on the stringers and floor beams of a Chicago and North Western railway bridge to determine the frequency of occurrence of maximum stresses in these short span bridge elements which carry unit trains as well as regular service freight trains. The results may be summarized as follows: Track without rail Joint: 1. The frequency of occurrence of maximum stress was in the range of 3.0 to 4.0 ksi in the stringers and the floor beam under the combined loading of unit trains and regular service freights and was on the order of 2 to 9 percent of the total occurrence respectively. 2. The loaded unit trains comprised 5 percent of the total cars recorded and produced 46 percent of the maximum stress occurrences greater than 3 ksi in the floor beam and 7 percent in the stringers respectively. Track with Rail Joint: 1. The frequency of occurrence of maximum stress under combined loading of unit trains and regular service freights was on the order of 4 percent for the floor beam and 1 to 3 percent for the stringers of the total occurrence.

THE CONTINUOUSLY SUPPORTED RAIL SUBJECTED TO AN AXIAL FORCE AND A MOVING LOAD

The recent practice of welding railroad rails to each other suggests that considerable axial compression forces may be induced in the rails because of a rise in temperature. This in turn may reduce the critical velocity for the track to the range of operational velocities of modern high-speed trains. The purpose of the paper is to demonstrate that this is indeed a possibility.

THE FRACTURE TOUGHNESS OF CARBON-STEEL, ALLOY-STEEL AND HEAT-TREATED RAILWAY RAILS
The static and dynamic fracture toughness of standard carbon steel rail was determined using precracked Charpy bars. The static, fracture toughness was found to be higher than the dynamic fracture toughness across the entire range of railway operating conditions. Since rails are subjected to dynamic loading conditions, dynamic fracture toughness tests were conducted on specimens from alloy-steel and heat-treated rails in order to compare fracture properties. In addition, the standard British rail steel and two heat-treated grades of British rail steel were evaluated. It was found that carbon levels above 0.55 w/o did not affect fracture toughness while increasing silicon decreased fracture toughness in both high and low carbon rails. In line with earlier work, it was found that decreasing pearlite spacing increased fracture toughness. In addition, the effects of manganese, chromium and molybdenum are discussed.

THE EFFECTS OF MICROSTRUCTURAL VARIATIONS ON THE STRENGTH AND TOUGHNESS OF RAIL STEELS
An experimental program was carried out on fully-pearlitic rail steel to determine the effects of microstructural variations on tensile and impact properties. A heat treating schedule was developed to isolate the effects of prior austenitic grain size, pearlite interlamellar spacing, and to a minor extent, pearlite colony size. Grain size was varied by a factor of ten, and pearlite spacing by a factor of two. Room temperature yield strength increased monotonically with decreasing interlameller spacing, with the latter controlled by the transformation temerature and prior austenitic grain size. Charpy impact tests were performed to obtain an evaluation of toughness, and showed that toughness increased with decreasing grain size, and was largely independent of an influence of pearlite spacing. Dynamic fracture toughness values, (KID), obtained from instrumented impact testing of precracked Charpy bars, were compared with the standard Charpy results, and yielded Similar findings. Thus, it was found that strength and toughness are controlled by different microstructural parameters, and can be varied independent of each other to optimize service performance.

SUMMARY OF PERFORMANCE OF STANDARD-CARBON AND VARIOUS WEAR-RESISTANT RAILS IN TEST CURVES ON THE CHESSIE SYSTEM-SECOND REPORT
This report contains the summary of the second annual inspection of a service test installation of fully heat-treated, induction head-hardened, intermediate- manganese and standard control-cooled rail on the Chessie System. The field inspection is part of the cooperative effort on rail research of the American Railway Engineering Association, the American Iron and Steel Institute and the Association of American Railroads to observe and analyze those rails in curved track that display some potential for improvement in wear-resistance and retarding the onset of shelling. Measurements were made and recorded of curvature, superelevation and gage of four service test curves located near Oakland, Maryland. General track conditions were observed also. Rail head cross-section contours were taken and recorded of the 80 test rails contained in these curves. Rail wear has been calculated for the second year of service for the various types of rail in test.

RAIL FAILURE SYSTEM
File name is ENRF. Computer program. The "Rail Failure" application is designed to compile statistics of all types of rail failures. The system employes two highly regimented input forms entitled "Rail Removal Order" and "Rail Insertion Report" which also serve to cause the appropriate physical action to take place. The system is modular and as such contains over twenty (20) separate programs re: data validity edits, maintenance and print routines which can provide monthly, year-to-date and yearly statistics, e.g.: (a) "Audigage and Reflectoscope; Detector Car; and Service Rail Failure Statement": a three part statement, i.e., a separate report for each potential input source, giving a complete description by Division and District of type of track, location of rail, position, grade, weight, mill, etc. of all failures reported. (b) "Rail Insertion Report Statement Covering Service and Detected Rail Removal Orders"; this statement lists all rail that has had a defect and that has been replaced by a new rail, angle bar repaired or taken out of service. (c) "Annual Report of Rail Failures, Service and Detected, in Rail of All Ages and Sections". (d) "Rail Removal Orders not Covered by Insertion Reports on the Eastern, Western and Coast Lines". Report will flag any removal order over 30 days old for which as insertion report has not been issued. (e) The "Transverse Fissure Rail Heat Statement": This statement provides listing of all transverse fissure heat failures over the system. The statement is written out in mill order and year rolled plus pertinent detail data. (f) The "Thermite and Butt Welded Joint Failure Statement"; This statement lists all thermite and butt welded rail failures by division, district, mile post, type track, weight or rail, mill and year rolled. Each report is year to date.

ALLOWABLE GROSS LOADS ON VARIOUS RAIL SECTIONS
File name is RAILSTR. Computer Program. Application: Used as a one-time guide for determining the maximum allowable loading on various rail sections. Contains many assumptions and some "retrofit" based on actual loadings previously known to have been carried. This program computes the maximum allowable total gross weight for any type rail equipment with identical axle loads on 15 different rail sections. The theory and formulas are based on the rail acting as a continuous beam on a continuous elastic base (AREA proceedings of 1918, Vol. 19, pages 875-1058). Two moduli of elasticity of rail support are assumed for each rail section, one for "good roadbed and one for "poor" roadbed. Input consists of all information required about the axle configuration of the equipment being considered. Output includes documentation of the input, a listing of each rail weight and the assumed impact for each, and the allowable gross weight for good and poor roadbed for each rail section. This program makes many assumptions having to do with roadbed, impact, and unit stresses which may or may not be justified.

RAIL AND TRACK CHARACTERISTICS PICKER PROGRAM
File name is Track Characteristics Master, Rail Defect Master, Derailment Master. Computer Program. The purpose of the rail and track characteristics picker program is to provide the information with which to develop the relationships between various rail and track characteristics and their correlation with rail failures, rail defects, and derailment frequency. The Track Characteristics Master contains rail type (jointed versus welded, kind of steel) weight, rail rolled and laid dates, history of surfacing dates, rail and track inspection and test data, grades, curves, load limits, and traffic density (tons per year) for all system track. Locations of rail failures, rail defects, and exceptions to track geometry standards found by testing and inspection are contained in the rail defect master. The derailment master contains pertinent data on all derailments. The rail and track characteristics picker program selects and prints out track locations from the track characteristics master with user-defined selection criteria; these can be minimums and/or maximum for any combination of the characteristics listed above. Up to 50 different combinations, i.e., cells in a matrix can be requested at one time. For each cell or specific request, the number of miles of track and the number of ton-miles is printed out. In addition for each cell, the progrm gives the types and numbers of rail defects and derailments reported over a time period selected by the user. Once relationships have been established, the program can be used for developing rail laying and timbering and surfacing programs, anchor and double spiking programs, problem area identification, budgeting, and other applications.

RAIL CONSIST AND HISTORY
File name is EN980930. Computer reporting program of all pertinent information on main line and branch track of Union Pacific Railroad. This track information can be reported to one one-hundredth of a mile accuracy for main line and branch track. The output shows milepost from, milepost to, track miles involved, degrees of curve, weight of rail, what company rolled the steel and type of treatment of the steel, the length of the rail in either 39 feet, 78 feet, or CWR, the year laid, work order number, if the steel was transposed, cropped, welded, or ground the size of the plates and year installed, million gross tons, of traffic over given segments of rail, passenger and freight speed allowable, and failures reported for the last two years broken done into three classes fo failure, then combined to show defects per mile per month. This Consist and History program evolves from four other basic programs plus a failed rail master. The four programs used to generate Consist and History are a tonnage master (EN9601), the description table (EN9602), an initial track master file (EN9603), and a revolving track master file (EN9805). EN9601 is a program which generates a tonnage table and a tonnage code. The railroad is broken down into segments depending on the million gross ton miles per year run over those segments. This program is fed into the initial track master file, EN9805, for a basis to calculate the million gross ton miles in the Consist and History report. The tonnage table for a given section of track has been calculated from our Way Bills to insure accuracy. EN9602 is a program which generates heading information for given sections of track (e.g. direction, and milepost limits). Also, it generates a cost center description so that the final report can be produced either by cost center or divisions. This program also genrates an order number, which we have assigned to help us segregate different parts of track. EN9601 and EN9602 are combined into EN9603 which begins to set up the initial master file. EN9603 at this time inputs all of the curve information of the railroad. EN9805 then adds the actual track relay information into the program.

RAILWAY TRACK RESEARCH--THEORETICAL AND EXPERIMENTAL
Presents theoretical approach for determining stresses that result from vertical and lateral bending of track and stresses that act in the vicinity of the contact area between wheel and rail. The influence of thermal and residual stresses on track behavior is discussed and the dynamic deflections and stress resulting from the action of moving wheels and track irregularities are considered. The occurrence of track failure is analyzed on the basis of failure criteria and fatigue theories.

SOME PROBLEMS OF RAILWAY OPERATION AT HIGH AXLELOADS
Long high-axle-load trains create cracking, shelling, crushing and corrugation of the rail head while weight transfer further accentuates the situation. "Worn" tire profiles can reduce contact pressure by 30 percent, but excess cant will increase crushing on the inner rail and axle-loading must be considered in relation to rail steel quality in the track. Three-axle locomotive power trucks set up higher lateral forces than two-axle types. Locomotive and car suspension characteristics must be considered in three planes.

STRESS OF THE SUBGRADE BY DIFFERENT TYPES OF SLEEPERS
The stress of the subgrade by prestressed-concrete sleepers BS 65 and BS 66 mainly used by the German Railways is different. Early measurements obtained with tests of the prestressed-concrete sleeper BS 72 showed that subgrade stresses are lower than for BS 62, BS 65 and for the timber sleeper, and are of the order of the values calculated. However, for a statistically safe statement the number of measurements is still insufficient. Therefore trials will be made in tests sections to obtain early results. [German]

TRACK TESTING FOR VALIDATION OF COMPUTER MODELS
The purpose of the track stiffness test was to obtain data to assist in validation of the L/V and Lateral Train Stability models as an extension of earlier dynamic tests conducted at the Transportation Test Center. The first series of tests conducted was to obtain instrumented data on Vertical Track Modulus (VTM). The second series of tests were designed to collect data on rail to rail stiffness using various rail loads combined with and without static vertical loads. The third series of tests were conducted to measure lateral track stiffness with and without rail loads on a tangent segment of the track, on both left and right hand curves.

WIDE GAGE INVESTIGATION. VOLUME 1
One of the immediate problems in track maintenance and improvement is Gage Widening. Track lateral stability has been of great concern in recent years, both from the thermal load aspects involved in the use of continuous welded rail, and the train dynamics aspects of heavier equipment and rail, and the train dynamics aspects of heavier equipment and longer trains. Two particular problems attributed to track-train dynamics interactions are wide gage and rail rollover. For this investigation of wide gage in tangent track, an experiment was conducted on a stretch of track on the Union Pacific Railroad near Pocatello, Idaho. Eight sections of track with different combinations of tie plates and fasteners were installed by the Union Pacific at a site noted for recent wide gage problems. The purpose of the experiment was two-fold: first, as a track train dynamics study, to identify specific factors contributing to development of wide gage; second, as a fatigue test,

to evaluate the ability of various test sections to maintain gage under heavy, high speed traffic conditions. Measurements of gage and observations of track conditions at the test site were periodically collected by Union Pacific personnel, so that long term trends could be established. In addition, field experiments measured the dynamic response of the track to traffic during both summer and winter ambient conditions. Volume 1 presents a description of the wide gage experiments and results from the summer field experiment, during which 315 trains were recorded over a 3-week period about 1.5 million gross tons of traffic.

AN INVESTIGATION OF FACTORS CONTRIBUTING TO WIDE GAGE ON TANGENT RAILROAD TRACK
Wide gage--a fatigue failure of the track to maintain the nominal lateral distance between rail heads--is one of several modes of track failure on which the AAR-FRA-RPI-TDA Track Train Dynamics Program has focused attention. To investigate the generation of wide gage on tangent track, experiments were conducted to measure track dynamic response and long-term fatigue life of track sections on the Union Pacific Railroad in Idaho. Results of these experiments have defined the important factors in this mode of track fatigue.

This paper was contributed by the Rail Transportation Division of the ASME for presentation at the Winter Annual Meeting, Houston, Texas, November 30-December 5, 1975.

AXIALLY STRESSED RAILROAD TRACK ON AN ELASTIC CONTINUUM SUBJECTED TO A MOVING LOAD
The recent introduction of the welded railroad track raises the possibility that high axial compressive forces may occur in the rails due to constrained thermal expansions. This in turn may reduce the critical velocity of the track to within the operational velocities of present day trains. Recently the effect of axial forces upon the critical velocities of the track was analyzed by A.D. Kerr using the Winkler model for the base response. In this study, the effect of the axial compressive force on the critical velocity of the track is studied assuming for the base an elastic half space with inertia.

LIMITED ANALYSIS OF THE SAFETY IMPLICATIONS OF THE PRELIMINARY SYSTEM PLAN FOR RAILROAD CONSOLIDATION
This Study looks at the safety impact of the system changes resulting from the reorganization of the railroads of the Northeast and Midwest due to the reduction of ton-miles of freight transported by rail, the increase by truck, the elimination of rail-highway crossings, and the upgrading and improved maintenance of the system. The subjects considered are the rail system itself, interaction with its surroundings, and interaction with other types of transportation. Only the change in transport mode of freight originating or terminating on the lines scheduled for abandonment is considered. Tables comparing safety performance for different transport modes are included.

ARE FRA RAIL STANDARDS RESTRICTING RAIL-FLAW DETECTION
Since the FRA Track Safety Standards were implemented the number of defective rails has decreased, but the number of accidents due to rail failures has increased. The article tries to explain this discrepancy. A 10% increase in the availability of test equipment has resulted in only 6% increase in test mileage. In fact, Railway Companies lack the means of applying regulations concerning defective rails and this could lead them, in some cases, to put off inspection. Moreover, there is no flexibility in existing standards in so far as the priority removal of potentially hazardous defects known to be in the rail is concerned. The article discusses the need to tighten regulations or make them more flexible.

A1 129403
COUPLED VEHICLE/TRACK DYNAMICS
Dynamic coupling occurs between a railway vehicle and the track due to the reaction forces acting between the wheels and the track, and the elasticity of the track and the foundation. It has become apparent that track elasticity can influence the dynamic behaviour of the railway vehicle, yet in most of the research work in the area of railway vehicle dynamics reported so far, the track is regarded simply as a rigid structure, providing the reactions to the loads of passing vehicles. In this paper the models used for the analyses of the vehicle dynamics (on rigid track) and for the coupled vehicle/track dynamics are described. The equations of motion are derived, and the results obtained for the coupled vehicle/track model are presented and compared with those obtained for the case of an infinitely rigid track. Particular empahsis is on the lateral stability and the response to vertical track irregularities.

ELASTICITY OF RAIL STRETCHES IN RELATION TO THE PARAMETERS OF THE FASTENINGS [Uprugost' rel'sovyh nitcj v zavisimosti ot parametrov promezutocnyh skreplenij]
The article examines the theoretical correlation between, on the one hand, the rigidity parameters of rail fastenings during the intermittent actions of loads on the bearings and, on the other, the elasticity of the track during wheel stresses on the rail segment. Results are given concerning the experimental research into these problems. On the basis of tests with the fastening devices both in laboratory and under operating conditions, the theoretical research explained in the article provides an overall insight of wheel action, which is vital when defining the optimum parameters of fastenings. TROUBLED TRACK
This article puts the industry in perspective, noting deferred maintenance is not confined to the publicized difficulties of the Northeast railroads. Over the past two decades railroads have worked themselves into an overwhelming imbalance with equipment money being available and investments having been primarily above the rail. Money-starved track has then been punished by higher speeds and heavier axle loading. Government could decide it is time to equalize the "public cost" for transportation right-of-way betterment. Technology is of little use unless the railroad right-of-way is fit to serve contemporary needs and railroad personnel learn to use technology to best advantage.

EFFECT OF RESIDUAL STRESSES IN HARDENED RAILS ON THE FORMATION AND PROPAGATION OF STRESS FISSURES DUE TO CYCLIC STRAINS [Vlijanie ostatocnyh naprjazenij V Zakalennyh rel'sah Vozniknovenie i rasprostranenie ustalostnyh trescin pri Cikliceskom izgibe]
The authors have reached the following conclusions: The railhead, as a result of heat treatment or cold straightening, can develop a considerable drop in the stress limit, a drop in the number of cycles completed before stress fissures occur, a drop in the number of cycles completed during the stress fissure propagation period, a reduction in the critical size of each stress fissure, or a drop in the curability of hardened rail, 2) the residual compression stresses which occur in the rail head accentuate the above characteristics. [Russian]

RESIDUAL STRESSES IN SERIES P65 HARDENED RAILS [Ostotocnye naprjazenija v Zakalennyh relsah P65]
This article gives the results of a study on residual stresses in core hardened rail produced by the Nijni Taghil (Central Urals) steel combine. The authors discuss new rail, as well as rail over which trains of various tonnages have been hauled. A comparison of diagrams showing residual stresses in new rail and those in rail over which 152 and 235 million gross tonnes have been hauled show that, for the most part, there is no difference between the location of these stresses in the web and the rail flange of new rails, and those in rails which show wear. However, the study showed that the type and extent of residual stress on the contact area of the rail head is modified when trains run on these rails. Traction stresses of 8.1 kgf/mm2 were recorded on the rail head of new rails, whilst stresses of 4.5 and 3.1 kgf/mm2 were recorded on rail heads over which 152 and 235 million gross tonnes had been hauled. RESIDUAL STRESSES IN RAILS [Ostatocyne naprjazenija v zeleznodoroznyh relsah]
The article examines the effect of residual stresses on rail breaks along the length of the web and on stability during rupture tests on core hardened rail: the aim of decreasing residual stresses in core hardened rails and the formation of residual stresses in the rail head can be achieved by making further improvements to the cold hardening process; residual stresses do not have any substantial effect on stability during rupture tests on rails when the break begins because of a drop hammer failure and, before the break occurs, the rail changes considerably; this is precisely what happens in tests on core hardened rails when the temperature changes from-60 degrees to 20 degrees C. [Russian]

USE OF THE MAGNETIC ANISTROPIC METHOD TO ASSESS THE STRESSES OF TEMPERED RAILS [O vozmoznosti ispolzovanija metoda magnitnoj anizotropii dlja ocenki ostatocnogo naprjazennogo sostojanija zakalennyh relsov]
The most practical method of determining residual stresses without damaging the rail is by magnetic anisotropy which makes it possible to obtain information rapidly and without difficulty. A special device called "Pion" was built in the Soviet Union for application of this method. It is made up of a magnetic core in the form of a cross with a coil which generates a magnetic field in the centre and measurement coils (2 to 5) on the sides making up the arm of the bridge. The article gives the results of tests on certain types of rail in the Soviet Union using this device. [Russian]

INFLUENCE OF THE CONCRETE CONDITIONS OF CONTACT BETWEEN WHEEL AND RAIL ON THE RUNNING OF VEHICLES OVER RAILWAY LINES [Einfluss konkreter Rad-Schiene Beruhrungsverhaltnisse auf das Laufverhalten von Schienenfahrzeugen]
The authors speak of the effects of a number of different wheel, and rail profiles on the stability of rolling stock, and also of the influence on such stability of the wheel/rail friction coefficient. From the studies carried out, it transpires that a wheel profile close to the shapes created by natural wear between wheel and rail is more advantageous than conical profiles as regards maintenance and running stability. THE DEVELOPMENT OF ANALYTICAL MODELS FOR RAILROAD TRACK DYNAMICS
A renewed interest during the past decade in high-speed rail transportation has underlined a need for better understanding of the dynamic interaction between vehicle and track. Speeds in excess of 160 km/h tax the presently used rail-tie-ballast track structure in terms of long-term stability and required track accuracy. Hence, the investigation of improved structures with better dynamic response characteristics and greater stability has followed in the wake of improved high-speed railcar design. This paper presented some recent developments in analytical modeling of railroad track structures for the study of vehicle-track dynamic interaction by computer simulation. Field measurements taken on main-line track of several North American railroads were used to evaluate the accuracy and define the necessary modifications of the computer model. Predictions of better overall system response and long-term stability from this computer model have aided in the preliminary design of several new track structures which are currently undergoing field evaluation.

STRESSES AND BEHAVIOR OF RAIL TRACKS DURING THE PASSAGE OF TRAINS TRAVELLING AT VERY HIGH SPEEDS; STANDARDS ADOPTED BY THE SNCF FOR ITS FUTURE VERY HIGH SPEEDS LINES (250/300 KM/H)
On the Paris-Madrid line in Southwest France, between Bordeaux and Dax, there is a section on which there are two straight stretches of 20 to 45 km, separated by a curve with a radius of 2850 meters. This SNCF line allows tests to be carried out at speeds of over 250 km/h. Since August 1972, two prototype trains, the TGV 001 turbotrain, and the Z 7001 electric motor train, have been traveling four times a day at speeds between 250 and 320 km/h. This paper summarized the knowledge acquired in France as the result of systematic tests carried out at those speeds in anticipation of the new Paris-Sud-Est line on which trains will travel at speeds of over 250 km/h. Although the problems are not yet completely solved, they are at least now defined very clearly, and none of them is of a fundamental type. The doubts raised a few years ago now appear to be baseless, at least for speeds of up to 300 km/h.

WEAR ON EXTERNAL SURFACES OF WHEELS AND RAIL DUE TO FRICTION [Verschleissvorgang im Grenzschichtbereich der Reibpaarung Rad/Schiene]
The stresses borne by rail and wheel elements are analysed on the basis of several fundamental definitions of wear by Fleischer. A number of studies were carried out on plastic deformation, running surfaces and wear characteristics. Partial oxidation can occur when the external surfaces of wheels or rails are deformed because the materials come into contact with the surrounding atmosphere. Oxidised metallic particles are then worn away. Wear is often affected by the characteristics of the process itself or by layers of martensite which are produced by shoe brakes. [German]

THE EFFECT OF LATERAL RESISTANCE ON TRACK BUCKLING ANALYSIS
A model which exhibits the essential features of track buckling mechanisms is used. It is represented by four bars constrained at the interconnecting joints by spiral springs. The bars deform axially according to Hooke's law and the law of linear thermal expansion, but are "rigid" in bending. The author analyses the mathematical model according to three different assumptions. He compares the results obtained and draws conclusions as to the critical temperature at which buckling can occur and the assumption which is most representative of track buckling.

TEST TRAIN PROGRAM, SEVENTH PROGRESS REPORT
This report describes the progress of the Rail Engineering and Test Support Program during the period July 1, 1974 to June 30, 1975. Primary emphasis of the program was placed on the establishment of a viable operational track measurement capability. This emphasis resulted from efforts to meet the requirements of the National Track Inspection Program under implementation by the FRA's Office of Safety. Also covered in this report are special tests performed by the FRA test cars; operational improvements to the test car track measurement instrumentation; improvements in data-processing techniques that permit an analysis of track conditions in a more timely and more efficient manner; and highlights of other efforts performed under the Rail Engineering and Test Support Program.

WIDE-GAUGE RESEARCH LEADS TO A NEW STANDARD ON UP
Following research on the causes of wide gauge, Union Pacific has adopted as standard a 16-inch tie plate with a 1:30 cant. Gauge widening is a problem common on high-speed,heavy-duty mainline track and this phenomenon was investigated on UP as part of the industry's Track Train Dynamics Research Program. Tie-plate cant varied from standard 1:40 down to 1:14. The 1:30 design finally chosen is to reduce the incidence of rail rollover and to reduce overloading on the gauge side so that the wear pattern was down the center of the rail.

OBSERVATIONS ON THE EFFECT OF HEAVY WHEEL LOADS ON RAIL LIFE
The Bessemer and Lake Erie Railroad has operated 90-59 open-top cars since 1931 and has some statistics on rail wear and rail life under the stresses imposed by such equipment. Rail life on tangent track has been around 440 million gross tons for jointed rail and beyond 650 million gross tons for continuous welded rail. Statistics are also available for Curvemaster and controlled cooled rail on curves. On newer ore carrying railways, rail life appears to be appreciably shorter. Among possible reasons are the bidirectional operation of loaded trains on B&LE, the mixing of various capacities of cars, and the predominance of traffic on solid, rather than roller-type, journal bearings.

EFFECT OF HEAVY AXLE LOADS ON RAIL AND TIES
The Quebec North Shore and Labrador Railway was built in 1953 to handle iron ore from mines 350 miles north of the St. Lawrence River. Trains of up to 280 cars with five locomotive units are operated. This presentation reports the maintenance experience on track which carries up to 50 million net tons annually, and has handled almost 700 million gross tons since opening. Among the findings: line, surface and gauge must be maintained even on tangent track; corrugated rail develops quickly on grades and curves and must be countered promptly; joint bars must be kept tight and rail ends restored; oilers are all-important on curves.

A1 132974
EFFECT OF HEAVY AXLE LOADS ON BRIDGES
It is estimated there are 3500 miles of bridges on American railroads; replacement cost is estimated at $10 billion. The problem is not the spectacular, long-span steel bridges, but the many structures built many years ago for much lighter loading. As reconstruction is deferred, more speed and weight restrictions will have to be imposed; modern equipment may have to be prohibited from many lines. With scarce capital it will be many years before the frail steel spans of 1880-1900 are replaced. The Cooper E-60 rating permitted by the AAR Mechanical Division does not produce cars capable of unrestricted operation over the rail network. Timber trestles are particularly vulnerable to closely spaced axles.

WHEEL-RAIL ADHESION
The subject of adhesion between locomotive wheels and rails has been an area of vital interest to locomotive manufactures and to the railroads. Horsepower of internally powered locomotives has continued to increase significantly, thereby providing more power for traction. The trend of increasing horsepower has been the product of progress in technology and engineering development. Wheel-to-rail adhesion within the lower speed range has been a limiting factor in tonnage ratings for locomotives in drag service on U.S. railroads. Factors Affecting Adhesion are: (1) Vehicle Factors, (2) Track Factors, and (3) Contact-Area Common Factors. Additional discussion of the conclusions follows.

FRICTION CREEP PHENOMENON OF ADHESION BETWEEN STEEL WHEELS AND RAILS
The purpose of this article is to present a summary of the laboratory and field tests which have been conducted by EMD to evaluate the friction and creep phenomenon of adhesion between steel wheels and rails. The available adhesion coefficient between the driven wheels and rail is a primary factor in determining the amount of power that can be converted to tractive force by the locomotive. For this reason, experimental investigations into rolling contact friction-creep phenomenon were conducted on model equipment in 1968 along with full scale field tests on an SD-45 model locomotive.

RAILWAY TRACK VIBRATION INDUCED BY TRAIN MOVEMENT
The railway track under train movement suffers progressive deterioration, which is equivalent to multiplication of repeated train load and vibration induced. The paper presents the results of measurements on the aggravated track vibration and the comparative study of track vibration on the concrete ties and on the traditional ties. Ballast acceleration in two sections laid with concrete ties using tie-pads of 110 t/cm spring constant averaged 23 percent and 35 percent respectively, less than that of the section laid with common ties. The value in a section laid with concrete ties using tie-pads of 250 t/cm spring constant averaged 24 percent larger. There is a conspicuous difference in occurrence distribution of acceleration at the welded joint.

RAIL WEAR LIMITS
The Southern Railway, after reviewing rail wear conditions which were thought to have been a principal contributing factor to derailments, found that approximately 40 percent of loss of rail head wear for 130-132 lb. rail was the amount beyond which such derailments had occurred. Limits to show the top wear limit and side wear limit to be allowed for the different rail sections for various classes of track. The corresponding limits for the smaller sections of rail were pretty much a matter of judgment, using the limits for the 130-132 lb. sections as a guide.

EXPERIMENTS ON LOCAL STRESSES OF RAILS IN PRINCIPAL USE IN SEVERAL COUNTRIES
There is room for improvement in the current JNR standards for rail section with respect to their effectiveness as beam members and also to their pattern of distributed local stress. The project of the new Tokaido trunk line construction now being pushed forward has prompted JNR to the renewed design of its rail section from various angles since 1958. Laboratory and field tests were conducted for contributing to a better design to the two tentatively designed rail sections of 67 kg/m for the new trunk line and to the current 50 kg/m one, as well as to the five sections of imported rails.

GAS-SHIELDED ARC WELDING OF HIGH-MANGANESE STEEL RAILS
In the present study the aim was to realize automation of the welding of manganese crossings which has been conventionally executed by manual arc welding process, thereby sharply raising the welding efficiency and obtaining sound welds with good mechanical properties and free from welding defects. As a basic step to automatic welding of manganese crossings, the case of automatic welding of cast high-manganese steel rails is treated here.

DISPLACEMENT OF ADJACENT ROADWAY AND GROUND SURFACE DURING CONSTRUCTION PERIOD OF OPEN CAISSON
As the open caisson pier foundation was to be constructed very close to the existing roadway of embankment of weak strata in recent double tracking work on Chuoh line, observation of displacement was carried out to judge the degree of danger for running a train during construction period. According to the results of observation it was confirmed that the protection method by sheet piling was very effective and in this case the displacements or strains were too small to disturb the track or to interrupt the traffic.

ARC WELDING OF AUSTENITIC MANGANESE STEEL RAIL TO CARBON STEEL RAIL--IN CASE OF WELDING WITH COVERED ELECTRODE
This study is to establish the procedure to weld manganese crossing and carbon steel rail together which has been thought to be very difficult due to the difference of their metallurgical properties and others. The authors paid special attention to the procedure to join them by manual arc welding after buttering the groove face of carbon steel rail. Various fundamental experiments were performed to select electrodes for buttering and joining, and welding conditions. Based on the results obtained, austenitic manganese steel rail and carbon steel rail were welded together, and the welded rails were subjected to bending test, drop-weight test and so forth. The results show that considerably reliable welds are obtained in case the authors' proposal is adopted.

FATIGUE STRENGTH TESTS ON RAILS
Fatigue strength data on rails have seldom been published. Japanese National Railways, in connection with the adoption of long rails (0.5, 1.0, 1.5 or 2.0 km) and speed-up of train operation, is vigorously pushing fatigue strength investigations as well as qualitative study of rails. Soundness of the welded rail is hard to evaluate through a mere external inspection; therefore, nondestructive testing methods such as ultrasonic, magnetic detection and mechanical methods such as static bending, repeated drop weight should be coupled with it. Present demand is to secure a sound welded rail in the field through fatigue strength comparison between the base metal of rail and the welded joint.

QUALITY OF RAILS AND MEANS OF GUARANTEEING IT; EXAMINATION OF THOMAS STEEL RAILS OF THE THIRD SERIES OF TESTS BY MEANS OF THE RALUS ULTRASONIC PROCEDURE; DOCUMENTARY REPORTS OF IRSID AND BAM

The investigation of the quality of steel rails and the means of guaranteeing it has been entrusted to the D 45 Specialists Committee at the request of the 7th UIC Commission. Two series of tests have already been made within the scope of this work. A third series of tests was then carried out on rails having shown a 'good' performance in the track and on those having shown a 'bad' performance, these performances being defined beforehand according to some accurate criteria. The definition tests and the special tests on the Thomas steel rails of this series have been dealt with in Interim Report No. 9. As many as possible of the Thomas steel rail samples of the third series of test have been examined by means of the RALUS ultrasonic equipment, developed by IRSID and designed for the automatic industrial ultrasonic inspection of the rail head. The results of this examination have been dealt with in this report (RP 10), which also contains a documentary report by IRSID on the RALUS method and one by BAM on the investigation of rails for non-metallic inclusions.

Restrictions on the use of this document are contained in the explanatory material.

NEW SHAPE OF TRANSITION CURVE IN HIGH-SPEED RAILWAY TRACK AND ITS ALIGNING

The quantity called "Track Irregularities" is usually used as basic data and technical inferences are made from it. From the view-point of safety and comfort of traveling, we are requested to decrease the track irregularity especially with regard to high speed railway track. Must first of all grasp the essential meaning of "Track Irregularity" and consequently the next two quantities clearly: (i) difference between geometrically practicable shape and the actual shape of railway track. (ii) difference between physically rational shape and geometrically practicable shape of railway track. These two items are almost self-evident for the straight railway track, but for the curved railway track, especially transition curve, there are many problems yet to be solved.

TRACK-TRAIN DYNAMICS STUDY PROJECT TR-14 RAIL-VEHICLE INTERACTION STUDY REPORT NO. 1 (PRELIMINARY ANALYSIS OF SAMPLE DATA)
As a result of various derailments, a task force was formed to investigate the dynamic forces exerted by locomotive and freight car wheels against the rail. Critical study was directed at the 3 and 2 axle trucks of high horsepower locomotives, 85 feet TFC cars, and 50 feet box cars. The objective of this investigation was to determine if dynamic forces of sufficient magnitude to cause derailment were being generated by equipment, track structure and operating practice, and to recommend whatever corrective action might be indicated. Extensive field tests of wheel-rail interaction were conducted in various territories between Los Angeles and Pine Bluff, Arkansas. An analysis of these test results led to the following general conclusions: 1. Dynamic forces of sufficient magnitude to cause derailments are being generated in every day operation of revenue trains. 2. The forces are also sufficient to cause greatly accelerated wheel and rail wear. 3. Forces of sufficient magnitude to exceed the ability of the track structure to resist permanent deformation in alignment are also being generated.

FIFTH PROGRESS REPORT OF THE ROLLING-LOAD TESTS OF JOINT BARS
This is a report on the tests of joint bar failures and it gives consideration to the revision of design and specifications Observations of tests are: Joint bars for 131-lb RE rail subjected to a wheel load increased in proportion to the increased section modulus of the bars, thus giving equivalent bending stress, render approximately the same joint bar life as the 112-lb bars. The cyclic life of the 131-K14 36-in. bars tested was somewhat longer than that of 24-in. bars of the same type. Top surface bearing at the rail end is wider on TR bars with the 11/16-in. fillet radius than on 112-lb headfree bars with 3/8-in. fillet radius. The average cyclic life of TR bars greater than that found with 112-B34 bars. Rolling-load tests on one lot of 112-B34 bars show an increase of cyclic life resulting from shot-peening. Variations in hardness from bar to bar of the same heat may result from variations in quenching temperature. Surface decarburization usually found on joint bars is readily detected in the Rockwell Test.

RECOMMENDATIONS ON NUMBER AND PLACING OF ANTI-CREEPERS FOR VARIOUS CONDITIONS
The rail creepage measurements were made from reference stakes set at 1/8-mile intervals. Considering the performance of the anchorage methods in respect to holding the rail against creepage and maintenance of line and gage during the test period. Test sections have shown equally good results. Some local condition in section G-2 probably caused the larger westward

movement of the south rail. Methods H and I of the arrangements initially installed, have shown superior performance throughout the 33-month test, and with only 8 and 10 anchors, respectively. The problem of anchoring rail in track carrying traffic in both directions is considerably different from that on tracks with traffic in only one direction. In a majority of the miles in this test the south and north rails have moved in opposite directions. It therefore seems logical to anchor the rail to resist creepage in both directions. Further, for the best conditions of maintenance, staggered anchoring seems undesirable because of the excessive tie skewing and the adverse affect on the line and gage of the track. Also, for greater efficiency in resisting the rail movement immediately, the rail anchors should be boxed. However, an adequate number of anchors should be used to arrest creepage in both directions and to avoid having the anchor ties churn and lose their trmping. To obtain maximum rail restraint with the minimum number of anchors they should be spaced evenly throughout each half panel, as in most of the methods where consecutive ties were anchored the resistance of one crub of ballast proved to be insufficient to hold the anchored tie in place.

A2 033306
THE EFFECT OF THE RATIO OF WHEEL DIAMETER TO WHEEL LOAD ON EXTENT OF RAIL DAMAGE
This is a report of progress on studies of pressure as affected by the area of contact between wheel and rail. One phase of this investigation involves the conduct of rolling load tests of rails subjected to wheels of various diameters and loads. To summarize, a depth hardness survey on a 112-lb rail removed from service after approximately 12,000,000 tons of traffic shows the maximum hardness to be at a depth of approximately 0.04 in. at a distance of 1-3/6 in. from the center of the head toward the gage side, the maximum hardness being Rockwell C 34.6. Tests on a full section 131-lb rail under a 75,000-lb load after 1,333,000 cycles (100,000,000 tons) of testing are as follows: For the 33 in. wheel--a hardness of Rc 15 on the tread and a maximum of Rc 32 at a depth of 0.15 in.; for the 50 in. wheel--a hardness on the tread of Rc 23 and a maximum hardness of Rc 27.4 at a depth of 0.10 in. Using "mutilated" head specimens and a 50-in. wheel it was found that a 58,000-lb load could be carried for 100,000,000 tons, but that a 63,000-lb load would break down the rail tread after 15-45 million tons.

INVESTIGATION OF THE IMPACT EFFECT OF FLAT WHEELS PRELIMINARY REPORT
The test reported the effect of wheel flat upon rail, tie plates, ties. Test situation included a test track over which a loaded coal car with a 4 inch long flat spot, was run. Stress was measured by special M.I.T. testing gear and a high speed camera. The tests were run at speeds of 5 to 40 mph to determine effect of speed upon stresses created by out-of-round wheels.

STUDIES OF THE PRESSURE AS AFFECTED BY THE AREA OF CONTACT BETWEEN WHEEL AND RAIL. EFFECT OF WHEEL SIZE
The following is a progress report on one phase of this investigation, namely, rolling-load tests in which wheels of various diameters are rolled to and fro on a short length of rail for the purpose of determining the number of cycles of load application required to produce failure. The results of the rolling-load tests to fracture show considerable "scatter" and no very marked difference between the results of tests under a 50-in. wheel and those from tests under a 33-inch wheel. The vertical wear on rail 757C (33-in. wheel) was 0.046 in. at failure, whereas the wear on rail 757C1 (50-in. wheel) at 580,900 cycles was 0.041 in. At failure, 750,100 cycles, the wear on rail 757C1 was 0.0425 in. A second type of test being tried to ascertain the effect of wheel size on the rail is to measure the depth of work hardening in the rail head. The rail head appeared to have been work hardened down to a depth of about 0.45 in. by the 33-in. wheel with a maximum hardness of 296 at a depth of 0.15 in. A test on a section from the same rail rolled with the 50-in. wheel appears to have been work hardened down to a depth of 0.20 in. with a maximum hardness of 269 at a depth of 0.10 in.

SPECIAL COMMITTEE ON STRESSES IN RAILROAD TRACK. SEVENTH PROGRESS REPORT
Since 1914 this committee has conducted analytical and experimental investigations on the action of railroad track under the loads of locomotives and cars running at various speeds and for a variety of conditions. The tests herein reported were made to obtain information on the action of various types of rail joints in track when subjected to the loads of locomotives and cars at speeds up to 90 miles per hour. Testing equipment enabled tests to be made accurately and expeditiously in a way that had not been accomplished before. Tests were undertaken particularly to obtain information on the action of different forms of rail joints in track under the traffic of locomotives and cars running at various speeds and to learn the magnitude of the bending moments developed in the joint bars as compared with those developed in the full rail away from a joint. It was also desired to learn if possible how speed of train affects these various matters. To serve as a basis of comparison, the stresses and moments and depressions of the full rail in the same track under the action of the same locomotive and cars were needed. Tests were conducted at Elkton, Md. The test site was on a 14-min. curve to the right with superelevation of 1-1/2 in. Ahead of and behind this curve the compound curve became 33 min. The total curve extended over a distance of about a mile.

MANUFACTURE AND TEST OF TRIAL PC TIES FOR FROST-HEAVE SECTIONS
The intensity of frost heave varies depending on the soil components or the weather and accordingly the distribution of reaction differs from tie to tie. The main objective of the present test is to know the changes of supporting conditions for ties through measurement of the bending moment produced in them by the train load. Though the changes due to frost heaving and thawing could be definitely noted, there were observed no remarkable phenomenon as initially feared of ties being supported only at midpoint; they were seemingly supported more often at both ends as the result of frost heaving.

ON THE LIFE OF RAIL
Annual trend of rail failures of the Japanese National Railways in recent years amounted to 5264 in 1963. There are included in rail failures the numbers of broken rails, cracked rails and defective rails all together, they do not always cause interference to train operation. It is known from the figures that end break ranks the first and amounts to more than 60 percent. The number of end breaks is divided into two parts, namely in tunnels and out of tunnels. End breaks in tunnels are more frequent for their track length and the rails in tunnel have shorter life than the ones out of tunnels, due to unfavorable conditions of corrosion in tunnels of our country. End breaks almost occur as results of rail fatigue by train loads. Stress induced on rail varies in magnitude according to train speed, wheel load, lateral force and position of wheel contact on rail, and the stress distribution was found in many measurements to be a normal distribution or its combination in most cases.

SECOND PROGRESS REPORT--JOINT INVESTIGATION OF CONTINUOUS WELDED RAIL
Report of committee on welded rail includes a brief resume of past research and then continues into the present research area. The first covered is the testing of welded rail joints under repeated wheel load. The procedure, the endurance limit and fractures developed are included. A comparison between welds and joint bars was included. Metallographic tests of the welds are included and such tests as hardness, etching and metallographic examination of the welds are also included. Mechanical tests of the welded joints were also part of the test sequence. A complete comparison of the test are indicative of metal qualities rather than joints, and that the quality of metal is important to the joint strength as weld outline, cracks and other stress raisers in the joint.

AN INVESTIGATION OF RAIL-TO-CONCRETE FASTENERS
Prestressed concrete railroad ties are being increasingly used. This investigation deals with the rail-to-concrete fasteners for concrete ties, bridge decks, and tunnel linings. For spring-clip fasteners in concrete ties, three methods of electrical insulation were studied. These fasteners were subjected to tie-wear tests, longitudinal-slip tests and electrical-resistance tests. The anchors used were also subjected to pullout tests. For fasteners in bridges and tunnels, three different fasteners were tested under repeated loading. In addition, the "second-cast" method of construction was studied.

TESTS WITH ASPHALT-TREATED BALLAST ON THE SOBU LINE
Discussion of testing of asphalt treated ballast of several types as a means to reduce track destruction. Results suggest that the asphalt treated ballast was more stable but there were problems in the use of a tie-tamper because ballast does not move freely. When loose ties are replaced, small crushed stones are required underneath. In addition, it is suggested that where renewal of the track in conjunction with ballast renewal of asphalt treated ballast, better results may be expected.

TEST OF VACUUM DEGASSED RAIL
One of the problems of rolling rail in lengths longer than 39 feet has been the problem of the cooling beds for producing controlled cooled rail. A potential alternate to controlled cooling is a process of vacuum degassing of rail. Such rail has been produced in small quantities by United States Steel and is under test in the tracks of the Penn Central Railroad. Analysis of the vacuum degassed rail indicates a chemistry superior to that in the present controlled cooled rail, and it is heavily indicated that this process will provide a somewhat superior rail and in lengths in excess of 39 feet. The rail under test on the Penn Central Railroad in the vicinity of Lancaster has now been in service one year and has carried some 49 million gross tons, and appears to show no noticeable wear even though it has been laid in a 3 deg 45' curve. The Norfolk and Western Railway Company is in the process of installing approximately 400-132 lb vacuum degassed rail for test in heavily traversed and heavy tonnage territory, some of which has already been laid.

PROTECTION OF RAIL JOINTS FROM CORROSION TO PREVENT RAIL END BREAKS
Many parts of the railway track including the rails are made of carbon steel. Carbon steel excels in strength but is prone to be corroded. Rail end breaks are considered as fatigue destruction caused by corrosion. Since stress and corrosion act at the same time, cracking is developed easily. It is because the fatigue strength of a rail decreases sharply in acid environments, that end breaks are more liable to occur in non-electrified sections than in electrified sections. Since corrosion has much to do with end breaks of rails in tunnels, the application of a proper protective method prevents end breaks of rails.

FASTENING THE RAIL
French type of doubly-resilient rail fastening features vertical holding of the rail between two components of well defined resiliency: 1. Grooved sleeper (tie) pad in rubber, positioned under the rail. 2. A spring-temper steel leaf type clip, the bearing of which is exerted on the rail by means of bolt (in concrete or steel tie) or screw fastening in wooden tie. Advantages of these fastenings are shown as extending into the economics, as retightening is extended to every four to six years, as against the yearly maintenance required with rigid fastenings, and the reduction of the number of tie screw reconditionings required.

A2 033402
HIGH SPEED RUNNING AND RELATED TRACK PROBLEMS
High-speed running does not set any track-make-up problems. The conventional type is quite suitable. Strengthening the track is not a must, neither from the angle of safety nor that of fatigue. Strengthening, which could be useful on the lines carrying both dense fast traffic and numerous slow heavy trains, could be carried out simply at the time of the scheduled renewals. The layout problem is more difficult. On certain important lines on the S.N.C.F. there are sufficiently long sections where the radii are over the minima indicated above. Consequently, scheduled service traffic at 200 km/h could be envisaged on these sections in a not too far distant future.

THE RAIL
Article on rail is descriptive, highlighting the development of appropriate specifications for the necessary requirements of resilience and strength. Rails in the process of manufacture are subject to continuous ultrasonic testing by an instrument called the RALUS. Rails in service are tested regularly by an electro-magnetic system for detection of fatigue faults. The elimination of joints has further improved rail life in track and the choice of the proper weight and profile of rail for the service to be imposed needs to be considered.

BOUTET PROCESS FOR WELDING RAIL JOINTS
Boutet welding process for rail joints, which uses the "aluminothermie", has been advanced to a three piece mold, which permits the welding of joints, even over the ties without moving them aside, and the use of a small portable machine for making the molds. This makes possible the speedier welding of joints at the rate of a joint per man-hour or less. Technical advantages of being able to center accurately all parts of the mold around the joint, and the practical elimination of any bead under the flange. Limited preheating welding (a rapid process) has been developed to minimize the effect of rail movement during the welding preparations. The elimination of the bead has made possible a high quality joint, highly resistant to the drop and fatigue tests.

A2 033414
END-HARDENED RAIL
Rail joints are the most vulnerable spots in the track structure and many manhours are spent on their maintenance. These parts are subjected to repeated impacts which are far larger than those inflicted to the other parts of the track. Moreover, the rails with joint holes bored in the web are structurally weak. Since the quality at the end of the rail, in spite of these weak conditions, is the same as the other part, the rail end has been apt to suffer a battering and rail joint depression. Because of progress in the rail welding technique and the improvement in the quality of the rail fastenings, the rails have come to be increasingly welded to "long rails". Standard length rails are expected to continue in use in considerable quantities. Strengthening the rail ends through production of rail steels with less non-metallic inclusions and heat treatment of rail ends to making them a better impact resistant structure was taken up as a research project.

STRENGTHENING OF TRACK STRUCTURES
On the JNR, the passing tonnage has nearly doubled and the average train speed has increased approximately 20 percent, in the last 30 years. Increasing traffic, coupled with unfavourable conditions such as a shortened train interval for maintenance due to increased frequency of train operation and a decrease of manpower for maintenance, it becomes very difficult to keep the track in good condition to meet the increased traffic. Necessity of strengthening the track structures to cope with such trends and overcome these unfavourable conditions, is stressed.

TURNOUT WITH NOSE RAIL MOVABLE CROSSING
For the New Tokaido Line the Japanese National Railways required that the turnout at stations should allow passing trains the same maximum speed of 200 km/h as they use on the rest of the line. It is necessary to have a special turnout which would minimize the wheel shock to the turnout structure, both vertically and laterally. Worked out was a turnout with a nose rail movable crossing having welded joints, skew joints, no guard rail, and no guiding flangeway of wing rail. Several types of such turnouts having nose rail movable crossings have been experimentally designed in JNR beginning in 1960. Experience of service so far made suggests no troublesome problem concerning track maintenance. Furthermore this new turnout needs only a little maintenance labor.

A2 033426
TURNOUT FOR N TYPE RAIL
At present, there are about 58,000 sets of ordinary turnouts. Most of them, however are of antiquated designs, being based on designs worked out as early as 1925. As they have become inadequate, under the present train load conditions, from the points of track maintenance and train operation, JNR has been doing its best to improve them. Yet such improvements have been only partial; no systematic overall improvement has been made yet. But extensive research work to design turnouts capable of allowing high speed train operation has been done in the last 10 years, and has enabled us to understand, theoretically, how turnouts can be improved. So, JNR is pushing forward design and development of improved turnouts which can meet all possible requirements placed on them under present and expected future train loads, paying at the same time, attention to make them interchangeable with existing turnouts. Marked improvements are expected, not only in maintenance efficiency but also in transportation capacity, with the introduction and full-scale use of these new turnouts designed for N type rails.

MECHANIZED MAINTENANCE OF TRACK ON THE JNR
The Japanese National Railways are making continuous efforts to mechanize track maintenance work in line with the policy towards general modernization of operation. Emphasis is laid on the wider employment of small-sized equipment which will allow a train to pass or which can easily be taken out of the track when a train is coming. So-called overall track renewal using heavy equipment is carried out where an interval of 3 or 4 hours is available between midnight and 4 o'clock in the morning as in the case of the electric multiple unit train lines in and around Tokyo and Osaka. This method is also used on some trunk lines, such as the Tokaido Line in cases where sufficient work time is available by blocking one side of the double track. Outlined are the principal kinds of maintenance work in which such equipment is used, and the measuring devices.

A 101 TYPE RAIL FASTENING DEVICE (THE NEW TOKAIDO LINE STANDARD TYPE) FOR P.S. CONCRETE SLEEPER
Numerous variations of rail fastening devices have been tentatively fabricated for the new Tokaido line. As the final prototype, the rail fastening device, which was originally developed for 50 kg PS rail, has been modified for application to the new Tokaido line 50 kg T rails. Statical characteristic test and lateral fatigue test were conducted on the tentative product and the results were checked with the anticipated values. The most suitable plastics and compound materials were sought for spring support and the durability of fastening parts was confirmed. The results suggest that a spring clip in the setting area will present no trouble. In this type of fastening, where a hexagonal bolt is screwed into the insert plug embedded in the concrete itself, special care should be taken in designing, so that the bending moment may not directly act on the bolt. There will be no practical trouble with this device, provided the above point is fully attended to.

GLUED RAIL JOINT FOR INSULATION
To develop the new type rail joint for insulation having not only sufficient vertical rigidity but also sufficient strength to be able to bear the axial force due to temperature variation in a long welded rail, the following study has been undertaken. Rail and fishplates of the joint are glued with high-polymer adhesive. This type of rail joint will not only make maintenance of the track easy but also make riding quality good.

EFFECT OF WHEEL FLAT ON THE CAR VIBRATION
A series of running tests was performed with the prototype "B" train for the new Tokaido line. The object is to investigate the effect of the wheel flat on the car body and truck vibration. The data were expected to give a reference for design and maintenance of car, and to give a base for determining the allowable limit of the flat length in practical operation. The running speed was 200 km/h for the flat up to 90 mm, and 50 km/h for 110 mm. So far as the truck and car body vibration is concerned, flat caused more vibration at a low speed than at a high speed. So car vibration is not considered the most decisive factor limiting the allowable length of flat.

PROBLEM OF INCREASE OF SPEED, AS FACED BY THE RAILWAYS IN DEVELOPING COUNTRIES
The immediate problem, in many of the developing countries, is not that of attaining very high speeds, but is that of reaching moderately high speeds. The economic conditions in these countries require that such increase of speeds should not entail any appreciable additional capital investment nor should it result in an increase in the maintenance and operating costs. The Indian Railways have undertaken investigations, research and studies with a view to achieve moderately high speeds on their "broad gauge" and "metre gauge" railway systems. The results of these studies are discussed.

DESIGN AND MAINTENANCE OF HIGH-SPEED PERMANENT WAY IN THE U.S.S.R.
The track on high-speed lines is subject to special criteria. A high level of design including the use of long welded rail sections, temperature-stressed concrete sleepers is required. Maintenance requirements are severe. Of vital importance is the control of track in the horizontal plane. The wear of rails and the permissible magnitude of corrugations, etc., are strictly limited. Great attention in the U.S.S.R. is paid to the increasing of speeds of trains since a comparatively small increase in maintenance gives a considerable economy in railway stock, reduces the cost of freight and passenger services, increases railway capacity. Experience, maintenance, design and labour problems are discussed.

DETERMINING THE INCREASE IN BALLAST DENSITY UNDER TRAFFIC BY MEANS OF THE GAMMA ABSORPTION METHOD
The increase of running speeds on main lines to 140 km/h or 160 km/h and the increase of axle loads of motive power units and goods wagons, the question has been studied for some years whether the undoubtedly higher maintenance cost to be incurred for the permanent way could be reduced by special measures. The mechanical compaction of ballast between sleepers will repay after 2-1/2 years because the extension of the interval between track overhauls will also entail a reduction in the number of tamping machines required.

GUIDING PRINCIPLES FOR THE DESIGN OF POINTS AND CROSSINGS (UIC 54 AND UIC 60 RAIL PROFILES). FACTORS AFFECTING THE CONSTRUCTION OF SWITCHES
The present interim report-Document No. 2-deals with the 3rd part of the Programme of Work "Conception of Switches". Based upon the three fundamental requirements of safety from derailment, steady riding of vehicles and economy in construction and maintenance, the interim report examines particularly the incidence of high speeds and heavy axles in the negotiation of switches. The calculations and the measurements taken to this end, are developed in two appendices where a study is made on bogie coaches for an analysis of accelerations in respect of comfort and on a V60 diesel shunting locomotive of the DB 25,000 series electric locomotive of the SNCF for an analysis of forces causing wear and fatigue. The reduction in basic components, the simplification of machining and increased life in service, with a choice of assemblies and materials which should ensure mainimum maintenance cost while retaining the maximum traffic availability, are sought in the choice of "pose" (3-20) and "Construction" (3-30).
Restrictions on the use of this document are contained in the explanatory material.

TRACK-TRAIN DYNAMICS STUDY PROJECT TR-14 RAIL-VEHICLE INTERACTION STUDY--REPORT NO. 2 (COMPLETE ANALYSIS OF DATA USING COMPUTER TECHNOLOGY)
Following a description of the problem involved in preparing a hybrid computer program for the analysis and reduction of transient data taken in the actual field tests of the TRACK-TRAIN DYNAMICS STUDY

PROJECT and an explanation of the computational approach, there is a description of the method of interfacing the digitized data with the digital computers used to obtain an in-depth engineering analysis of the results of the tests. The evaluation of the numerical data indicated that under controlled operating conditions, the L/V ratios were significantly repetitive, which fact can be helpful in future studies. However, the inability to measure the track lateral deflections simultaneously to obtain the combined effect of vertical and lateral displacements in the rail was a severe limitation, and it was not possible to derive any information concerning track stresses and probable damage due to high dynamic loads. Graphs and bar charts were developed from the computational results to show the relationship between speed, drawbar load and L/V ratios for locomotives and cars, and graphs were used to illustrate the accumulative distribution of dynamic rail deflections on various segments of the railroad where the tests were run. Parameters that were not included in the field measurements which could have possibly contributed to the establishment of a more definite pattern include: the relative velocity between instrumented cars, track curvature and truck hunting action and the cross-level of track.

INCREASE OF TRAIN SPEED ON CURVES
For a train to reach the destination in shorter time is to increase speed on curves and gradients. It would involve enormous investment to eliminate curves and gradients through re-routing the track in a mountainous country like Japan. Thus, the alternative would be to achieve an effect of speed by selectively investing in certain high-speed trains. Introduced a bogie truck TR96 which is an experimental one built for the purpose of exploring the possibilities of increase speed on curves. The data collected using this truck will offer the basis upon which a new high-speed train will be developed for actual service in a few years.

DESIGN AND MAINTENANCE ASPECTS OF FREIGHT ROLLING STOCK RELATIVE TO THE EFFECTS ON THE TRACK
A modern Railway has grown up in this country with new and more powerful forms of traction and improved signaling and track, but the majority of wagons in use still consist of small four-wheelers, the basic design of which has not changed for over 50 years. These wagons incorporate a 'Box-on-Wheels' design which was robust and cheap, suitable for the low axle weight, low speeds, and low utilization of their day. They are, however, incapable of meeting today's conditions of high utilization and speeds without an unacceptable degree of maintenance and inspection. Until recently very little was known of the behaviour and design parameters necessary for high-speed wagons, and because of this, in 1963 when it became obvious that improved wagon suspension was required B.R. adopted the U.I.C. Double Link Suspension. This was a proven design which was, and still is, in wide use on the Continent, but here again problems arose when operating at higher speeds and axle loads permitted in this country. These problems concerned the rapid wear of the links and saddles due to the friction necessary for lateral damping and spring failures caused by the torsion induced in the spring superimposed on the normal vertical loading.

THE RAILS ON THE GERMAN FEDERATED RAILWAYS [DIE SCHIENEN DER DEUTSCHEN BUNDESBAHN]
With the introduction in Germany of greater train loads and higher operating speeds, it was necessary to replace earlier rail, known as S49 with heavier rail, designated S54. Its usage is on main lines at operating speeds

of 140 km/hr and tonnage in excess of 30,000 gross tons per day. Another rail, S64, is used where axle loads are in the range of 30 to 35 tons and in tunnels on German railways. Rail breakages are compared for the various rail. Qualities and properties of the steel are discussed and theoretical stress lines in the rail sections are depicted. The shape of the rail head on the newer designs was changed to provide improved contact with the profile of the wheel tread. Specific costs of rail replacements on the German Railways are given for the various rail designs. [German]

WEATHER AND SITE EFFECTS ON RAIL TEMPERATURES

The effective operation of de-icing baths installed on open sections of the London Transport Board system is dependent on advance warning of icing risk so that they can be switched on before traffic ceases at night. When these baths were installed there was a lack of information on the relationship between weather and rail temperature, and led to an investigation to provide this information. It was decided to try to relate rail temperature to air temperature. Analysis of the data provided by the chart records was carried out in a variety of ways, according to the particular information desired. The maximum and minimum values of rail temperature or air temperature was plotted so as to show seasonal trends; diurnal variations of rail temperature at different times of the year, were studied; and the extent to which rail temperatures fall below air temperatures is of interest in connection with icing risk forecasts. The results of some such analyses are discussed.

PERMANENT WAY TECHNIQUES ON THE NETHERLANDS RAILWAYS

The use of block sleepers with steel tie-bars and universal type of spring fastening by Netherland Railways is described in terms of track resistance to longitudinal and transverse displacement. Epoxy resins are used to bond the steel tube cross ties in the concrete blocks, and a DE (Deenik and Eisses) spring clip is the common rail fastening.

TRACK STRESS RESEARCH

The purpose of this work was (1) to verify the speed allowance formula, (2) to investigate the increment of stress over and above the static effect under normal conditions from track defects, (3) to investigate the conditions of support at rail joints, (4) to investigate the stability of ballast, and (5) to investigate the effects on rails and sleepers of the lateral forces set up by the hunting movement of locomotives. In regard to (1) and (2) it was found that experimental static deflections and stresses are in reasonably close agreement with calculated values. In regard to (3), it was concluded that stronger fishplates are needed to facilitate maintenance and rail joints of inadequate strength are the cause of much of the impact effect. Increasing the number

of sleepers will reduce this impact effect. In regard to (4), the shape of the sleeper was found experimentally to have no noticeable influence on its deflection under a given load, but stress distribution between the sleepers and subsoil requires investigation. In regard to (5), further investigation on curved track was recommended to confirm the consideration that design to rolling stock to reduce nosing on the sharper main-line curves would reduce the secondary stresses and thus offset the increased stress due to centrifugal effects.

BRITISH RAILWAYS TRACK-SPRAYING TRAIN
The article describes a track spraying train for weed control that incorporates re-designed equipment to reduce water consumption and which permits operation at 40 mph. Water consumption has been reduced from 80 to 40 gallons/acre at 20 mph and is still further reduced to 20 gallons/acre at 40 mph. This led to a reduction in size of the main diesel engine from 12 hp to 7 hp, and in the main pump output from 260 to 100 gallons/mile, effecting considerable space savings. The train stores sufficient weed killer for 130 miles of spraying at 14-1/2 feet swath or over 400 miles of cess-only treatment.

TRACK-LINING EQUIPMENT
The Matisa range of equipment for simple and accurate track lining is described. The equipment consists of a roll ordinator, a slewing gauge, and a curve corrector. The conventional method of surveying track for lining purposes is by "string-lining." It is claimed that one man, using a roll ordinator can string-line a curve at twice the speed and with more accuracy than the normal three-man team. Following string-lining, an alignment adjustment can be arrived at, by operating on the measured versines, either mathematically or mechanically, by using a multistation curve calculator.

THE EVOLUTION OF THE AMERICAN RAIL
A review is presented of the development of the railway rail in America, including the change from iron to steel, the evolution of the modern American flat-bottom section, up to 152 lb. per yd. in weight, and present-day American rolling methods. Rail sections arranged in chronological order from the 5 ft. long, cast iron plate, used in 1767, to the 131 and 152 lb. rails introduced in 1930, are shown to trace the development of the American rail. Results are reported of a study to compare 100 lb. and 131 lb. rails as to maintenance costs and life, as affected by increasing weight loads. The heavier rails extended the life, not only of the rails, but also the sleepers and fishplates.

THE HEY-BACK METHOD OF RAIL FASTENING
The Hey-Back rail fastening has two components. One is a rolled-steel base plate with parallel ribs on each side of the rail seat to hold the rails to gauge. The outer side of each rib is curved over in such a manner as to form a keyway, into which there is driven a spring steel clip. The lower side of each clip is tapered from both ends at a leading angle to facilitate its entry into the keyway; as the clip is driven in, the taper forces the clip forward, with its double bend acting as a fulcrum in the keyway, until the opposite side is exerting considerable pressure on the rail-foot. To ensure perfect contact between key and keyway, each keyway is machined to a fine tolerance. The baseplate is held down to the sleeper by coachscrews, chair-bolts, or other fastenings of a normal type. Additional information is given relating to advantages and use with timber and concrete sleepers.

HIGHER SPEEDS THROUGH CURVES
Investigation of rail friction (mu (sub y)), made on both wet and sanded rock, at speeds between 6 and 72 km/h, showed values ranging between 0.4 mu (sub y) and 0.5 mu (sub y) with banding leading to higher values. Values of mu (sub y) for lateral slip versus wheel-load are given as are values of mu (sub y) for a range of R(m) from 300 to 890 at speeds from 80 to 110 km/h. It was noted that the use of bogie intercouplers reduce rail friction (mu (sub y)) and flange wear.

TRACK-RELAYING EQUIPMENT
A number of Secmafer Boyer Schwarz M.6 track-relaying gantries have been supplied to British Railways. Each gantry weighs 7-1/2 tons, and the overall width is 11 feet 4 in., with 9 feet 6 in. inside clearance for lifting the load. With the twin rams and screw-jacks mounted in the side frames both fully extended a pair, or one unit, of gantries can load or unload up to four concrete-sleepered sections high on a standard Salmon wagon, with 2-in. of timber packing on the wagon deck. Power is supplied by a standard Renault Dauphine engine. The machines have operated successfully on an incline of 1 in 40. The speed of lift of the twin rams is 22 ft. per min., and of the screw jacks is 12-8 ft. per min. when the two movements are made simulatneously, these speeds are approximately halved.

PRODUCTION AND MAINTENANCE OF LONG WELDED RAILS
From 1938-1948, flash-butt welded rails, 300-ft. long, have become the accepted practice of London Transport, for both maintenance renewals and

new works, and were used on more than 70 miles of main line by 1949. Some of the problems involved in the production and maintenance of this type of track are described. The machined joints, in tunnels, and the expansion switches, on open sections, were used to relieve rail stresses. Wooden keys were also used instead of steel key for stress relief. Methods used by two automatic flash-butt welding plants to produce and test the long rails are briefly discussed. A temperature variation of 50 deg F, is the maximum to which this type of track should be subjected without being freed from stress. The long rails are unkeyed during early spring and at mid-summer. Examination of track maintenance records on 60 ft and 300 ft long welded rail revealed a savings in favor of the 300-ft rail.

FASTENINGS BETWEEN STEEL SLEEPERS AND FLAT-BOTTOM RAILS

As a result of extensive trails on main lines in India, the Mills spring steel loose jaw has become a standard type of fastening used with steel sleepers throughout India and Pakistan. It is used not only in plain track, but also in turnouts with steel sleepers, if track-circuiting is not required. The formation of the jaw and its installation on the rail is described. A longitudinal section of the center of the steel sleeper, showing details of the rail fastening, is illustrated. Fifteen years' experience using the Mills jaw has shown that no wear has taken place, and that gauge has been maintained.

TRACK FORMATION IMPROVEMENT IN HOLLAND

On the main line of the Netherlands Railways from Utrecht to Rotterdam, a seven mile section between Oudewater and Gouda passes through an area of waterlogged peat moor. Two methods were tried, in 1938, to strengthen the foundation for the track. The first method provided for the construction of two dams of sand, which completely enclosed the embankment. Large quantities of sand were deposited quickly, and the weight of this material pushed the semi-liquid peat aside. In the second method, the sand was deposited gradually, so that the peat became more compact, and less likely to move. The second method was used until 1948 due to the expense and the risk of serious disturbance of the track present with use of the first method. A third method was introduced in 1949. The top of the embankment is removed and replaced by a reinforced layer of fine sludge slag. This slag hardens into a substance resembling concrete. A layer of sand is placed between the top surface of the slag and the gravel ballast. Some 5-1/2 miles of double track are to be strengthened in this way.

THE RAILWAY FIGHT AGAINST SNOW AND ICE

The problem on the 2,387 miles of electrified track of the main-line companies and the 174 miles comprising the London underground network is ice. Probably the best protection against icing is to keep trains constantly running so that the ice does not form. London Transport has a fleet of "sleet" locomotives to keep conductor rails clear. These are fitted with pneumatically operated wire brushes carried on the collector shoe; they have roller ice crushers and can also eject on to the live rail a stream of de-icing fluid to prevent the ice-re-forming after the locomotive has once cleared it away. No fewer than 1,376 sets of points operating in the London area are provided with direct or indirect heating equipment, but other points and junctions have to be kept clear largely by use of rail scrapers, salt, or portable de-icing apparatus.

A NEGLECTED POINT IN SWITCH DESIGN

A derailment of the first car behind a 6-coupled saddle-tank shunting locomotive at the marshalling yard at Kantara during World War I is analyzed. Kantara was at the beginning of the military railway from Egypt to Palestine The locomotive, in a facing direction through a turnout to the right-hand diverging road, took the turnout correctly. The wheel flanges of both the locomotive and the car were considerably worn; those of the car more so that those of the locomotive. Rail climbing by the rather sharp flange of the car wheel was suspected, but no signs of this were visible. There were signs which showed that the wheels had dropped on to the sleepers as soon as the space between the diverging rails permitted. The events leading to the derailment were reenacted under observation. When the leading wheels of the locomotive were partly through the switches the point of the left-hand switch commenced to open about 0.375 in. The fire of the leading wheel of the wagon entered this opening with the result described. The switches, which had a heel joint with a standard clear flangeway of 1.75 in., were struck by the wheel flange at the right rear of the locomotive as the locomotive's worn tire ran hard against the left rail. Detailed illustrations are given to describe the derailment cause.

DEVELOPMENT AND MANUFACTURE OF PRE-STRESSED CONCRETE SLEEPERS

The Tallington factory, completed in August, 1944, has 20 lines, each accommodating 100 standard main-line sleepers. Filling the moulds at one fixed place in the production line, allowed a vibrating table to be used and a water cement ratio of 0.39 for the concrete. For wiring, the coils of wire are carried on a track and the wires are drawn off under semi-tension, which obviates the need of first straightening the wires. As they leave the wire carrying truck they are automatically cleaned by passing through a scrubbing box containing carborundum granules. The method of manufacture allowed three minutes of working time per pair of sleepers during concreting and removal, this time factor also being maintained for the wiring processes. The reduction in labor costs using the mechanized mass-production process showed a savings of 88 percent over an earlier method described.

FLAT-BOTTOM TRACK IN GREAT BRITAIN

The L.N.E.R. laid a system of switch-and-crossing work in flat-bottom rail in 1944, for experimental purposes. The turnout, which used 110-lb. flat bottom rails, is illustrated. The normal 1 in 20 rail cant or tilt is retained through the connections, and heel-less switches are used; the lifting of the switch above the stock rail has been eliminated. In general the switch angles, radium of switch curve, and the top planing are similar to bull head British Standard design. The usual type of fastening used in this flat-bottom switch and crossing work is the hook bolt and malleable iron clip to secure the rail to the cast-iron base plates, and chair screws to fasten these plates to the timbers.

PORTABLE WELDERS FOR JOINING RAILS
The portable welder is mounted on a wheeled chassis complete with transport rollers, cold saw, centrifugal pump for cooling water, tanks for water, fuel, and lubricant, milling machine, and guide pieces, besides the usual alternator, exciter, and switchgear. Two sections of the rail to be joined are clamped in the machine and brought together, and as the current passes through the point of contact, the metal is warmed; by repeated separation and re-union, an effective preheat is accorded to the ends. Flashing then follows, during which, by applying moderate force to the fixed piece, the rail is slowly pressed forward, and to the accompaniment of a shower of sparks, molten metal is ejected. The rails attain the desired temperature for welding during this treatment, and with a powerful upset motion become united. The system is completely automated. When the rail ends to be joined are at hand, from 7 to 10 joints an hour are made. Each weld requires two to three minutes.

USE OF CONCRETE SLEEPERS AND STEEL SLEEPERS ON THE SOUTHERN RAILWAY
War time shortage of timber in England prompted experimentation with concrete and steel for sleeper construction. The first experience with the use of reinforced concrete sleepers on a main line in 1912 resulted in shattering after only 5 years' life. Concrete 1:1-1/2:3 unvibrated, reinforced with four 3/4 in. main bars were in good condition after 14 year's service on the main line between Exeter and Plymouth. Speed of trains in this section rarely exceeds 25 to 30 mph. Testing results of concrete sleepers on fast-running main line is incomplete since these sleepers have been in service less than one year. Steel is difficult to obtain during wartime; however some results on the use of steel sleepers are reported. Weight losses are reported for three types of steel sleepers. Steel sleepers are unsatisfactory when the track is to be electrified or track circuited.

ALTERNATIVES TO THE WOODEN RAILWAY SLEEPER
Due to the difficulty of importing timber during World Wars I and II to make wooden sleepers in Britain, this study examines the limited data available on substituting steel and concrete for wooden sleepers. A half million steel sleepers, 98 percent consisting of mild steel, were laid from 1922-1929, under all types of service conditions. Five percent were removed after 13 to 14 years' life due to excessive corrosion. Two other steel sleepers, the Sandberg and the United Steel Type 2-A, may have longer life, but further testing is required. Only small scale trials on concrete sleepers have been made due to failures encountered in early trials, and the comparatively high cost and greater weight of concrete sleepers.

PRE-STRESSED CONCRETE SLEEPERS
During concrete sleeper manufacturing, the steel reinforcement is subjected to a high tensile stress. This stress is then utilized to induce in the concrete compressive stresses which will be directly opposite to those tensile stresses produced by the external forces imposed on the sleeper. A high-tensile steel is used and the value of the applied force is calculated so that the advantage of pre-stressing is retained permanently in the sleeper. The tensile stresses by the process of pre-stressing are so reduced as to permit dispensing with all shear reinforcing, which results in a saving of steel of between 70 percent, and 80 percent, over the ordinary reinforced concrete sleeper.

PERMANENT WAY OF THE FUTURE
The properties of the ballast bed and the savings in maintenance obtained by using a concrete bed in its place are apparasied. For 300 km/h service, the use of U 80 rails of 60 kg/m mounted on concrete blocks with cross-ties and double-elastic fastenings is recommended. Such fastenings allow a greater degree of vertical movement of the rail and the sleepers would be laid on a ballast bed 35-cm deep. Japanese experience with continuous welded track and 53.5 kg/m rail mounted on pre-stressed monlithic concrete sleepers with double-elastic French-type fastenings is cited. Mention is made of the problem of ballast and the continual maintenance it incurs. Swiss studies on ballastless track for tunnels is reviewed.

PLASMA TORCH PROVED FOR LOW SPEED APPLICATIONS
The article discusses research results of the British Railways attempts to improve adhesion of rail vehicles by using a plasma torch to remove materials from rail surfaces. Laboratory tests confirmed the feasibility of using such a device, in two areas: low speed operation for freight trains and high speed operation for passenger trains. A test vehicle was made up to field test the plasma rail vehicle. Results of the testing show that mechanical condition of the rail head is important; old rail with large areas of contact required higher output than new rail. The tests show conclusively that starting and low speed operation of freight vehicles with low adhesion can be resolved by the application of the plasma torch.

BALLAST CONSOLIDATION AND DISTRIBUTION ON THE TRACK
Two machines introduced by Robel and Company for ballast distribution and consolidation after the track has been laid have been introduced. The

ballast plough incorporates a novel design to meet the higher capacity of the modern 32-tool tamper. High-speed vibrators mounted on the guiding forks exert a compacting force of up to 10 tons. The machine exceeds along the track at 1,000 to 1,500 m/h and consolidates continuously. This matches the greatest working speed of double head tamping machines and guarantees a consistent compacting effect for the whole length of the bed over which it is run.

KEEPING THE TRACK IN ITS PLACE
The lateral stability of track laid with continuous welded rail may be affected by unusually warm periods which cause trouble at points where insufficient care was taken in clamping at correct combination of rail temperature and stress. Adding ballast to the shoulders is only part of the answer. If the shoulders are to resist lateral movement they must be compacted after the track has been lined and levelled and the sleepers tamped. Machines are now available to do this work.

HYDRAULIC TENSIONING OF CONTINUOUS WELDED RAIL
Stretches the rail to the expansion which would occur by a temperature rise from the installed temperature to the mean of the normal extremes of heat and cold to which the rail is subjected in the annual weather cycle. Rails installed in ambient temperature conditions higher than the specified ideal temperature range are not adjusted at the time of installation. The rail is laid, the temperature is noted, and at the first suitable opportunity it is brought into the optimum stress condition.

ULTRASONIC RAIL TESTING AT THE ROLLING MILL
Studies have shown that fatigue defects which appear in rails in the track can always be traced back to segregations in the metal, inclusions or micro-cracks. Metallographic tests which show up these defects are lengthy, costly and must inevitably be restricted in scope because they involve destruction of the specimen tested. Consequently, it was necessary to find a non-destructive method of detecting these defects by sounding the whole length of the rail head. The ultrasonic method using echoes was chosen by SNCF and ORE. The Ralus equipment was designed to detect heteorogeneities which are particularly harmful to the performance of the rail in the track: non-metallic inclusions and flakes located in the critical zone of the rail-head where most fatigue defects originate. Studies have shown that the Ralus testing method does give a reasonable indication as to the quality of the rails.

NEW RAIL FASTENINGS FOR CONCRETE TIES [EIN NEUE SCHIENENBEFESTIGUNG AUF BETONSCHWELLEN]
The development of concrete ties has produced a rigid reinforced, pre-stressed concrete tie that has proven so successful that there are more than twenty million of them in use today on the German Railways. From both the engineering and economic standpoints, they are giving fully satisfactory service, even on heavy travelled routes. However, the search is still going on for a fastening to hold the rail in proper relation to the tie. Hopefully a fastening will hold the rail firmly to guage under both vertical and horizontal load; provide the necessary elasticity; afford resistance to lateral and longitudinal movement of the rail; provide full electrical insulation between rail and tie: and have the lowest total cost. Data and charts are included to show the relative worth of the various fastenings that have been tried, and are in use today. [German]

THE REQUIREMENTS OF THE RAILWAY AND ITS FURTHER DEVELOPMENT FOR HIGHER SPEEDS AND AXLE LOADS [BEANSPRUCHUNG DES EISENBAHNOBERBAUES UNE SEINE WEITERENTWICKLUNG FUR HOHERE GESCHWINDIGKEITEN UND ACHSLASTEN]
Constant research has been conducted in the permanent way with the rails, ties, ballast bed and the underneath ground structure for improvements to cope with the increasing axle loads and higher speeds. This article considers the more sophisticated concrete rail bed structure. The conclusions are as follows: The present ballasted rail structure with rails of 90 kp per mm (super 2) is suitable for axle loadings of 25 to 28 tons, at present speeds. With rails of 110 kp/mm (super 2) and weight per meter of 70 kg, the axle loading can be increased to 37 to 42 tons. However, the ballast bed must be strengthened. For speeds greater than 220 to 250 km/h, there will need to be new developments for the railroad track structure. Because the present ballasted right of way would require too much maintenance under such conditions. The concrete rail bed for urban railways has a potential for effecting substantial savings in track maintenance costs, thereby reducing the over all cost of the track structure. [German]

REAL PROSPECTS FOR INCREASED SPEEDS ON THE RAILWAYS [REALE MOGLICHKEITEN FUR EINE STEIGERUNG DER GESCHWINDIGKEITEN BEI DEN EISENBAHNEN]
A comparison is made of door-to-door times for automobile, train and plane travel between cities separated by up to 200 Km, 200 to 400 Km, and 400 to 800 Km. The potential for the railways to offer service more competitive in elapsed time to that of air travel is explored. The increase in speed must take into account passenger comfort as well as safety. The closer spacing of ties will improve the riding qualities and provide more favorable stresses in the track structure. The use of curvature of 2400 m radius in switch turnouts to permit speeds up to 140 Km/h is possible. Signalling developments are also considered. The prospects for higher speeds in passenger service on the railways are necessary. [German]

PREPARING BRITISH RAILWAYS TRACK FOR HIGH SPEED RUNNING
Before speed limits are raised to 125 mile/h or higher, action must be taken to eliminate bolted rail joints and gaps in the rail at crossings. Experience with 100 mile/h trains running in quantity indicates that the standard continuous welded rail track on prestressed concrete sleepers will be capable of carrying trains at 125 mile/h without any particular difficulty. At speeds of 100 mile/h or over, the presence of all kinds of rail joints and of crossings present an increasing problem in maintenance. The desirability of providing monoblock or swing-nose crossings increases as the speed rise.

RESILIENT RAIL-SEAT PADS IN BONDED RUBBER CORK
Concrete cross ties are less resilient than the flexibility of a roadbed of ballast, and wooden cross ties. Therefore, it is necessary to insert a pad between the concrete crosstie and the rail or baseplate. Such padding is important to avoid abrasion of the rail and to damp out noise and vibration, as well as an insulator of track circuits. Rubber has been used, but when compressed, solid rubber tends to spread sideways, leading to abrasion and finally to rupture. Combinations of cork with synthetic or natural rubber permit use of pads of pre-determined load/deflection characteristics. The rubber also seals the cork from moisture, as well as helping the pads to adhere to rail foot and crosstie.

BROACHING HOLES IN RAILS
Anything that can be done to reduce bolt hole stresses will increase the fatigue life of rails. The perfect result is achieved by completely eliminating fishbolt holes. Four methods of improving fishbolt holes are: 1. careful drilling to produce holes of smooth fish; 2. radiusing the edges of the holes; 3. reducing the diameter of the holes; 4. work hardening the internal surface of the holes. Work hardening the hole is achieved by forcibly increasing its diameter after the initial drilling. The fatigue strength of the drilled rails is improved by at least 25 percent by work hardening.

THE NATURE, MAGNITUDE, AND FREQUENCY OF LOADS AND FORCES APPLIED TO RAILROAD ROADBED
The magnitude, nature and frequency of loads imposed on railway roadbed by track structures and by traffic on the track structure is summarized for use by engineers in designing alternate types of roadbed construction. An SD-40 locomotive was studied to test severe loads Magnitude of reactions in the roadbed depends not only on the loads themselves but also in the spacing of the loads and the type and composition of support. In conventional track, the contact pressure on the bottom of a tie is not uniformly distributed either laterally or longitudinally. The total load on an individual tie depends on track conditions, size and distribution of load, and size, spacing and condition of the ties. There are traditionally two ways of handling impact loads, i.e. "equivalent static load" and "energy load." Of the two, "equivalent static load" is usually given for railroad situations and will be used here. Longitudinal loads come from inherent stress (from manufacture and laying of rails), reaction to locomotive traction, wheel flange friction and braking, thermal rail stress, and longitudinal component of train weight on grades. The longitudinal component of train weight can be calculated statistically knowing gross weight, grade, length of train, etc. Fortunately, this load is not concentrated but is spread out over a considerable distance. With conventional track construction the perpendicular component of train weight increases the frictional restraint of ties in ballast so that this is of little consequence. Longitudinal loads applied to the track by traffic have been the subject of considerable study in both this country and Europe. They are difficult to analyze because they are affected by so many variables, and uncontrolled variables at that. Transverse, or lateral, forces are particularly important since if they exceed roadway resistance they cause unstable alignment or buckled track and likelihood of derailment. Mathematical calculations show the rail reaction for the SD-40 on 122 lbs rail.

THE SELECTION OF AN ECONOMICAL RAIL SECTION
Six existing rail sections of 6 different weights from 115 to 140 alloys were analyzed, which have been designed or improved to meet requirements of heavy, high speed loads with an adequate margin of safety. With at least a 9% rate of return for both railroads, a combination of the existing sections is needed to satisfy the various requirements of the new rail territories-140 lb for the high, 133 lb. for medium and 115 lb. for the low traffic density and speed territories. A new 122 lb. rail section has been designed which embraces 98% of the B and O-C and O new rail territories. Cost savings by use of the single 122 lb. section for both railroads is estimated.

ENGINEERING AND ECONOMIC ANALYSES OF WOOD TIE-VS. CONCRETE TIE TACK
Engineering and economic studies were conducted to determine the conditions under which concrete cross ties would be justified. In the process of comparing wood and concrete ties the following factors influence the outcome: (a) in-place cost of ties, (b) service life of ties, (c) service life of rail, (d) cost of rail renewal, (e) tie spacing. The investigation of engineering aspects has been confined to the effect of tie spacing on the track stability, with particular attention to the allowable increase of spacing when concrete ties of selected types (MR-2 and B-58) are used instead of wood ties. For a realistic evaluation of the economics of wooden ties vs. concrete ties, the discounted differential cash flow method was applied.

PROBLEMS OF RAILWAY MAINTENANCE OF WAY
A historical discussion is presented on the achievements of heavier axle loads and higher speeds. The planning of new and larger cars for the Rheinische Braunkohlenrevier is included. These cars will have an axle load of 50 tons. This is followed by both a theoretical presentation and actual results of tests of the behavior of the track structure under the loading of locomotives and cars. One interesting point brought out is that there is practically no difference in the depth and frequency of the deflection of the track under an E-10 locomotive at 10 KM/H versus 200 KM/H. Studies show the effect on track deflections with closer spacing of narrower ties, and also on a concrete track bed plate. Problems encountered with long, continuous welded rail are presented, and the stresses in the rail are shown under the varying conditions of temperature. The importance of exact alignment of the track laid in curves is stressed. It is concluded that with stiffer section, harder rails of steel free of impurities, heavier axle loads may be safely carried without damage, especially when the track is laid on narrower ties spaced more closely together (50 cm) on a deeper rock ballast bed. Further research will be required to determine if a new concept of track bed will be required for speeds of 250 KM/H and 40 ton axle loads.

CONTINUOUS WELDED TRACK IN RAILWAY OPERATIONS (HUNGARIAN STATE RAILWAYS)
The author evaluates the engineering and economics of continuous welded track on the Hungarian State Railways. The details of the engineering of the track construction are described, and show the continuous welded rails are laid on concrete ties 8 feet long, spaced 24 inches apart, on a rock ballast bed 20 inches deep, with 16 inch shoulders, and having a base 16 feet wide. A theoretical consideration of the improved riding conditions provided by the continuous welded track, and the reduced maintenance made possible reveals that this construction can effect substantial savings over the jointed track to justify its extra cost, depending on the traffic density.

DETERMINATION OF THE COMPACTING OF BALLAST UNDER SERVICE LOADING BY THE GAMMA ABSORPTION PROCESS
Increased train speed and axle loadings require effective measures to keep maintenance costs and maintenance work on the track within acceptable limits. An important factor in this is a well compacted road bed. The authors describe how the effectiveness of compacting of the road beds performed by the various makes of tamping machines had hitherto been measured by a so-called "water substitution" method. The new gamma absorption method of making this determination of the specific gravity of the compacted ballast bed, and the measuring procedure associated with it, are described. Charts of measurements are given, showing the correlation of this new with the old method. Data as well as theory are included. Information is also given, showing the increase in resistance of the track structure to lateral displacement and longitudinal creep from a well compacted ballast bed.

LONG WELDED RAIL INVESTIGATIONS
The Western Region of British Railways has been carrying out valuable investigations into the behavior, control, and economic factors relating to long continuous lengths of welded rail. The test lengths of long welded rail in South Wales were subjected to apparatus for measuring and recording movements of the rail. Nine pairs of instrument stations 100 yd. apart were initially established with recording instruments grouped at a central point. The behavior of the track recorded was mainly longitudinal movement due to changes in temperature but transverse movement was also registered. Laboratory static tests were for resistance to longitudinal movement of a rail through its fastenings, and a dynamic testing machine was also evolved for equating track loading and deflection under the equivalent of the passage of a locomotive at 60 mph. Long continuous rail lengths carrying fast traffic must be provided with ample ballast and a firm foundation. Maintenance must be to a first-class alignment and special attention must be paid to the maintenance of the fastenings. More accurate means of costing maintenance will also have to be devised for ascertaining the economics of long welded rails.

WELDED RAIL IN THE U.S.A.
The elimination of rail-joint maintenance is claimed to be more than covering the additional cost of welding, transporting the welded strings to site, and handling them. In general, few troubles have been experienced. Expansion and contraction at the ends of welded strings has been little more than normal, and has been restrained by increasing the number of rail anchors applied over the last six lengths of rail (234 ft) at the end of each string. Given proper anchorage, no trouble is experienced with buckling, but that considerable care has to be exercised as to the temperatures at which continuously-welded rail is surfaced.

HIGH-SPEED JUNCTIONS AND CROSSOVERS
British Railways has developed two new switches in 109-lb. f.b. rail. They are the "Curved F" and "G" switches and are both of the chamfered type, which, by the undercutting of the stock rail, permits the retention of sufficient metal in the switch rail to provide the robust section desirable at and near the switch toe when very fine entry angles are used. In the Southern Region a speed restriction of 50 mph is considered suitable for Curved F switches diverging from the straight. G switches will be used where higher speed restrictions up to 75 mph from straight are required and site conditions permit. Layout drawings for a double junction embodying G/24 turnouts have been completed. By the use of two-level baseplates and transition curves as necessary, a practially constant cant deficiency of just over 2-1/2 in. at 75 mph is possible.

RAIL-END HARDENING IN NEW ZEALAND
Flash-butt welded, 91-lb. rail is being flame-hardened to increase the Brinell hardness of the rail end 50 to 100 points above the remainder of the rail. The hardening extends 1.5 to 2 in. from the rail-ends, to a depth of 0.189 to 0.25 in. Experiments have been carried out at temperatures from 32 to 90F, with practically no variation in results. The hardening process is described in detail.

HANDLING CONTINUOUSLY WELDED RAIL
The Denver & Rio Grande Western Railroad has perfected a new unloading method for continuously welded rail, which pushes the rails off the rail train rather than to pull them off. This eliminates the danger of damaging the rail as it drops from the train in the pulling method. The new method uses specially adapted flat cars located directly behind the locomotive to thread and push the long rail onto the track. A crew of 4 or 5 section men in addition to the train crew are needed to lay the rail.

LONG-WELDED RAILS ON EAST COAST MAIN LINE
The first long-welded rails on the East Coast main line were laid on a section of line where a continuous stretch of almost a mile now exists. Normal 60-ft. rails were first flash butt welded into 300-ft. sections. On the site, the ends of the rails to be joined together were held in a mold and heated. A mixture of powered metal and magnesium was ignited and the powered metal melted into the gap between the rail-ends. The mold was knocked off as soon as possible and spare metal trimmed by cold chisel and grinder. Each weld took about 45 min. to complete.

EXPERIENCE OF UNDULATORY WEAR OF RAILS
Undulatory wear on corrugation in rails is universally considered to be of two main types: roaring rails or washboard track; and what is sometimes described as saddles. The majority of railways consider that speed has no relationship with corrugations. Undulatory wear appears from 3 to 12 months after laying. The general opinion is that braking decreases washboarding but increases saddles. In the U.S.A. experiments with an acetylene torch to temper the Martensitic area of the high polished spots of washboard corrugations caused the ridges in the track to disappear. Various methods of grinding have been tried, but none have proved permanently successful.

LONG WELDED RAILS
A survey was taken to determine the uses and value of long welded rails, their manufacturing and laying techniques, and maintenance. The results were reported to the Seventeenth International Railway Congress. The maintenance costs are at least 15 percent less for the welded rail than for conventional track. The most suitable length for welded rail and anti-creep devices are discussed. Isolated cases of breakage due to welded defects, buckling due to disregard of temperature regulations of poor ballasting, and creep due to thermal stress are cited.

HEAT-TREATED RAILS
There has been a considerable increase in the heat treatment of rails for U.S.A. railways. Apart from controlled cooling, which is applied universally as a protection against the development of transverse fissures, rail-end hardening is extensively practiced, to reduce batter of the rails at the joint. In one specific case mentioned the addition to the basic price for rails control-cooled, end-hardened, chamfered at the extreme ends on the running surface, and drilled for fishbolts, was about 59 percent. It was considered advantageous to use heat-treated rails in switch and crossing work. For trackwork subject to exceptionally heavy wear an alloy steel, such as chrome-vanadium is preferable, though this is more costly than heat-treated rail. The disadvantage of such alloys is that it is impractical to weld them by the oxyacetylene method, so that on site repairs by welding are ruled out.

LONG-WELDED RAILS LAID IN CONTINUOUS OPERATION
The method allows one track-mile to be laid in 600-ft. lengths in one continuous operation. Up to 36 welded rails, 300 ft. long, can be loaded on to the bolster wagons at the new rail welding depot. Pairs of these rails are fishplated together to form 600-ft. lengths. Eventually continuous welded rails 600 ft. long will be available. The rear wagon of the train has special gantry equipment designed for guiding the lengths of rail off the wagons at normal rail spacing of 4 ft. 8-1/2 in. and for lowering the rail ends.

RUBBER RAIL-TO-SLEEPER FASTENING
A rail-to-sleeper fastening on trial on British Railways is applicable to ordinary flat-bottom rails, but is specially designed to resist any tendency towards buckling in long-welded rails. The advantages claimed are: simplicity; cheapness in first, maintenance, and replacement costs; safety, sufficient elasticity to protect the sleepers against impact and so increase their lives; and no interference with track-circuiting. The fastening consists of a cast-iron baseplate enclosing a rubber pad upon which the rail-base is held securely both vertically, transversely and laterally by metal-rubber wedges fitting tightly into jaws cast integrally as part of the baseplate.

ADHESIVES IN RAIL-JOINT ASSEMBLIES
Railways are testing the use of adhesives in rigidifying rail-joints to eliminate rail-end batter and reduce maintenance. Preliminary tests showed that joints so rendered inflexible ensured a smooth-running continuous rail likely to add 10 to 15 years to the life of existing track. The glued joints also reduced maintenance by eliminating the expansion and contraction in ordinary joints. A 300,000-lb resistance to slipping is reported with Bondarc applied to clean, sand-blasted fishing surfaces, and by butt-glueing the rail-ends additionally a further 40,000 lb is obtained. As no fishbold tension in excess of 20,000 lb was needed it was not found necessary to use high-strength bolts. Tests were conducted in Northeast Canada to ascertain the effects of a combination of the lowest temperatures and heavy traffic on glued joints.

"FROZEN" RAIL JOINTS
The Delaware and Hudson, on its main line stretching from Albany, New York, to Montreal, has experimented with frozen joints for continuous-welded rails. For frozen joints, the rails are laid tight, allowing for no expansion at the joints. The elimination of joint maintenance is a main argument in favour of welding into long lengths. The weld itself is expensive, not to speak of the extra cost of handling the long lengths of "ribbon rail." Furthermore, if a rail is damaged, it can easily be replaced, whereas with ribbon rail the section damaged has to be cut out. There may be extensive potential maintenance economics to be effected by laying rail tight with frozen joints.

RAIL-END HARDENING IN NEW ZEALAND
A paper from the British Commonwealth Welding Conference is summarized. In New Zealand the rails as originally received are from 30 to 40 feet. long but the 91-lb rails are now being flash-butt welded into 210-feet lengths, and it is the ends of these long rails that are hardened at three main depots. The composition of the rail has the greatest influence upon the results obtained from flame hardening. The methods used to harden and quench the rails and the apparatus used are described. The principal aim in heat treating a rail is to obtain a definite percentage increase in hardness over that of the untreated rail. To this end in New Zealand, the 91-lb rails now being end-hardened are treated for 1-1/2 to 2 in. from the end and to a depth of from 3/16 to 1/4 in. To avoid surface cracking or shelling there should be a definite hardness range which should not be exceeded.

LONG-WELDED RAILS
A comparative study of methods for welding very long rails was made for Great Britain, South Africa, New Zealand, Australia, Sweden, Japan and the U.S.A. The use of long rails is largely experimental and no definite policy has been reached as to the length of section to be laid with them. Wood, steel, and concrete sleepers are being used and their numbers vary from 1,240 to 1,920 per km. Methods of fastening the rails to the sleepers include dog spikes, elastic spikes, clips and bolts, and cast iron chairs with keys. The most favored method of manufacturing long-welded rails is by flash-butt welding in the depot into transportable lengths and then by thermit welding into long sections on site.

SPECIAL COMMITTEE ON CONTINUOUS WELDED RAIL
Rolling-load tests were made of specimens of continuous welded rail in the 12-in stroke machine on four acetylene welds, 4 electric welds, and 4 thermit welds. All of the thermit welds failed in this test. One acetylene weld also failed just below 2 million cycles. Other rolling-load tests were made in a 33-in. stroke rolling machine primarily to test the welds in the rail bases. All the acetylene and electric welds ran to over 2 million cycles without failure. Two thermit welds developed failures in the rail heads. A few other observations on possible causes of weld failures are listed, including grinding burns electrode burns, and cases where the flame goes out in oxyacetylene welding. The fastenings subcommittee reports five methods used to anchor welded rail across open-deck steel viaducts or long deck steel spans.

SERVICE TESTS OF DESIGNS OF MANGANESE STEEL CASTINGS IN CROSSINGS AT MCCOOK, ILLINOIS
This report covers the service performance of the solid manganese test castings in the crossings between the double-track lines of the Baltimore and Ohio Chicago Terminal Railroad and the Atchison, Topeka and Santa Fe Railway at McCook, Illinois. This solid pedestal design that was not depth hardened on the tread corners was retired after a service life of 3.60 years. This casting was removed from service because of the combined weakening effect of the cracks from the top to the bottom of the casting. On June 3, 1957, for the same defects, the solid pedestal design with depth hardening was retired after 4.44 years of service in the same crossing. Although the USS depth-hardened casting had more cracks at its retirement than the unhardened specimen, it is judged that the major portion of the increase in life for the depth-hardened one can be attributed to that treatment.

ESTIMATING WEIGHTS OF RAILS IN THE TRACK
The Railimeter measures rail in two directions simultaneously, and indicates the weight of the section in lb. per year by a pointer on a scale. If side cutting is present, a reading from a side-cut gage is subtracted from the reading of the Railimeter. Where the rail is galled it is of course necessary to displace the chair at the gall when measuring the weight of this section. A chart estimating rail life based on the Railimeter reading is illustrated. The results obtained with this instrument compare favorably with more laborious methods previously used.

VEHICLE DESIGN RELATED TO TRACK CONDITIONS
Recommendations which may influence improvements in the safety and comfort of passenger-train rolling stock are made in a paper, Vehicle Suspension and Bogie Design in Relation to Track Conditions, by Mr. R.M. Hancock of British Railways. The paper deals with the necessity of relating vehicle suspension and bogie design to the track conditions likely to be encountered in practice, particularly where lateral and crosslevel wave shape are concerned, as these are most likely to produce discomfort. The vehicle-response basis of systematic testing main routes as carried out with the Western Region track-testing car has provided much of the experience from which the illustrations in the paper are drawn. The effects of coning and track shape, in relation to the riding of four-wheel vehicles, are considered with reference to an investigation of their derailment in fast trains.

THE EFFECT OF TRACK GEOMETRY ON RIDE QUALITY
In this test, acceleration measurements were taken with one lateral and one vertical accelerometer attached to the floor of the test car. The sensitivity of ride roughness to changes in crosslevel during the negotiation of a curve is shown. Also shown is the change in ride response due to bolted to welded rail transition. The track geometry measurements used in this investigation were: centerline profile, the average profile of both rails; alignment; gauge; rate of change of gauge; and warp. The track and ride data were then sorted according to speed. The data for the 100-110 mph tests are plotted on scatter diagrams. Correlation coefficients were then computed for each of the six track exception densitites and the density of the sum of all exceptions with vertical, lateral, and mean lateral/vertical ride. The results are shown.

Though sample populations are small, data correlation is sufficiently reasonable to lend support to the approach.

Paper recommended by IEEE Land Transport Committee of the IEEE Industry and General Applications Group for presentation at the joint IEEE/ASME Railroad Conference, Montreal, Quebec, Canada.

THE SUPERELEVATION OF RAILWAY CURVES

The most suitable superelevation for a given curve is determined as follows: the average speed on a tonnage basis should be ascertained from the actual known speeds of all trains, and the curve given the full theoretical superelevation corresponding to this average speed; and the maximum permissible speed on the curve should then be fixed as that corresponding to the above superelevation plus 4 inches. The first condition will result in equal loading of the two rails, and hence equal head wear and even maintenance of surface. The second ensures passenger comfort, and gives an ample factor of safety against derailment which is uniform for all curves, while at the same time it fixes an upper limit to the lateral forces acting on the track which is also the same for all radii. A table gives the superelevation for various radii for different average speeds, and the corresponding maximum permissible speeds.

TRACK MAINTENANCE AND HIGH CAPACITY TRUCKS

The high capacity truck from the maintenance of way standpoint is the means by which the increased gross weight of the large modern freight car is transmitted to the track, roadbed, bridges, trestles, viaducts and culverts, over which it must pass. As such, its design, dimensions and position are of vital concern to those responsible for the satisfactory operating condition of the railroad. Stress in rails and joint bars, track deflection, maximum load on ties and effect on undergrade bridges require specific consideration in determining whether or not a car can be accepted for movement; and if so whether it will be free-running or whether it will be restricted as to speed and routing. An immediate concern in relation to high capacity car trucks is the anticipated increase in shelling rail failures due to increased bearing pressure. Shelling rail failures are the result of the plastic flow of metal from the middle portion of the head toward the guage corner under high shearing stresses produced by intense wheel loads eventually starting a horizontal crack. The Joint Committee on Relation between Track and Equipment has recommended maximum axle loads of 52,800 pounds on 33 inch wheels, 58,400 pounds on 36 inch wheels, and 62,400 pounds on 38 inch diameter wheels.

SNCF PROBES THE 200-300 KM/H SPEED BAND

Recent tests at high speeds have shown that ample adhesion exists to overcome train resistance at 300 km/h and no technical factors need prevent

commercial operation on steel rails at this speed. High speed running does not seem to produce any particular wear of parts other than wheels, although a close eye is kept on the friction linings that damp the pantograph. For the track, the SNCF does not consider it economically desirable to raise maintenance standards beyond those now considered necessary for speeds of 150 km/h. The policy is to build the rolling stock in such a way as to exert no greater forces on the track at high speeds than the trains of 20 years ago caused at the lower speeds then prevailing. Ride quality and current collection are discussed.

SOME RECENT FACETS OF CONTINUOUS-WELDED TRACK PRACTICE IN BRITAIN
Maximum working temperatures have been laid down for continuous welded rail above which it is not permissible for consolidation of the track or work to be undertaken on it. With slag or crushed stone ballast this temperature has been set at 32 deg C. Should slewings at any time exceed 1-1/4 in. the whole of the rail length affected must be restressed. An important aspect of continuously welded track is the strict adherence to restressing and destressing procedures. These have been developed to ensure that continuously welded track is kept in a uniform and safely stressed condition at all temperatures.

WEAR OF RAILS ON CURVES
Abrasion caused by locomotives and electric motor coaches, the condition of the track, and methods of alleviation are discussed. Insufficient information is available to say what type of vehicle produces the most rapid wear in the outer rails on curves. Increase in tractive effort may result in increased transversal reaction and greater lateral wear of the rails. Rate of wear varies inversely as the radius of the curve, but no quantitative relation between degree of wear and radius has yet been established, nor have the effects of irregularities in curvature. What is certain is that excess or deficiency in cant causes unequal wear on rails.

RULES FOR THE DESIGN OF CURVES
To ensure safety and the riding comfort consideration has to be given to the cant of the track, the rate of gain of the cant, the gradient leading up to, or down cant deficiency, and rate of gain of cant deficiency. In providing cant on a curve, precise rules alone cannot be applied. Usually it should be the equalibrium cant for a selected or equilibrium speed. On curves carrying mixed speed running, a mean speed should be selected-- usually the average speed of ordinary passenger trains-- and equilibrium cant should be provided for that speed. The maximum speeds for turnouts and reverses for some typical crossovers between straight mainlines with various spacings, and laid without cant are shown.

INTERIM REPORTS ON DERAILMENTS AT LICHFIELD, SOMERTON AND SANDY
This is an accident report of three derailments in England which occurred during June-July, 1969. All took place in welded rail and all were caused by distortions or buckling of the rail. No definite conclusions as to the cause of the incidents aside from an inherent track weakness were reached. Causes for track distortions, during the period 1958 to 1968, are reviewed.

INSPECTION AND MAINTENANCE ON A HIGH SPEED RAILWAY
Despite consistent operation at 200 km/h, cars on the Tokaido Shin Kansen now cost less to maintain on a distance-run basis than JNR's 3-ft 6-in gauge electric railcar fleet which is limited to 120 km/h. As a result of a review of maintenance procedures for rolling stock and fixed equipment, the labor force now used to maintain 515 km will be redeployed in 1972 to cover the 165-km San-yo extension as well. Periodic inspection and maintenance routines are given and failures of electrical equipment over a five year period are itemized.

RUNNING THROUGH CURVES
Economic considerations demand high average, rather than occasional high maximum speeds. Rapid acceleration and retardation are essential and vehicles must also be able to negotiate curves at high speeds, which is of particular importance for lines with many curves. The forces acting on a vehicle running in a curve are shown and the limiting valves of speed and the effect of axle load on speed through curves are established mathematically. Transverse flexibility is important in reducing dynamic forces at curve irregularities. Time-speed and time-distance curves for a single car and for a car and trailer are plotted for electric hydraulic and mechanical transmissions.

DEVELOPMENT OF THE CONCRETE SLEEPER
The article discusses the unique advantages of concrete crossties as outlined by the French National Railways. There are three basic types of concrete crossties; reinforced concrete, prestressed concrete and special, which is defined as asbestos cement, longitudinal and zig-gag. Representative crossties within the categories are described and some are illustrated. The manufacture of these ties is described as well as experience with them on French, German, Swedish, Italian and Netherlands railroads.

BALLAST COMPACTOR
The windhoff ballast compactor has been designed to follow immediately behind a tamping machine, reprofiling and compacting the ballast to its previous standards. It is self-propelled and has 10 vibratory compacting arms. Eight of these are mounted vertically, two on each side of each rail, while the remaining two are larger side-mounted units for compacting the ballast shoulders. Shoulder compactors are adjustable to suit the cross-section of the ballast, and the static pressure, frequency and intensity of

vibration, as well as its duration, can all be regulated to obtain optimum results.

DESIGN STANDARDS FOR EUROPE'S FIRST 250 KM/H RAILWAY

This article is concerned with changes made in the rail line which runs from Rome to Florence, Italy, so that speeds of 250 km/h may be attained. Problems include the rough terrain such that 31% of the route will be tunnel and 13% will be over viaduct. Details of bridge design, electrification, as well as characteristics of tunnel design and roadbed construction are discussed in relation to the requirements of high speed operation.

PERMANENT WAY CONSTRUCTION AND PROCEDURE STANDARDS ON THE FRENCH NATIONAL RAILWAYS

The author details the standards of track construction and track maintenance procedures on the French National Railways. Prescribed superelevations are given, together with the transitions. The shape and form of the standard cross-section of the ballast are shown on a drawing. The tracks are grouped in classes as to usage and load, ranging from IA, IB, II, IIA, IIIB, to IV. Many other details are given relating to rail fastenings, rail joint bars (6 hole), concrete ties, and expansion joints in the rails. Altogether, this is a comprehensive presentation of the French track standards.

ELASTIC RAIL SPIKE DEVELOPMENT

The development of a simple and economical fastening for use with flat-bottom rail resulted in development of the elastic rail spike. This provided a simple and economical fastening for use with flat-bottom rail on wood sleepers. The lockspike baseplate fastening, which is an alternative to the elastic rail spike, is a simple one-piece spring spike designed specifically to secure baseplates to wood sleepers. It fills the hole in the baseplate by spring action in a lateral direction, and holds the track gauge secure with the baseplate fixed firmly to the sleeper. For high speed track it is evident that an indirect rail fastening is desirable. A large number of designs have been developed and tried on many railways in an attempt to obtain the ideal independent rail fastening. The need to reduce track maintenance led to the development of spring clip. The Pandrol fastening, which is designed for reduced track maintenance, provides an adequate toe load on the rail, and this toe load is the result of considerable deflection which is more than adequate to absorb normal manufacturing tolerances and small wear which could occur in service. The Pandrol rail fastening is also ideally suited for use with steel sleepers. This assembly is one of the most economic methods of securing a rail to a steel sleeper and at the same time providing adequate resilience and freedom from maintenance problems.

WELDING JOINTS FOR HIGH-MANGANESE CROSSINGS

The efforts by the Budapest Research Institute for the steel industry to develop a technique for welding Hadfields steel to ordinary rail steel so as to enable these fishplated joints to be eliminated have been successful, and patent rights have been taken out. The process developed by Kalman and Kisfaludy enables welding to be carried out without allotropic conversions taking place, and the two types of steel can be welded without difficulty. Joints welded in this way have been submitted to a mechanical bending-rupture test with 1-m separation of the supports. The joints withstood the specified 15 mm buckling with cracks. These joints have already been in service without a failure for over a year.

FLANGE AND RAIL LUBRICATION

The Japanese National Railways has experimented with systems to reduce wheel and rail wear. Results of tests show that rail oiling reduces electric current consumption by 66%, reduces wheel wear to 1.25%, and reduces rail wear to 1%, compared with dry rail. Three systems have been suggested for lubricating the rails: site lubrication where it is picked up by the flange; flange lubrication in the vehicle; and automatic lubrication of the inside rail edge. A comparison of various devices to accomplish lubrication is included as well as a description of each system. Benefits of lubrication for different situations are included in a series of tables and charts.

STRESSES BENEATH A RAILWAY TRACK

By physically testing track structure the British Railways attempted to confirm the validity of theoretical stress calculations. Those stresses studied were located beneath the track, between the sleeper and ballast, and within the track formation proper. Results show blanket material does not influence stress level. They found agreement between measured and theoretical results. There is a greater degree of reversing shear in the formation than in the blanket layer.

SIMPLE STABLE RAIL FASTENING

The Springlock fastening, designed and patented for use with pre-or post-stressed concrete cross ties and long welded rails, comprises a steel stirrup cast into the sleeper body, a spring-steel vee-clip, an insulator and a heel block. The last two items are precision-injection mouldings in thermo-setting plastic materials. The stirrup is an accurate pressing made in Corten steel to resist corrosion, and the vee-clip is hardened and tempered to ensure a constant and consistent grip loading. Insulators are positioned on the rail feet, the vee-clip is slipped in beneath the stirrup by hand, the heel of the clip is then raised and lowered on to the heel block. The whole procedure is quick, no further adjustments are needed.

SYNTHETIC RESIN BONDING

Solventless adhesives do not require heat or pressure to provide sound joints, and therefore, have proved useful in railway engineering for they are amenable to site application. Two types of adhesive in particular have permitted these advances: polyesters and epoxides. A sleeper which has been made good with epoxide resin mortar is illustrated. Repair of E4 concrete sleepers under chaired track is carried out by displacing the sleeper and drilling holes, so that fastenings may be made good by using a polyester resin to secure rubber inserts in the concrete. Resins have been used to repair manganese steel crossings. Limitations on the use of adhesives for fixing chairs and baseplates to concrete sleepers appeared to be the difficulty of surface preparation of the metal, large glue line thickness, and low resistance to impact and peeling forces of the adhesives used. Cable hangers have been attached to a tunnel wall using an epoxide adhesive.

A2 037837
CONCRETE SLEEPER TO RESIST THE EFFECTS OF FROST
Serious frost heaving is a menace which is encountered frequently in Japan. The pre-requisites of a prestressed sleeper to be used in such winter climates are that it must resist the distructive action of frost, and the metal and rubber parts of its fastenings must not become brittle or deteriorate at low temperatures. To ensure this resistance, air-entrained concrete should be used and its surface must have no holes, hollows or depressions, however slight, in which water can lodge. Rough edges and corners where deterioration in the concrete begins must be avoided, and the whole must be of fine concrete and quite smooth. The design of both sleeper and fastenings must be such that they will resist abnormal rail-loading and ballast reaction during frost-heaving and subsequent thawing. A special sleeper, Type 3F, was prepared for a series of tests in mid-winter in Japan. This prestressed sleeper contains 20 pairs of 2.9 mm diameter prestressing wires. Stresses were recorded during the most severe season of frost heaving. The expected centre-binding of the sleepers did not take place during the frost-heaving; instead many sleepers were supported under the ends as beams. In the cross-sections of the sleepers under the rails the measured values of the resisting moments were below the design values during both frost-heaving and the following thaw. Further testing is considered necessary before these sleepers are accepted as a standard.

LONDON TRANSPORT RAIL DE-STRESSER
A new device was designed for de-stressing long-welded rail after any disturbance to them in cold weather. The machine, a rail-heating trolley is so geared that it is easily propelled along the track by one man at the low operating speed required--about 2 mile/h. At each corner of the trolley is carried a 100-lb bottle of propane, and from these, flexible hoses run to the rail heaters. The equipment is designed for use on the open sections of line. De-stressing is not necessary in tunnels as the temperature remains almost constant throughout the year. On open lines, rails are de-stressed after they are installed, and it is only necessary then to de-stress them again when they have been disturbing for changing a block-joint or resleepering outside the mid-range temperature.

CROSS-SECTIONS BY PHOTOGRAMMETRY
When exceptional loads have to be conveyed by rail, measurements must be made along the route to determine by how much the normal loading gauge may be infringed. The Swiss Federal Railways has devised a method based on stereoscopic photography and has built a special measuring vehicle that houses the appropriate equipment. Stereo photographs coupled with a special viewing attachment permit the recording of continuous profiles as a cross-sectional diagram. The vehicle is equipped with a dark room to provide immediate on site inspection of exposures. An electric tractor is used to take the vehicle to site and also provides a 220V supply for the spotlight, heating, and charging of the car-lighting batteries. In transit speeds up to 56 mph are permitted. While operating, the speed is limited to 18 mph.

WEAR AND CORROSION OF RAILS
The use of the Shaw Rail Contourograph to measure vertical wear is described and illustrated. The wide limits of specific rail wear on the British Railways and London Transport are shown as a result of corrosive influence of atmospheric pollution in tunnels and industrial areas. Annual wear is approximately proportional to the square root of the number of axles passing per annum. A comparison between the British and American rail wear values shows much lower values in America for specific wear at the same traffic intensity. This may be partly because of the higher carbon content in America where the relative humidity is above 80 percent for much fewer hours per annum, and atmospheric pollution from industry is less concentrated than in Britain. The effects of steel composition, axleload and braking on rail wear are discussed.

V-CLIP RAIL FASTENING FOR CONCRETE SLEEPERS
This fastener was developed for S.H.C.-type concrete sleepers, in hope of achieving a larger working deflection than the standard S.H.C. rail-fastening. Whereas the rectangular clip has a thickness of 0.225 in. the V-clip is 0.196-in. thick, to provide a toe-deflection of 0.420 in. with a minimum toe-load of 3.4 ton. The toe-load and deflection of the rectangular clip were 0.90 tons and 0.30 in. so that the improvement effected by using the V-clip made the effect of rail, sleeper, and hoop tolerances much less significant. The V-clip is less expensive to manufacture than the standard clip and laboratory and track tests confirmed the technical advantages of the V-clip.

BRITISH RAILWAYS TO STANDARDISE F.B. RAILS
The conversion of the British Railways, excluding the London Transport railways, to 109-lb flat-bottom rail for main lines and heavily travelled secondary lines and high speed lines and 98-lb flat-bottom rail for lightly travelled lines is discussed. The conversion from bull-head rail for 22,000 track miles is projected to take 40-50 years. The 109-lb rail will be 4 percent heavier than the 95-lb bull-head rail per track mile. Cost savings are expected due to increased life, reduced maintenance and fewer components, such as fasteners, needed when compared to the bull-head rails.

THE NEW STANDARD BRITISH RAIL
The British Railways, excluding the London Transport lines, has adopted as standard the flat-bottom rail instead of the traditional bull-head type. Diagrams are given of 113-lb, 109-lb, and 98-lb flat-bottom rails. The 109-lb rail will be used on main-lines and others carrying intensive traffic at high speeds. It will replace the 95-lb bull-head rails. The 98-lb flat bottom rail supersedes the 85-lb bull-head rail for secondary lines. The new rails will be much stronger both vertically and laterally than the bull-head types they are replacing and will keep better alignment. Comparisons of the properties of the 109 lb and 98-lb flat-bottom, rails are made with the bull-head rails they will replace.

EXPANSION IN LONG RAILS
Experiments have been conducted on rails up to 1 mile long. These rails are fixed by means of the resistance of the fishplates, sleeper fastenings, and

sleepers themselves embedded in the ballast; thus, for a 75 degrees F temperature variation above and below the temperature at which the rail was laid, a total force of about 61.3 tons (137,800 lb) is brought into play for a 96-lb rail, and the tendency to push the rail ends away from the center of the rail is resisted, and contained within the rail in the form of compressive stress (or with the tendency to contraction, tensile stress). The prevention of a rail from expanding or contracting causes an internal stress of 195 lb per sq. in. for each 1 degree F change in temperature. To minimize these high internal stresses, it is customary to lay long rails at the mean average annual temperature, and thus reduce the tendency of the rail to buckle, if the fastenings should become weakened. One of the great difficulties with long rails, apart from the practical limitations provided by transport, is that the opening up of the track can be done only at approximately the same temperature as that at which the rail was laid. The London Transport railways has used sliding expansion joints at the ends of the long sections. this expansion joint enables the keys to be knocked out, and any tendency toward expansion or contraction which may be imprisoned in the rail can exhaust itself at each end before further operations are begun.

FORMATION STRENGTHENING ON THE BOURNEMOUTH LINE, SOUTHERN REGION

Extensive blanketing work was undertaken to stabilize the roadbed. Most of the worst trouble was experienced in the neighborhood of certain of the bridges over cuttings where lifting of the track to provide a greater depth of ballast over the soft formation has been impossible. Rather than raise the bridges, which are mostly brick arches in good condition, it was decided to dig out the weak formation materials. In 1948 and 1949 nearly a mile of double track was treated in this way, and in addition, extensive drainage work was undertaken to collect the water flowing into the cuttings. All of this work was highly mechanized and one of the characteristics was the small amount of labor required. A diagram of a four-mile section between Brockenhurst and New Milton shows the location of blanketing works.

LONG WELDED RAILS IN THE CASCADE TUNNEL, U.S.A.

The long welded rails were used in the recent renewal of four miles of track in the Cascade Tunnel. The tunnel, which is 7 miles 1,397 yd. long carries the main line of the Great Northern Railway from St. Paul to the Pacific coast through the Cascade Mountains. The railway was laid with 110-lb rails, rolled to the standard American length of 1,326 feet de-stressed by heat treatment, tested magnetically for flaws, cleaned, and given a coat of anti-corrosive paint. The new rails are secured by four cut spikes in every baseplate. The rails are anchored by 48 grip-type anchors in each 39-foot panel. To provide anchorage in both directions, these are applied in pairs for each rail against both faces of alternate sleepers. Insulated joints are inserted in the track at intervals of one mile.

A DIESEL-ELECTRIC TRACK SWEEPER

To remove cinders and wagon spillings from the track, a combined diesel-electric scarifer, sweeper, and conveyor machine is now in service on the Pennsylvania Railroad. The scarifier consists of 18 curved strips of spring steel each having a detachable digging tooth. Ten of the prongs rake between the rails and the other eight outside the rails. The sweeper is a rotating broom comprising a metal shaft with a number of arms or brackets to which are bolted steel segments forming a closed cylinder. The train travels about 2 mph and the broom rotates at 100 rpm. Refuse is removed to a level just above the sleepers and is thrown onto a series of three conveyors, which deposit the sweepings into a series of hoppers. Photographs show the sweeper train and the sweeping equipment.

IMPROVEMENT OF TRACK FORMATION

The problems involved in maintaining a satisfactory track on unstable formations, and the remedial measures adopted are considered. In recent years, it has become the practice to remove all overstressed and disturbed materials with the best load spreading properties. The biggest range of problems arises on formation renewal work of the blanketing type. Considerable success has been claimed in America for pressure grouting and driving a pointed "spud" at close spacing into the formation, and filling the holes with sand. In France and in Denmark, blanketing with sand has proved satisfactory. On the Netherlands Railways, fine sand or ashes are used for blanketing clay formations. In Sweden, weak tracks have been strengthened with a continuous mattress of logs laid transversely under the ballast on a blanket of fir tree branches or a layer of fascines. On the Norwegian railways, dried peat has been used as a precaution against frost-heave.

TRACK STABILIZATION AT WADDESDON, EASTERN REGION

Sand piling was adopted as part of the treatment of soft clay formation in a shallow cutting. The operation consists of driving a 9 in. dia. steel spud into the formation between and at the ends of the sleepers, withdrawing on reaching a specified depth and finally filling the hole with sand. A pattern of four piles every sleeper was found to be satisfactory. The track, as was expected, heaved as the piles were driven, the average heave being 2 inches. the rock layer was encountered at depths varying from 3 feet to 5 feet and was missing altogether in places. The drainage is being renewed; precast concrete channel drains are being used.

TYPES OF SLEEPERS AND SLEEPER MAINTENANCE
Wood, steel, and concrete sleepers are compared based on experience to date with each type. No alternative has been found to the cross-tie or sleeper and timber was almost universally preferred at the time. Steel sleepers begin to fail from corrosion followed by cracks around the baseplate. Concrete sleepers may fail through cracking with ultimate exposure of the reinforcement. On an annual cost basis concrete may prove to be the cheapest sleeper-but this opinion is based on an estimated 50 year life for pre-stressed sleepers and experience is insufficient to justify the estimate. Preservation of wood sleepers is usualy by creosoting. The article concludes that treated timber sleepers with fastenings are approximate in cost to steel sleepers, with concrete sleepers costing more than either.

LONG WELDED RAILS IN THE U.S.A.
Experience to date with continuously-welded rail has revealed the following facts: (1) A sound practicable welded joint can be made. (2) Welded rail in long lengths can be transported and installed readily. (3) In the climate of that part of the U.S.A., welded rail should not be installed at a temperature under 60 degrees. (4) Welded track can be surfaced, lined, and otherwise worked without risk when done at a temperature equal to or less than that at which laid. (5) There are fewer failures in welded rail than in jointed rail. (6) Proper superelevation must be maintained on curves for the type of traffic handled to secure the maximum life of the rail on curves. (7) It is practicable to transpose welded rail on curves to increase rail life. (8) It appears that a less expensive fastening for welded rail is possible. (9) Difficulties experienced with continuously-welded rail can be eliminated by proper construction and maintenance. Considerable statistical data are included on costs and number of welds.

BALLAST CLEANING
The cause and cleaning of dirty ballast are summarized. Information presented was extracted from a technical paper. It was found that if the ballast shoulders and the "cribs", or ballast between the sleepers-together comprising under 40 per cent of the total section-are cleaned, the work will be more than 60 per cent effective. In opening out the ballast preparatory to cleaning, care must be taken not to disturb the part under each sleeper and, in removing the shoulders and cribs, at least 1 in. or 1-1/2 in. should be left intact against the sleeper and the excavation sloped off thence at 1 to 1. Permanent way staff are warned against scooping 3 in. or 4 in. of ballast from under the ends of sleepers to remove the mud which tends to collect there to form compact dams round and under the sleeper-ends. Good ballast cleaning with modern plant will remove 85 to 90 per cent of the dirt.

PREVENTION AND DESTRUCTION OF WEEDS ON THE PERMANENT WAY
A number of suggestions are advanced for clearing tracks of weeds that have gained a foothold in the ballast. The expedient of renewing the ballast has been tried on certain lengths, where perennial weeds have become particularly troublesome. This has not always had the desired effect as the new material appears to have acted as a fertilizer. Annual weeds, although not so deeply-rooted as many perennials, call for special attention, as they grow quickly. The grasses growing on embankments and the sides of cuttings can give serious trouble, if they are allowed to seed on to the ballast. This can be prevented by cutting the grass early in the summer, before the seeds have formed. A second cutting, in August or September, is advisable, to prevent late seeding. The disposal of old and dirty ballast has an important bearing on the problem of weed prevention. The introduction of weed-killing trains, fitted with chemical sprayers, has alleviated considerably the task of the maintenance gangs, but it is not always easy to find paths for these trains on lines that carry a heavy traffic.

FLAT-BOTTOM TRACK
In a comprehensive review of the potentialities and development of flat-bottom track extensive reference was made to experiments on the L.M.S.R. and showed that compared with the 100-lb B.S. bull-head rail, the 110-lb. B.S. flat-bottom section had the advantage or 41 percent, increased strength in the vertical plane, and the wide foot (6 in.) gave considerably greater resistance to bending in the horizontal plane. Taking the standard 95-lb B.S. bull-head as a basis, the 100-lb. flat-bottom was 43 percent stronger in the vertical plane, the 113-lb 62 percent, and the former 131 lb. American section 85 percent stronger. Considered as a beam, the 113-lb. flat-bottom rail was 62 percent stronger and 88 percent stiffer than the B.S. 95-lb. rail. The 113-lb. flat-bottomed rail was approximately two and a half times as stiff laterally as the bull-head section, due to the bottom flange of 5-1/2 in. The B.S. 110-lb. flat-bottomed was even better in this respect and with its 6-in. base, was three times as stiff. The article concludes that a considerable period of experiment would be necessary before it became possible to translate into terms of an accurate financial comparison, the relative merits of full-head and flat-bottom track.

THE PROBLEM OF THE TOP RAIL
It is a matter of common knowledge that the least reliable part of any normal steel ingot is the top. Standard rail specifications require that the rail shall be free from all top-of-the-ingot defects, and though in principle this requirement is carried out, in actual practice the average top rail from the ingot is not 100 percent free from the influence of these defects, as the broken rail records of every railway show. Theoretically the top rail should be the equal in quality of the middle rail or the bottom rail; practically it is not always so. Things that can and cannot be done to insure sound top rails are reviewed. From the manufacturing point of view, additional precautions can be taken to assure sound top rails, but they add to manufacturing costs. One is to cast the ingot large end up and provide it with a head encased in a refractory lining, which keeps the top of the metal molten until the ingot

proper has solidified. Another precaution is to cast a larger ingot, so that a greater percentage of crop may be removed from the top end.

CROPPING BATTERED RAIL-ENDS IN THE TRACK
The Southern Railway of America has perfected a method of cutting off the battered ends of rails in the track, and restoring the road without interruption of train service. The method involves cutting off rails in situ, re-drilling, drawing up the rails, and inserting closures as necessary to compensate for the removed materials. It is estimated that the life of the rails will be extended by 6 years, and joint maintenance will be reduced by 10 percent. A maximum of 263 rails has been cropped in a single day of light traffic, but the average is 150; cost has varied from $0.98 to $1.26 for each rail-end cropped, or an average of $1.10, which works out at $2.20 for an entire rail. In a year, 42 miles of track have been successfully reconditioned.

HOW LONG CAN A RAIL BE?
The continuous welding of rails as practiced in the United States by five railways is summarized. Summarizing the collective views at the time of this article, it was clear that expansion and contraction would not present problems. It was equally clear that there are appreciable savings in the costs of maintenance as compared with standard jointed track. There are good prospects of longer rail life, because destructive action on the part of the rails is reduced. Rolling stock rides more quickly and smoothly. Track circuits give less trouble, and can be lengthened.

LARGER SOLEPLATES FOR SLEEPER PRESERVATION
The Norfolk and Western Railway introduced a large steel soleplate to increase the life of bridge timbers directly used for the support of railway track. It was soon realized that if these plates were substituted for the 13-in. plates already in use on bad curves in main lines, the former would bridge the spike-killed portions of the timber, and make it possible to drive the holding-down spikes in sound wood. It was hoped also, with the greater length to reduce if not to eliminate plate-cutting. So far as possible the 18-in. plates have been inserted only as part of a complete relaying operation. Where desirable, special methods have been devised lengthening the existing soleplate seats in order to accommodate the longer plate. The operation of substituting the new plates is performed by a gang of 20 men, who first draw the old spikes, remove the old plates, adze the sleepers, plug the old spike-holes, and then insert and spike the 18-in. plates.

EXTENSIVE USE OF FORMATION GROUTING
Cement grouting as a cure for unstable railway formation is not intended to provide a concrete slab under the ballast, but to stabilize the existing formation by driving out from it all free water and semi-liquid soil, which surges under passing trains. In fact pressure grouting has a double function by filling all the voids and setting in them, it seals them against penetration of further water by pumping action from below, and also from above. The grout, which is usually one part cement to five parts of sand, forms with the lower ballast a cemented mass that distributes the load evenly over the formation. The experiences and technical achievements of the AT&SF Railway with cement grouting are reported.

FASTENING FLAT-BOTTOM RAILS ON CONCRETE SLEEPERS
The Skull Hoop Clip fastening consists essentially of two steel hoops cast into a class "F" concrete sleeper on each side of the rail seat, and two resilient spring steel clips. Insulation of the assembly is provided by a rubber rail pad and two insulators to fit between the rail flange, the vertical bars of the hoops, and the spring clips. Laboratory testing included torsion, creep, and moment of resistance tests. The results showed an efficiency superior to that of most other fastenings tested in the same manner. Besides a superior holding-down efficiency compared with a number of other types of fastenings, this clip features simplicity of design, ease of assembly, and extraction of the clip without the need for specially designed tools.

THE A.D. RAIL FASTENING FOR CONCRETE SLEEPERS
A new type of rail fastening, for use with flat-bottom rails and Class F concrete sleepers with modified rail seatings, are in use with long welded rails on a main line of the British Railways Track sections are illustrated. The assembly consists of an insulating clamping block, malleable cast-iron containing collar, and triple-coil spring washer. These are secured firmly in position against the rail foot by a holding-down bolt, tightened by a flanged nut and restrained by a locking pin which passes transversely through the concrete sleeper and also through a hole in the end of the holding-down bolt. The rail is seated on a rubber pad.

MODIFIED BLANKETING
The two main types of soil foundation failure are pumping and strength. Pumping failures derive from slurry formed from ballast or erosion in the vicinity of the sleepers, especially near rail joints. Strength failures occur with a greater time-lag than pumping failures, and are recognizable by heaves of soil in the cess, six-foot way, or four-foot way. A modified method of blanketing is described and cost estimates are made for the re-ballasting process.

AUTOMATIC WELDING, GRINDING, AND HANDLING OF LONG RAILS
An electric, automatic, flash welding machine, designed by a Swiss firm, is being used to weld 132-lb., 39-ft. rails for the Louisville & Nashville Raolroad. Rail ends are ground to remove rust, then heated to plastic consistency and forced together with a 30-ton force. A 50-ton hammer-blow

forces foreign matter, gases, and surplus molten metal from the weld. An automatic grinder removes mill-scale and hand-grinders are used to remove any remaining roughness. The welding unit, grinder, and pusher are mounted in tandem on a 60-ft. all-steel car. About 60 welds per 8-hr. shift can be made by a crew of 8.

SOME PROBLEMS OF WHEEL/RAIL INTERACTION ASSOCIATED WITH HIGH-SPEED TRAINS
The objective of the study is to identify and evaluate potential problems involving wheel-rail interaction which could limit the speed of a high speed rail (HSR) system. The study is based upon a survey of existing knowledge in the areas pertinent to wheel-rail interaction; no extensive analytical work is presented, but several approximate calculations are given. An attempt has been made to investigate possible wheel-rail speed limitations and to set aside some of the 'non-problems' which may at first appear to constitute a serious constraint upon rolling HSR concepts. The results and discussion are concentrated in four main areas; estimation of the dynamic loads; wheel behavior and structural integrity; rail dynamics and structural integrity; adhesion, hunting, and related problems. STABILIZED BALLAST INVESTIGATION
The purpose of the investigation was to evaluate the ability of a compound to enhance the load resistant characteristics of conventional stone ballast. This compound, an emulsion based on a new butadiene-styrene block copolymer, was sprayed on the stone ballast of a short section of railroad track. A second section of track, similar but untreated, provided the sample of conventional construction. In the conduct of the investigation pulsating, single point, vertical loads varying from 5000 lbs. to 50,000 lbs. (and to 75,000 lbs. in some cases) were applied to, first, the untreated track and, then, the treated specimen in a uniform manner for 4,000,000 cycles. The treated ballast was finally subjected to 11,000,000 vertical stress cycles. Static lateral stress was also applied to each section. Comparisons established through this study are, conservatively stated, that the permanent settlement of ties supported on the untreated ballast was 10 times that recorded for the ties of the treated ballast test phase. Resistance to lateral displacement was, at least, five times greater for the treated specimen than for its companion. (Author)

A STUDY OF NEW TRACK STRUCTURE DESIGN, PHASE II
Phase 1 of this research investigation was undertaken in September, 1966, for the Office of High Speed Ground Transportation (OHSGT) of the Department of Commerce by Battelle Memorial Institute for the purpose of conceiving new and improved track structures for high-speed trains. As a result of the Phase 1 program, a number of track structures and fasteners were devised which met the specified requirements. Following the conclusion of the Phase 1 program, the OHSGT requested additional studies and computer analyses of track structures and rail fasteners. The additional track structures of interest were chosen by OHSGT from many designs which had been submitted to them. In addition to the analysis of the track structures, they were interested in a more detailed analysis of rail fasteners, particularly any analysis which was amendable to computer techniques. This project (which was then designated as Phase 2) was then conducted, and the results are summarized in this report. The report contains detailed discussion of material summarized in: 'Studies For Rail Vehicle Track Structures,' PB-194139, and is a reference source sited in that document.

BALLAST TAMPING
The first types of mechanical tampers sought to imitate the action of the beater packing. These tampers resemble a road drill with a blunt T-head steel which delivers about 90 blows a min. to the ballast at the bottom of the sleeper. The type of mechanical tamper which has been most widely used is that having a "vibrate and squeeze" action. The use of vibration (about 2,000 blows a min.) causes the ballast to flow into a closer arrangement of particles, and by combining this with a squeeze it is possible to obtain the result more quickly and to control the formation of the ballast mold. The standard Matisa machine was produced to meet the special requirement for packing hollow steel sleepers. The Matisa machine applies its squeeze mechanically by means of left-and right-hand threaded shafts.

CIVIL ENGINEERING MAINTENANCE WORK
Regular examination is the basis of railway civil engineering maintenance work, ranging from daily examination of passenger-carrying lines to underwater examination of the piers or abutments of a bridge at 20-year or longer intervals. The Matisa track-recording self-propelling trolley unit, introduced during the last two years, enables reliable records of cross level, track curvature and track gauge to be obtained at a running speed of about 20 mph. Examination of rails with manually-applied ultrasonic-type flaw probes was introduced in 1954. A special rail-mounted adaption of the principals and mechanism of the Simon hoist has been developed to provide better means of regular examination of high masonry vaiducts. At the end of 1958, only two major equipment developments were being pursued. First, a prototype "on track" self-propelling machine was under construction. This is designed to excavate track ballast from outside the ends of sleepers, and screen it, and replace the clean ballast. Secondly, a design of a type of low-loading lorry with both pneumatic-tired road wheels and steel flanged tired wheels is being developed.

RAILWAY SLEEPERS IN ASBESTOS CEMENT
A brief description is given of asbestos cement sleepers, the method of manufacture, characteristics and present usage. Asbestos chrysotile a hydrated silicate of magnesia, is very pliable and contains an extremely high tensile strength approximating that of steel wire. Railway sleepers are manufactured by compressing several thin layers of asbestos cement while still in a pliable condition and arranged in such a way that the fibres are evenly oriented. The sleepers are supplied in two classes. These vary in thickness dependent on their intended use, principally in respect of traffic density and speed. Two types of rail fastening are offered; a rigid fixing for secondary lines and sidings and spring type clips for high speed traffic. Asbestos cement offers very high insulating characteristics. While the life of the asbestos cement sleeper can only be assumed, practical tests show that it remains unaltered after 20 years of use.

WHEEL AND RAIL LUBRICATION
Remarkable increases in life of rails and wheel flanges through lubrication, by as much as 700 percent, are quoted by Dr. Fritz Birmann, in his paper "Lubrication of Rails and Wheels." The requirements of a lubricating system to reduce wear of rails and tires, are that the lubricant must be prevented from spreading to the running surface of the rail, thereby reducing traction; that the efficiency of the system must not be spoiled by dust, dirt or weather influences; that the lubricating devices and spray nozzles must be profile free on the rail and vehicle; and that lubrication must not start too late on the curve, so that it is preferable, where possible, to lubricate tires before entering the curve.

RAIL CORRUGATION--CAN IT BE PREVENTED
This is a research report which attempts to determine the causes of rail corrugation. The author suggests that higher rail speeds may cause rail corrugations or undulations as deep as 0.01, which accelerate rail wear. A relationship is established between the natural frequencies of rail vibration and the wear length of the corrugation. Further experiments are required into the possibility of eliminating corrugation by axle redesign as well as changes in rail profile and tie spacing.

EXPERIMENTAL RESULTS OBTAINED ON THE LATERAL PROBLEMS OF THE LONG WELDED RAIL CONTINUOUSLY LAID ON SEVERAL SPANS OF THE BRIDGE WITHOUT BALLAST
To show the lateral stability of continuous welded rail on a bridge, and the character of the lateral load to the bridge as a result of such rail, a test was conducted by the JNR on an actual bridge. The data resulting from this test shows that even though there were no problems resulting from unballasted rail on a bridge, the lateral forces between rail and sleepers varies and may reach a value which is ten times the calculated value. The phenomena is a result of continuous rail laid on a bridge resulting from the high lateral elastic coefficient of the rail supporting system.

FEATURES IN THE SELECTION OF WEIGHT OF RAIL FOR NEW OR REHABILITATED LINES
The principal features to be considered in the selection of the weight of rail for a new or rehabilitated line will be: the type and axle loading of motive power and cars; the physical characteristics of the line; and the type, intensity and speed of traffic. Given these controlling factors a reasonable decision should be possible, which will result in minimum annual total cost of maintenance with a satisfactory condition of line and surface. New locomotives require stress calculations to determine the results of using existing roadbeds and rail.

A2 039473
SLIGHTLY STAGGERED RAIL JOINTS
The staggering of rail joints is logical because it avoids placing two weak spots, the joints directly opposite each other; it reduces the impact at the joints to that of a wheel load instead of an axle-load; and it produces a more uniform vertical continuity of the track. Certain railways in India experimented with short-pitch staggered joints. Graphs obtained with the Hallade track recorder showed that the running over the slightly staggered road was inferior to that over normal square-joint track. Selection of the optimum pitch for the stagger is half the length of the wheelbase of the standard type

of bogie fitted to passenger stock. This complies with the condition that the stagger must be less than the minimum wheelbase of any bogie allowed to run over the line, namely, 6 ft.

A2 039480
WHEEL HUNTING AND IRREGULAR RAIL WEAR
In addition to the "hunting" of rolling stock wheels, there is the constant side-to-side movement of individual pairs of wheels. The standard taper of coning of wheel-treads is at 1 in 20, so the tread of a new tyre may be at right-angles to the centre-line of the rails. Experiments have been tried in varying the angle of taper of the treads and the radius of the railhead, but the wear of tires and rails complicates the problem, and hitherto has made it difficult to come to any final conclusion as to how the hunting problem may be solved. Persistent bogie hunting can cause bogie stock to ride uncomfortably. Of even greater importance is the wear-and-tear of rolling stock and the damage to rails caused in this way.

A2 039481
THE MOVEMENTS OF RAILWAY VEHICLES ON THE TRACK AND THE FORCE ARISING THEREFROM
A critical analysis is given of the interaction of flanges and rails, together with a resume of the scientific principles involved. The friction arising between wheel and rail is fundamental for all railway transport. The frictional force R is equal to or less than the product of the frictional factor f and the wheel load Q, which are the variable quantities. As the direction of force R coincides with the resulting sliding motor between wheel and rail, its action is opposed to the direction of motion. Force R determines not only rolling resistance, but also that due to curves, guiding pressure, security against derailment, maximum tractive and braking power, axle strain, wear of rail and flange, and--last but not least--freedom from hunting. Methods to determine the precise position and value of R are discussed.

FASTENING RAILS TO A CONCRETE DECK
Engineering design criteria for rubber-bonded cork pads on concrete are developed to account for geometry, the compression characteristics of the pads, axle loading and compression spring characteristics. An inspection coach, wagon and modern train with rubber spring wheels were run over the test track and vibrations in the rails and concrete slabs were measured. It was found that soft pads have better damping properties than hard pads for all frequencies, and ballasted track has less satisfactory damping properties than soft rubber-bonded cork pads. From sound level measurements, it was concluded that rubber-bonded cork also produces less sound to be critical in eliminating a very noisy hammer effect caused by separation of the rail and pad.

THE REPLACEMENT PROGRAM
A decision analysis is conducted to determine if concrete cross ties should replace wooden cross ties. Tie spacing using concrete is about 4 or 5 inches wider than is required for wooden tie spacing to handle the same traffic conditions. The examples shown indicate that concrete ties are a sound investment in high traffic density, heavy grade and sharp curve territories where sufficient savings can be accumulated in a relatively short period of time. On the other hand, tracks carrying an insignificant amount of traffic cannot produce an acceptable rate of return if they are constructed with concrete ties.

GUIDING PRINCIPLES FOR THE DESIGN OF POINTS AND CROSSINGS
Accelerations were analyzed with reference to comfort in passenger bogie coaches and two locomotives were used to ascertain the effects of the guide force on wear and fatigue of the switch fittings. The object of these studies were to discern the influence of the following factors on accelerations and forces at various speeds: size of the angle of impact; radius of curvature of the turnout; transverse stiffness of the track; and characteristics of the vehicle suspensions. An analogue computer and a digital computer were used for making the calculations. Results of the calculations are shown.

DETAILED INVESTIGATIONS INTO SLEEPER DEFECTS
In 1950-51, 400,000 failed wooden cross ties were examined and classified as to the type of failure: (1) decay, (2) plate-cutting, (3) splitting, (4) shattering, (5) spike killing, (6) braking (7) ring separation, and (8) accident. Five types of wood were involved, but 85 percent of the sleepers examined were of pine or fir species more universally used then the other two, oak and gum. Plate-cutting, splitting and shattering accounted for about 1/3 each of the total failures.

BALLAST CLEANING WITH SINGLE-TRACK OCCUPATION
Experiments have been made with methods involving the occupation of only one track when using mechanical ballast cleaners. In the present experiment, the conveyor discharging the dirt, drops its material on to a second conveyor mounted on a rail wagon, which in turn delivers the material into a hopper on a simple steel framework carried on a flat wagon. This framework is of sufficient headroom to permit a low type of dumper to travel underneath it. The dirt is released from the top hopper into the dumper through drop doors and the dumper then travels the length of the train and tips the dirt into wagons standing on the same line. Results to date are most encouraging and an output has been achieved approaching that obtained when screening into wagons on an adjoining road.

TRACK DRAINAGE BETWEEN HARROW AND SOUTH KENTON, L.M.R.
The renewal of the formation and the provision of new track drainage between Harrow and South Kenton became necessary when ballast became choked, resulting in the prevention of effective drainage and the formation of slurry which flowed into the track drains. The first stage in the renewal is the removal of track in one line of the natural formation to withstand the loading of traffic. The next stage is the graduation of the formation to a crossfall to the new drainage system. A sand blanket of sufficient thickness to blind the clay and prevent it pumping and fouling the ballast is then laid to the required crossfall, the drainage system is placed, and the track ballast unloaded. The track is then reinstated and fettled up.

FASTENING FLAT-BOTTOM TRACK
The Electric Rail Spike Co. has developed a new spike fastening for flat-bottom track which is claimed to solve rail movement, including creep, spike killing and wear of track components generally. The spike is made from one piece of silco-manganese steel bar, suitably formed to give a laminated shaft and head 5/8 in. square, then hardened and tempered. It is driven until the head makes contact with the rail foot, and thereafter a further amount of some 3/16 in. which flexes the head and puts proportionate (800 lb.) pressure on the rail base. The spikes stand up very well under derailment, and can be used with concrete sleepers in conjunction with a wood insert or for track circuits. The rubber-covered spikes can also be used with cast-iron or steel baseplates.

LONG WELDED RAILS
If very long weld rails are used to circumvent the many disadvantages of the jointed form of track, important safeguards are essential. The standard types of doubly-flexible rail-to-sleeper fastenings in use on the French railways are among the most efficient deterrents to the risk of fracture due to tension. With an 800 m. length an expansion joint of the sliding switch-blade and stock-rail type is used, allowing of a relative movement of up to 7 in. between the rail-ends. The French railways use arc-welding plant equipped with special finishing devices, in the shape of precision grinding and truing units working in both plan and profile, assisted by hydraulic jacks. It is too early to access precisely the economies resulting from welded track, but the

smallest calculated saving so far is about 30 percent, and was secured on the Paris-Marseilles line near l'Etang de Berre.

A2 039573
TIMBER, STEEL OR CONCRETE SLEEPERS?
In recent years timber costs have risen so abruptly that railways have had to search for alternate materials for their sleepers. The battering to which a sleeper is subjected under traffic has generally proved too much for the normal reinforced concrete sleeper, but with the introduction of pre-stressing methods, the prospects of concrete in this field are much more promising, especially if some form of resilient cushion is provided between rail and sleeper. The concrete sleeper, though it would appear to outlive its wooden competitor as a rule, is heavier and generally more difficult to handle. Moreover, a road laid with either steel or concrete sleepers is less suitable than a wooden-sleeper track for track-circuiting. It must also be remembered that steel sleepers laid near the sea or in areas where the atmosphere contains corrosive ingredients are subject to serious erosion and deterioration. The relative costs of day-to-day maintenance of wooden, steel, and concrete sleepers are not readily comparable, largely because there are so many different types of fastening used with each.

MATERIALS FOR TRACK BALLAST
It is generally agreed that the ideal ballast is hard stone broken to suitable sizes. The main characteristics of good ballast are that it should be hard, heavy, resistant to crushing, shock abrasion and weathering-- especially due to frost--clean, and reasonably binding but loose enough to permit of free drainage. Crushed stone such as granite, quartzite, igneous rock, or trap, has the advantage of being very hard and angular, and even broken limestone and sandstone may also be reasonably hard. Crushed slag has the characteristics of rock, but it induces dry rot in wooden sleepers. Cinders or ashes are the cheapest form of ballast; they provide good drainage, but powder and cake too easily for other than yard or unimportant branches. Their greatest fault is that they quickly corrode the feet of rails and steel sleepers in contact with them. Sand, as well as being cheap, makes a stable lower ballast.

GRINDING TRAIN FOR CORRUGATED RAILS
A new type of rail grinding train has been constructed, and after trials a train was supplied to the German Federal Railway. Immediately behind the locomotive is a tool wagon, followed by a van containing two diesel units generating 300 kVa., with the necessary ancillary equipment for driving the grinding assemblies. The other three wagons are the grinding cars. They contain the grinding machine sets and the control gear for the grinding operation. Each grinding car contains eight grinding units; four arranged on either side, so that in the complete train 24 grinding units are available, 12 for either rail. To obtain good results a relatively low traveling speed when grinding of 1.8 mph is imperative It is expected that in a full operational year about 2,500 miles of heavily corrugated rail may be ground.

CONTINUOUSLY-WELDED RAILS
To offset the increased cost of laying welded as compared with bolted rail ($1000/mi) important savings are being effected. The first is in general track surfacing work. The initial 5-1/2 miles of Elgin Joliet and Eastern Railroad welded track, laid in 1943, will not require general surfacing for another two or three years yet, though it carries 20,000,000 gross tons of traffic annually; in the normal course it would need general surfacing every seven years, and joint surfacing, now no longer needed, at much shorter intervals. Also, construction methods, maintenance benefits and costs are discussed.

TRACK STABILITY ON THE NETHERLANDS RAILWAYS
The science of soil mechanics is of greater importance in Holland than in almost any other country because the bearing capacity of the ground is generally low. For the preliminary exploration of the quality of the soil, two standard field tests are made by specially-trained inspectors. The first involves the measurement at intervals of the resistance to pressure when and as a cone of standard diameter and angle is forced down into the ground. The other is the sampling of the soil taken from borings at different depths; the samples are subsequently dried out and examined. Three track construction and stabilization works were in hand in 1950. A new 6-1/2 mile double line had to be constructed between Rotterdam and Nieuwerkerk, mainly over polder land 15 ft. below sea level. The second work was the strengthening of the formation under the double-track main line between Gouda and Oudewater where it is on embankment over peaty subsoil. In the third operation though an electrified and reballasted, traffic was maintained by laying a temporary track at one side complete with overhead conductor.

DISNEY RESILIENT RAIL CHAIR
These chairs were installed nine years ago on the double-line 350-ft. steel central span of the Victorian Bridge over the St. Lawrence and extensometer tests have shown "important reductions in impact stresses" in the superstructure. Other advantages claimed for this chair and its fittings include the elimination of sleepers and their renewal; of ballast, its cleaning, maintenance, and waterproofing; reduction of vibration, bridge dead load, and construction depth; also of excavation in tunneling. Moreover, the positive resilient grip on the rails minimizes wear between track and components, provides uniform distribution of stress, limits vibration, and ensures greater cleanliness and a truly-aligned track, as well as greater safety. It eliminates track maintenance, is economical and secures a long-enduring road and trouble-free operation.

SOIL MECHANICS AND THE CIVIL ENGINEER
The most satisfactory methods to be adopted in the stabilization of troublesome banks and cuttings can be decided only after a proper examination of the site by means of borings or trial holes. Should bridges, tunnels or other structures be involved, the engineer will need to know at once what earth pressures will be exerted on the structures and also what bearing pressures can be adopted without risk of either complete shear failure or excessive settlement or other movement due to subsequent consolidation of any compressible strata. The fields in which railway engineers are most in need of knowledge are: inexpensive waterproof

coatings or carpets which can be used on the side slopes of banks or cuttings to prevent the penetration of rain, and which will be sufficiently resistant to frost, heave or other effects of weather; corresponding methods of treating the formation; swelling pressures of clays and active pressures on retaining walls and other similar structures and whether appreciable plastic movement of a foundation on clay can take place at pressures below those calculated, which are based on ultimate shear strength.

A NEW FATIGUE DEFECT IN RAILS
The shelling defect has been most commonly encountered in the 131-lb standard flat-bottom section, though it has been reported in some degree in all sections from 100 lb. upwards. The first manifestation of the trouble is the appearance, on the running surface of the rail near the running edge of dark spots, which indicate the presence of horizontal planes of separation of the steel within the rail-head; these may occur at a number of different levels in the same rail. The shelling is the result of wheel action on the rail causing failure of the metal, either by direct stress exceeding the elastic limit, or by loss of ductility which is the outcome of constant reversals of stress. Factors which may influence the relative severity of the shelling are the inclination of the rail, the superelevation, the bearing pressure exerted by the wheels, the radius connecting the flanges and the treads of the wheels, and the radius of the gauge corner of the railhead.

RAIL CORRUGATIONS
Methods by which this defect has been minimized on the Queensland Government Railways are discussed. The correction of railjoint dip, closing in of joint sleepers, and provision of clean elastic stone or gravel ballast has made an even top and a springy rail which has reduced the wheel-rail contact stress so much that rail rippling and corrugation is no longer a major problem. The greatest cause of overstress is the solidity of the rail bed which reduces tremendously the depression of the rail under wheel press and thus increases the local intensity of the stress. Other causes are open and dipped rail joints, easily deflected rail ends at joints, pumping sleepers, and track out of gauge and level. The metallurgical treatment of the rail steel, rolling and work effect when shaping, finished shape of the head, and chemical constituents of the metal, are very important. Higher strength rails such as sorbitic or chromium-steel rails oven-cooled will reduce the defects considerably. Long rails assist. There should be sufficient ballast to give an even bearing on the sub-grade. Elasticity of the whole track is most important and here sleeper spacing with depth of rail is to be considered for correct proportioning.

BESSEMER STEEL IN RAILWAY SERVICE
The reintroduction of the basic Bessemer process at the large new Corby works in Northamptonshire, chiefly for the purpose of making tube steel, has proved that with iron smelted from the ore-beds of this and adjacent Midland areas it is possible to make a reliable basic Bessemer steel from British raw materials. Similarly the Luxembourg and Lorraine ores, such as minette, have been well suited always to basic Bessemer steel production, and British railways which were compelled in 1921 to buy basic Bessemer rails from Luxembourg. The War Production Board has now laid it down that in the manufacture of certain details of railway equipment the railways must be prepared if necessary to accept Bessemer in place of open-hearth steel. The list of such material covers 66 items.

CLEARANCE OF SNOW AND ICE
This article compares what has been done by European and North American railways to combat snow and ice. For snow clearance all railways seriously affected use ploughs which may be either of the ordinary steel-blade type for pushing snow aside, or of the rotary type. While the rotary type is more effective in deep drifts, it is more expensive in capital, maintenance, and operating costs. In addition, it is comparatively slow in operation. For removing packed snow and ice flame guns and steam lances are used in Great Britain. Electric point heaters are used in Great Britain, U.S. and Germany. Sheds and screens are used for avalanche protection in Switzerland and France.

U.S.A. RAILWAY TECHNICAL DEVELOPMENT
The U.S. railroad equipment and technology in 1940 and 1953 are compared. Rail usage in 1953 was declining due to highway and air competition. The types of locomotives in use in both years are compared. American track design is compared to British technology. Closer spacing of ties in the U.S. allows the track to carry heavier axle loads; however, ballast maintenance is more expensive due to the spacing. The C.T.C. signaling installations are described.

RAIL-MOUNTED TRENCH DIGGING MACHINE
A diesel-powered machine for cutting trenches for drains alongside the permanent way is undergoing tests by the Civil Engineers Department of the Western Region, British Railways. The machine is mounted on a framework which rests in a cradle pivoted on a specially adapted railway wagon. The machine has a maximum cutting depth of 6 ft. 3 in. below rail level, and the boom can be set at any depth between this and ground level. The bucket width is 18 in. which can be increased to 21 or 24 in. by the fitting of side cutters. Speed is continuously variable up to 6 ft. per min.

TRACK MAINTENANCE IN JAPAN
Due to heavy rains, extreme temperatures, excessive curves and grades, very heavy traffic and narrow gauge, track maintenance problems are intensive in Japan. Despite the use of greater depths and larger quantities of widespread stone ballast, closer-spaced sleepers, heavier rails, improved fittings and fishplates, and stronger joints generally, and a rapid extension of rail-joint welding, maintenance continues to be difficult. A rail-replacing machine and a mechanical ballast tamper are described. Both machine methods are labor intensive yet give more uniform results and are easier on sleepers than manual methods. The machines are designed to save time, since maintenance time is usually available in periods of less than 40 minutes between train traffic.

EXPERIENCE WITH WELDED RAILS
The railroads in the U.S. in the early 1950's began substituting 78-ft. rails for the 39 ft. standards. The 78-ft. rails decreased the number of joints by 50 percent, which justified the longer rail on the basis of a corresponding savings on maintenance. The same equipment can be used to lay both size rails. Wild grinding to reduce the bulge at the weld is discussed. The repair of continuously welded rail is described.

EASIER MAINTENANCE CONTROL FOR RAILWAYS
A small Canadian railway has initiated a planned maintenance system to detect excessive maintenance costs. The system is designed to point out when equipment should be replaced rather repaired. This method is applicable to anything that has to be maintained; locomotives and rolling stock; roadbeds and tracks; machine-shop equipment; buildings and their components (floors and roofs); paving of roads, and so on. Tables are shown as examples of the system. A measure of operating conditions are established using a Table of Wear Points. This Table shows arbitrary values for various degrees of operating conditions. Multiplying these wear points by each other a wear factor can be arrived at. History cards are kept on each piece of equipment to accumulate the wear factors.

FASTENING RAILS TO CONCRETE SLEEPERS
A new method of fastening rails to concrete sleepers has now been installed experimentally. The new type of fastening embodies certain features of German practice in conjunction with the use of a grooved rubber pad. The fastening is essentially of the clip type, the clip itself being secured by means of a long screw run into a corrugated wood plug cast in the concrete sleeper. The rail sits on a grooved rubber pad. The form of the wide V-shaped grooves, together with the hardness of the rubber selected, gives a very satisfactory load-deflection characteristic of the pad. Rubber has also been applied at both ends of the clip and rubber-bonded cork has been used under the head of the screw.

CONCRETE SLEEPER INSULATION ON SOUTH AFRICAN RAILWAYS
Large orders have been placed for two types of concrete sleepers suitable for neoprene pad insulation so that the programme of laying long-welded rails on concrete sleepers for main-line track may be carried out without hampering electrical signaling developments. One fastening uses a neoprene insulation pad, and a natural rubber resilient pad, togehter with a steel baseplate, coachscrews, and clips. Another has an alternative method of fastening of the Fist type. This also uses a neoprene pad between the rail and the concrete, but the fastening is a special spring-steel clip held in position by a bar that passes through the sleeper. This bar is insulated from the concrete with a phenolic resin compound. Experimental use of the pads has established the expectation of a five-year life for the pads at the minimum.

WORK-HARDENING BOLT HOLES IN RAIL ENDS
Analysis of rail failures has shown that the most frequently occurring type of failure is that classified as "4d" which takes the form of radial cracking from one or both boltholes known as star cracking. Various methods of improving the fatigue strength of drilled rails have been tested. The greatest improvement has been obtained by work-hardening the surface of the holes, by intially drilling undersize followed by broaching or drilling drifting with a spherical tool to the required size. The work hardening has resulted in increasing the fatigue strength of the rail by 50 percent, a figure which is maintained after exposure to corrosion. No trouble was experienced in workhardening any of the holes, including those where the axis is inclined to that of the rail.

USE OF WEEDEX IN CHEMICAL WEED CONTROL ON BRITISH RAILWAYS
The future of chemical weed control on British Railways lies in the use of the insoluble specially synthesized compounds. It is within the power of Weedex and Weedex "A" to give a high standard of weed control, both on the track and in the cesses, by single treatment at intervals of 12 months or more, without the necessity of supplementary handweeding. A revision of the spray programme and the introduction of modern technique of application will give a much better return, in terms of efficiency, on the money spent on chemical. Efficient chemical weed control is cheaper than handweeding. By taking full advantage of modern chemicals, improved application techniques, and scientific planning, a higher standard of weed control can be obtained at a far lower cost.

TRACKWORK STUDY. VOLUME II. RECOMMENDED TRACKWORK STANDARDS
The study provided the Washington Metropolitan Area Transit Authority with recommendations for trackwork design standards and criteria for use as a basis for the final design of trackwork for the entire METRO rail rapid transit system. The recommendations were based on analytical studies and the experiences reported by operating properties. Trackwork components were analyzed considering different combinations of components and varying physical parameters such as size, spacing, and estimated life of elements of the track structure. The report includes recommendations on rail weight, rail type, rail welding, fastener types and spacing, cross tie types and spacing, roadbed and ballast section, special trackwork, track appurtenances, track gauge and in-service test installations. FLEXIBLE RAIL CLIP FOR F.B. TRACK
The basic R.N. (Ressorts du Nord) clip and its modifications for use with insulated and welded rail and all types of cross ties are described. The clip consists of a heat-treated, manganese-chrome, spring-steel blade which is doubled back on itself and drop-forged so as to form an upper and lower leaf connected by a rounded portion in the shape of a spring "eye". The R.N. clamp for wooden sleepers differs from the clip already described in having a longer blade, so as to be less stiff and prevent fatigue of the coach-screw. The combination of rubber soleplates and R.N. fixings has been proved to afford a very strong and secure anchorage of the rail on sleepers of all kinds, resistant to the vibrations of express traffic.

LONG-WELDED CONDUCTOR RAILS ON THE SOUTHERN REGION
Improved methods have recently been introduced to enable the maximum length of conductor rail to be unloaded and renewed in the short possession times available, with the minimum amount of labour. Under the new system conductor rails are welded into 180 ft. lengths at the flash-butt welding depot and conveyed to the site on rakes of three 40-ton bogie rail wagons. Up to 26 conductor rails weighing 150 lb per yard are loaded on the rail wagons in four tiers of eight, seven, six and five rails. Using a tackle to pull-off the rail, a gang of six mean can unload 1-3/4 miles of conductor rail in a 4-1/2 hour track possession. Six lifting and traversing frames are used to transfer the rail from the four-foot way to the new insulators, and enable 16 men to complete the laying in, fishplating and bonding of 1/2-mile of 150-lb conductor rail in 4-1/2 hours.

REPAIRING UNUSUAL SLIPS ON WESTERN REGION MAIN LINE--2
The cause of the slip at Sonning was known exactly and, paradoxically, this meant that the ways of dealing with it were numerous. The method decided on is described and other methods, with the reasons for their rejection, touched on briefly. The object of the method chosen was to fix the slipping mass to the solid stratum beneath. The prime cause of the slip at Twyford was the hydrostatic head which had collected in the sand lens. This was reduced to an economic minimum by the use of 6-in. dia. cast-iron pipes, with perforated ends, which were built into the buttresses, the perforations being at the level of the sand lens. This article shows how a new cutting may be threatened by the existence of permeable strata, which are below the limit of excavation. If a preliminary investigation has been carried out and the presence of a permeable stratum found, the correct slope of the new cutting can be found using the calculation methods proposed in this article.

MECHANIZATION OF PERMANENT WAY
To allow most economical use of mechanical equipment, British lines are classified in three categories: (1) lines with intensive traffic moving at high speeds, where no weekday occupation, day or night, can be obtained: (2) medium-traffic lines, where adequate occupation can be obtained on weekdays or weeknights; and (3) light-traffic lines where machine can be transported freely from place to place by rail or road. On open running lines in the first category, routine maintenance is likely to remain manual, but major repair and renewal works must be as fully mechanized as possible--with ballast-cleaners, cranes, track-lifting and tamping machines--so as to leave the track in nearly-perfect condition. On medium-traffic lines in the second category which are of sufficient mileage to make it economical, there are likely to be minimum-strength length gangs, the bulk of the maintenance being carried out by fully-mechanized gangs. On light-traffic lines in the third category accessible for the distribution of mechanical equipment, expensive highpowered on-track machines probably could not be justified except for renewal works.

TRACK TESTS AT WOOD GREEN

This appendix taken from an unidentified report, describes a test conducted between London and Edinburgh on a section of track which was causing maintenance problems due to soil instability. The following measurements were taken through the use of pressure transducers: (1) transverse distribution of vertical stress beneath a test sleeper, (2) vertical stresses on the rail to sleeper reaction axis beneath both rails of the adjacent sleepers, (3) transverse horizontal stresses beneath the test sleepers, and (4) longitudinal horizontal stresses acting across the rail to sleeper axis. As a supplement to the stresses, induced by traffic, the in situ changes in the density and moisture content of the track foundation was determined by means of radioactive probes. This was done to check the behavior of the individual layers of the ballast, the blanketing layer just down and the formation under traffic loads. Findings are presented graphically.

SYSTEM OF RESILIENT RAIL MOUNTING

The Sectru resilient-grip mounting bolt has been applied to railway track fastening problems resulting in a new rail mounting system for all types of sleepers, espically concrete sleepers. This method of rail fastening combines positive location for the rail (both against longitudinal slipping and lateral displacement) with an essential measure of resilience. The rail foot is carried on a compact and rigid baseplate, which, in turn, rests on a rubber pad of equal size placed direct on the surface of the sleeper. The rail is secured to the baseplate by means of two simple, strong clips and two bolts. The rail is tied to the baseplate with great strength, through direct metal to metal contact, and this can be made more than adequate to hold the rail against any longitudinal slipping, even under arduous conditions of heavy train braking. Laterally, the rail is firmly located between the ribs of the baseplate, clips, and bolts together form essentially one single, rigid, assembled structure.

FRENCH NATIONAL RAILWAYS RAIL GRINDING TRAIN

This train operates at a speed of 24 to 28 mph but in order to remove corrugations of a maximum depth of 0.02 in. from 60 to 120 runs have to be made over the section of line from which corrugations are to be removed. The train is normally moved by two locomotives, one at either end. There are two rail grinding vehicles in the train separated from the locomotives by runners and from each other by two locomotive tenders; these two tenders provide water to lubricate the grinding blocks and to cool the surface of the rails. Each vehicle is equipped with 16 grinding shoes. There are two groups of four grinding shoes on each side of the vehicle. Each block measures 15 in. long by 2.36 in. wide, and the effective grinding material on each block when new is 5.9 in. thick. On the average, the blocks have to be replaced after each 120 miles. The abrasive block is made of aluminium oxide grit. The grinding shoes are brought into contact with the rail and a total pressure of 4 to 5 tonnes applied to the 16 shoes. This pressures is gradually increased to 10 tonnes the speed of the train being maintained constantly at 24 to 28 mph. To get the best results from the economic point of view it is desirable for the train to cover, while working, at least 62 miles each day.

A2 039980
THE RAIL SHELLY CRACK IN JAPAN
Investigation into the growth mechanism of shelly cracks and a method of prevention is reported. Examinations included track condition, materials quality, loading condition and friction and wearing phenomenon of affected rails. It was found that in the ordinary contact condition, the contact stress between tyre and rail is so large that plastic flow is caused. With the progress of plastic deformation, steel becomes hard and its elastic limit rises. After these changes, rail surface becomes fit for ordinary wheel load. Though before this time the progress of plastic flow nearly stops, the crack grows through the fatigue due to rolling with slide. It was also found that the existence of ferrite in the surface layer seems to take part in the growth of the crack. As a first step in preventing shelly cracks, rail steel should be strengthened against fatigue. Water decreases the wear of rail and accelerates the development of crack. These conditions promote the growth of the crack due to the rolling fatigue. Secondly, though the decrease of stress is difficult to realize in general, the decrease of lateral force and the decrease of contact stress by decreasing the difference of both curvatures in contact part of wheel and rail are found effective. Thirdly, as it is clear that the existance of water is unfavourable, total stop or restraint of watering is very effective. Since the same effect is achieved by oiling, it is necessary to be careful not to oil excessively.

CONTACT PRESSURE BETWEEN WHEEL AND RAIL AND ITS INFLUENCES ON MECHANICAL PROPERTIES OF RAIL STEEL
Since it was felt that there was still some uncertainty regarding various investigations on the very high contact pressure between wheel and rail and in relation to failures occurred in the heads of rails. It was decided to obtain additional data on the phenomena. This article addresses the following: contact pressure between rail and wheel, plastic deformation of rail steel due to local compression hardness distribution under running surfaces of used rail, and workbrittleness of rail steel.

GROUND VIBRATION DUE TO TRAIN PASSAGE--ON EFFECTS OF RAIL JOINT GAP
Ground vibration due to train passage is described referring to the results of a measurement carried out between Matsukawa and Kanayagawa on the Tohoku Truck Line in October 1964. The main purpose of the measurement was to study effects of rail joint gap on the noise and ground vibration. Results can be summarized as follows: (1) Horizontal vibration caused by an expansion joint is smaller at 2.8 m from the track center than at 5.8 m. (2) The dominant frequency of horizontal displacement due to the joint with the gap of 15 mm is lower than that of the expansion joint and the joint with the gap of 5 mm.

LATERAL FORCES ON TRACK AND EQUIPMENT DUE TO DYNAMIC BRAKING ON THE SOUTHERN PACIFIC LINES
This report embraces a description and analysis of data secured during the operation of regular scheduled freight trains on the Southern Pacific Company between Roseville, California and Sparks, Nevada. The purpose of the investigation was to determine the coupler forces and resulting lateral forces exerted on the rails by the passage of an 85 ft. car coupled to a short car in a train with the locomotive using dynamic braking while operating on steep grades and curves up to 10 deg. During the investigation, data were secured on coupler and car angles, lateral and vertical truck forces and longitudinal acceleration of the 85 ft. car with the train operating at various speeds. The analysis of data contained in this report may be summarized as follows: 1. The steady or longitudinal coupler forces for both pull and push conditions, as expected, are in proportion to the weight of that portion of the train behind the point of measurement. The compressive coupler forces were reduced considerably when the train air line pressure was reduced with the locomotive under dynamic braking on the descending grades. 2. The coupler angles are in direct proportion to the track curvature with the values obtained under the pulling condition slightly greater than those under the pushing condition. 3. The data indicate there is a linear relationship between the track curvature or coupler angle and the lateral truck forces acting on the rail. 4. The occurrence of slack action was rather infrequent due to the long and almost continuous grades for but some coupler forces as large as 90,000 lb were obtained by an application of the dynamic brakes which permitted the slack to run-in. 5. The sprung weight of the 85 ft. car was subjected to longitudinal accelerations as large as 2.2 g but there does not appear to be any direct relationship between the direction and magnitude of this acceleration with respect to the direction and magnitude of the slack action coupler force.

THE MECHANIZATION OF CURVE REALIGNMENT
A new procedure is described for the mechanization of curve realignment without the necessity of resurveying or re-staking the curve, by the use of a track lining machine. This method can be used for the realignment of transition curves. Particular emphasis is placed on the theoretical basis of the method. The method divides the curve into equal small parts. A comparison is then made of the height of the arc over the chord of each part. [German]

TRAFFIC IN A CURVE WITH RAILWAY COACHES FITTED WITH INCLINABLE BODIES
Further tests of the pendular type coach have been effected, during which the body has been given a boost to speed up the time taken for it to get the correct inclination when negotiating connecting transition. This is done by means of a hydraulic ram monitored by a accelerometer detecting, permanently, the non-compensated acceleration. Another arrangement is being worked out with a coach for which the axis of oscillation is below the center of inertia of the body. Tests are described which show that it is possible to get a coach to negotiate a curve with 0.3 insufficient cant, which is considerable, by employing assisted pendular motion. The first tests have shown that the assisted pendular motion gives considerably improved smooth riding while negotiating the transition as compared with natural pendular motion.

WHEEL AND RAIL LOADING FROM DIESEL LOCOMOTIVES
This review is divided into the following areas: sample derailment data; basic curve negotiation mechanics; experimentally determined wheel-to-rail forces; rail profile data; the effect of dynamic brake levels; and mechanical considerations. Sample derailment data was taken from all six areas and well illustrated with examples. A summary of results is shown. There are a number of mechanical areas involved in the locomoitve which can and do affect the wheel-rail loading. Among these, although there are many others, are the alignment control draft gear, matching wheel sizes, and maintenance of truck bolster stops.

DEVELOPMENTS IN THE QUALITIES AND SERVICE CAPABILITIES OF PRESENT-DAY RAIL STEELS
The service requirements are discussed for steel rails, which are constantly increasing to bear the heavier axle loads and higher speeds, and with increased resistance to wear, fatigue and fractures. The progress in the manufacture of rails is related, including the improvements in profiles, dimensions, quality and physical properties, as shown by tables and charts. The forseeable limiting area of tensile strength for self-hardening alloy steel for the rails is given as 192,000-206,000 psi. Improved resistance must be developed to wear, plastic deformation crushing and fractures in the rail head, by raising the tensile strength, yield point and fatigue limit. [German]

STEEL TIES FOR FIRST CLASS TRACKS
There is a revival of interest in steel ties due to newly designed shapes and improved manufacturing processes. The new ties have a higher moment of inertia and greater strength. Annealing after the cold working insures greater fatigue resistance and reduces the likelihood of cracks developing. Advantages of steel ties include: long life, the possibility of re-use later in secondary lines, and the reclamation possible after a derailment. Under switches, the longer lengths of steel ties are more easily provided. On electrified lines, steel ties provide an ideal grounding connection. The better quality of steel makes the welding process more usable for fastening the rail holding plates to the ties without the possibilities of fractures. [German]

THE INFLUENCE OF BALLAST BED THICKNESS AND TIE SIZE AND SPACING ON SUB-STRUCTURE LOADING
The steady increase in axle loading of railway vehicles and in train speeds not only cause greater stressing of the rails, but also higher loading of the sub-structure. Test results and theoretical considerations show the influence that the size, shape and spacing of the ties, the thickness of the ballast bed and depth of the formation, have on the loading of the sub-structure. Conclusions included the following: a ballast bed over a bad substructure that will carry 20 tons axle load, when over a good substructure, cannot carry more than 25 tons axle load. For axle loads of 30 tons, a protective layer over the substructure and a deepening of the ballast bed are necessary. With regard to the stresses on the ballast bed from an axle load of 25 tons to 30 tons, the tie spacing must be made smaller and with longer ties, the depth of the ballast bed and the thickness of the protective layer over the road bed can be kept to lesser limits. TRACK MAINTENANCE ON HIGH SPEED RAILWAYS
The results of six years of operation of the Tokaido Line of the Japanese National Railways, the 200-210 km/h high speed, single purpose line for passenger service, are given in detail as relating to track alignment and level deformations and maintenance requirements of the track structure to keep it within the necessary limits for safety and comfort. This work has been found to be much higher in amount and cost than first envisioned, and instead of the nightly freight runs first planned, the track maintenance work is now scheduled for the night hours. The number of trains run on this line has now increased to 85 pairs daily, with a loading of 60,000 tons per day on the track structure. The details of the construction of this track is tabulated, including the type of rail, ties and ballast bed. For this line, 160,000 tons of ballast are required yearly. Track maintenance, which approximates 50% more than anticipated, is compared with that on the German railways, where, with the mixed operation of heavy freight trains at 80 km/h and 200 km/h passenger trains, such maintenance is about 30% higher than on the lower speed and lesser load lines. STATUS OF COOPERATIVE RESEARCH ON WOOD TIES BETWEEN THE RAILWAY TIE ASSOCIATION AND THE AAR RESEARCH CENTER
Tie space was studied analytically using Talbot's formula, in laboratory tests using hydraulic pulsating loading jacks, and using test track on a field test. Cross ties of three cross sections, 6 x 8 inches, 7 x 9 inch, and 8 x 10 inch, and three lengths, 8 ft, 8.5 ft. and 9 ft. for a total of nine combinations, were used for all three tests. The study of the effects of tie size and spacing showed that irregularities in track cross level and rail surface are a function of the characteristics of the ballast and roadbed rather than of the tie arrangement. There is no evidence that the long ties are more effective in prevention of

center binding, because the shortest ties so far show no evidence of center binding. It seems probable that the cross section and spacing of the ties will be determined by the bending strength required to avoid tie breakage at the center of the track or under the rail. Further service use will indicate whether the increased tie plate load with the wider tie spacing used in some test sections will result in an increased amount of tie plate cutting into the ties.

GUIDING PRINCIPLES FOR THE DESIGN OF POINTS AND CROSSINGS (UIC 54 AND UIC 60 RAIL PROFILES) FACTORS AFFECTING THE CONSTRUCTION OF COMMON AND OBTUSE CROSSINGS
The present document studies the choise of a geometry and a construction for common and obtuse crossings. The choice of geometry, for safety and for comfort, takes account of the incidence of high speeds and heavy axles on common and obtuse crossings, and the consequences, on obtuse crossings, of a current tendency towards the reduction of wheel diameters. The choice of construction is of prime importance with speed and tonnage. Two methods of construction, one of which has the advantage of a long experience, are described with their respective characteristics.

DYNAMIC CHARACTERISTICS OF RAIL FOUNDATION
An experiment was conducted on track with P-65 rail, with 1840 ties per kilometer, with both wood and concrete ties, and stone ballast to evaluate the dynamic characteristics, particularily elasticity of the rail K1, coefficient of elastic friction of ballast L1, and equivalent mass of the track M1. It has been proposed that the tie reaction consists of an elastic component proportional to the rail displacement and a nonelastic component proportional to the velocity of vertical rail movement, inertia of the tie and adjacent layers of ballast and underlying soil. Linear differential equation were derived to permit theoretical analysis. The equations thus obtained are grouped to give proper number of simultaneous equations and solved as such. The results for various groups give different values of the coefficients and again their averages and maximums are given.

This unpublished material is based on a Russian article appearing in Railroad Transport Issue 7, 1964, page 16.

SUITABILITY OF SIX-AXLE LOCOMOTIVES FOR C&O--B&O SERVICE--THE INTERACTION WITH TRACK STRUCTURE
A series of tests was conducted with 6-axle locomotives in heavy, coal drag service on Cranberry Grade to investigate the interaction of locomotive tractive power and track conditions. Particularly, the performance of 6-axle locomotives in this service was investigated to determine the relative merits of that design versus the 4-axle units previously used. Five major areas were found to be significant and completely interdependent: I. Locomotive wheel life with 6-axle units. II. Rail cleanliness affects locomotive adhesion. III. The condition of the track and the rail govern overall acceptability of 6-axle locomotives. IV. Operating practices covering the use of sand are related to increased wheel wear and increased track maintenance. V. Instrumented wheel tests: A. To determine to what extent and under what circumstances the wheel and rail wear attributable to 6-axle locomotives exceeds that of 4-axle units. B. To determine effect of track surface on locomotive riding qualities. C. To determine suitability of 6-axle locomotives.

DYNAMIC LOADING AT RAIL JOINTS--EFFECT OF RESILIENT WHEELS
This study of a simplified vehicle model passing over an idealised dipped rail joint using values applying to a BR Class 86 locomotive shows that resilient wheels give an equivalent reduction in unsprung axle mass of 2,500 kg. The following conclusions were made: The suggested model for a broadened analysis of the vertical response of vehicle and track at a dipped rail joint is workable and produces dynamic wheel load values which are in full agreement with observed data. Fitting a Class 86 locomotive with resilient wheels will have the effect of reducing the dynamic wheel load increment at severe dipped rail joints by some 40 percent. The effect of resilient wheels on a Class 86 locomotive--based on the dynamic loading at rail joints--is equivalent to a reduction of the unsprung mass from 4,200 kg to 1,700 kg on the leading axle. Thus the results of the analysis suggest that a power-unit comprising axle-hung motors and resilient wheels is a highly competitive alternative to conventional, mechanically complicated and expensive arrangements used to obtain fully-suspended traction motors.

DYNAMICS OF RAILWAY TRACK SYSTEMS AND THEIR ECONOMIC CONSEQUENCES
British Railways has adopted concrete sleepers and continuous-welded rails as the best means to provide a high performance low annual cost track. Assessing the dynamic loading effect of different axles at different speeds on a less than perfect joint has been done and has produced a very close confirmation between field measurements and a previously calculated formula. Over 50 percent of the rail breaks occur in rails which are not more than ten years old, by which time none have reached the replacement stage due to loss of weight. Maximum bolt-hole stresses occur at the second running-on bolt, but rail-end failures start at the first bolt-hole. The joint consideration of the track and vehicle circumstances has resulted in the design of a three-axle bogie which not only increases the payload by 9 tons for a 2-ton increase in tare weight but reduces the axleload to 13-1/2 tons at an extra cost of less than 2,000 lb. a vehicle. While welded track requires higher installation costs the reduction in day-to-day attention is very marked. Taking 1969 prices, the costs per mile are: (i) long-welded rails on concrete sleepers, 29,000 lb; and (ii) jointed rails timber sleepers, 25,000 lb. But the "equalized" cost per annum is affected by the relative lives and is considerably less for long-welded rails.

LOADING OF LIGHT RAILS
Highlights of a paper presented at a meeting of ICE. The author describes cases of known damage to rails and sleepers caused by excessive loading and reviews some investigations which have been carried out into the problem. It is suggested that further attention to rail design is needed to ensure that the maximum loading benefit is obtained. There is a need for establishing the maximum loading and best arrangement of locomotive axles for any given weight of rail. One of the conclusions reached by the author is that use of the continuous elastic-support theory as a means of assessing the safe loads and stresses caused on the track by locomotives is useful in designing the axleloading and layout, but with heavy axleloads the curve effects on rail-fillet stresses become the critical factor. With smaller wheel diameters the local railhead stressing effects must also be watched.

STABILITY OF LONG-WELDED RAILS
In 1953 an exhaustive testing programme was initiated by the Civil Engineering Laboratory to investigate the conditions and factors affecting the stability of long-welded rails, mainly pertaining to British Railways field conditions. To study the factors involved in track buckling, lateral deflection was induced on a 120-ft. length of track mounted on rollers with a distance between lateral reaction points of 20 to 106 ft. It was soon seen that conventional deflection formulae did not apply, especially in respect of overall stiffness of track, and that this varied with the length deflected, amount of deflection, sleeper-spacing, type of rail fastening, and rail section. These preliminary investigations took no account of the effect of ballast. To obtain information on the behavior of sleepers, rails, and fastenings simultaneously, a lateral bending test was devised for deflecting a 30-ft. section of track under lateral point-loading. Various sleeper-spacings and types of fastening were used and suitable formulae were evolved. The effect of ballast was investigated in a series of tests to ascertain its resistance to the lateral and longitudinal movement of both timber and concrete sleepers. In the main buckling tests on a 120-ft. test-bed, a length of track was subjected to thermal stresses in such a way as to simulate the central portion of a length of long-welded rail which does not move with changes of temperature. Loss of load in the track when buckling occurred as a result of rail expansion could be calculated from the gauge readings and the alignment of the buckled track.

DEVELOPMENT TRENDS IN SWITCH POINT DESIGN
On the Swiss Federal Railways, with a total track length of 6,686 Km, there are a total of 14,669 switches, for an average 455 meters of track per switch. The Swiss Railways have had to engage in the development of switch designs to provide higher speeds for their train movements through switches. The design is described of the geometry of switch points and turnouts, with diagrams of four long radius switch turnouts from 900 m radius to 2200/3800 m radius. The design of various switches are shown. There is shown the arrangement of a switch lay-out on a ballastless concrete bed. The present maximum speed of trains, 140 km/h, is not foreseen as likely to be increased, so the development of switches capable of accepting trains at speeds of 125 to 140 km/h has become necessary, in order to maintain the flow of traffic as rapid as possible. In this development, the rail profile has been increased from 49 kg to 54 kg per meter. [German]

THE TAMPING OF TIES
A ballast bed must keep the rail deflections at minimum under the train loading, must not retain water, and must permit the underneath soil to dry out quickly, and must hold the track in stable alignment. To achieve this condition, not only is cleaning of the ballast essential, but also, proper tamping of the ballast around the ties is required. The various methods of tamping are described, with an evaluation of the effectiveness of each process. Tests have proven that the asynchronous method of operation of the tamping machines, combined with the compacting between and at the ends of the ties, provides the more nearly uniform homogeneity of the ballast bed desired under the ties. THE PROBLEMS OF TRACKWAY AND SIGNAL TECHNIQUES FOR RAIL
The problems relating to high speed travel are outlined. For speeds up to 250 km/h, the conventional form of track structure, with ties on the ballasted road bed, will suffice, using the presently available equipment and motive power systems. The following improvements in the present rail permanent way are suggested for attaining the full benefit in travel time reduction from the high speed operation: strengthening the present track structure system; improving the soil foundation under the track structure; improving the track with consideration for the centrifugal forces of vehicles on curves; elimination of close track spacing; elimination of railway road crossings; and equipping the high speed sections with continuous train control. DEVELOPMENTS AND EXPERIENCE WITH THE THERMIT SYSTEM WITH PARTICULAR REGARD TO WELDING OF DIFFERENT RAIL STEEL QUALITIES
The application is discussed of the Thermit welding process to rails, on the influence of the rail material on the quality of the weld, on the temperatures occurring in the rails during and after welding, on the changes in structure and hardness of the rail material adjacent to the welds as a result of the thermal processes. Detailed measurements show the expansion and contraction in the rail zones heated during Thermit welding, and the cooling behavior of various rail and Thermit steels, as well as possible damage to the welds and heated rail sections. The results of measurements of internal stress in the rail welds, with and without collar respectively complement the test data obtained in the laboratory. In addition to the practical experience derived from the many millions of rail welds, they are a valuable contribution to the metallurgy of rail metals, which should be taken into consideration in the development of new rail profiles.

RAILWAY TRACK STRUCTURE WITHOUT TIES OR BALLAST
Three different types of concrete track bed were designed and built. Results of tests of rail deflections, both vertical and lateral, under dynamic loading are given and shown on charts. The static vertical deflections of the three types of track beds are compared with that of the standard tie and ballast road bed, over a period of 19 months service. The economics of the concrete railway road bed indicate that the cost reflects about an 18% increase over the standard tie and ballast structure. A comparison of the vertical and lateral accelerations of a locomotive and car, measured at the start of the tests over the concrete bed track structure and 8 months later show no marked change in their values over the 8 month period. The uniform and

small settling did not increase beyond the initial values. Good riding quality of the trains passing over these sections at 200 km/h continued throughout the test. The shelling damage to the rail laid on the concrete rail bed is not higher than on the conventional track structure. [German]

DIGITAL PROCESSING OF TRACK GEOMETRY DATA FOR MAINTENANCE PLANNING
The concepts for data processing described in this paper and the resulting preferred formats for the presentation of track geometry data resulted from discussions with knowledgeable people within the railroad industry. Data on 450 miles of track geometry are recorded by the test cars in less than 8 hours. The analog chart data is then scrutinized and edited. Within 48 hours after the test run, the digital gage printout and the annotated charts are ready for review by the maintenance engineer. By use of digital computer processing, a vast amount of track data can be collected and reduced into meaningful form quickly and efficiently. The Gage Data Reduction Program is a tool actively providing maintenance engineers and key management personnel with information to direct the planning of maintenance-of-way activities. The crosslevel program, presently under development, will be providing information on another key track parameter.

DETERMINATION OF MAINTENANCE OF WAY EXPENSE VARIATION WITH VARIOUS TRAFFIC VOLUMES AND EFFECT OF USING SUCH VARIATIONS, IN TERMS OF EQUATED MILEAGE OR OTHER DERIVED FACTORS, FOR ALLOCATION OF AVAILABLE FUNDS TO MAINTENANCE OF WAY
The purpose of this study was to determine the relationship between the characteristics of traffic and track and track maintenance costs. In this preliminary study a procedure was developed and checked in a general way against actual maintenance of way costs as reported by the C&O--B&O for the year 1966, with reasonable correlation. For general application it is believed that some further improvements can be made in the procedure that has been developed, to take into account the effect of climatic conditions on weed and brush control, of age of rail, etc. Extensive data are shown.

VENTILATION RESEARCH PROGRAM AT CASCADE TUNNEL, GREAT NORTHERN RAILWAY
A test and research program was conducted in April 1966 in the Great Northern Railway's Cascade Tunnel to ascertain the effects of diesel-powered trains moving through the tunnel from the standpoints of ventilation and engine heat dissipation. The test program included establishing measurement stations in the tunnel and on a locomotive consist, recording the pressures, air velocities and temperatures at these stations, analyzing the results and using an analytical approach previously developed to predict the effects of train movements through a tunnel. The test program was generally successful and fielded the desired results. A comparison of predicted and observed results confirmed the validity of the analytical approach used.

1964 EARTHQUAKE DAMAGES TO THE ALASKA RAILROAD
The 536-mile Alaska Railroad, which operates from two tidewater ports, Seward and Whittier, on the north Pacific Coast, through to central interior Alaska suffered intense damage. Some 200 miles of railroad were totally immobilized. All communication with line points were disrupted. The damage was such that it was impossible to use the railroad to reach the distressed areas. In excess of 110 bridges were rendered unserviceable; miles of track were warped out of line and rails twisted. Landslides accounted for over 2 1/2 miles of lost grade, leaving rails suspended in mid-air. The port and terminal facilities at Seward were all but wiped out by a combination of seismic action, tidal waves and fire. Whittier fared somewhat better, but was far from operable. Two hundred and twentyfive pieces of rolling stock were either lost or badly damaged. The Railroad property loss was estimated at $35,000,000. Photographs of some damaged areas are shown. Railroad repair problems are briefly discussed.

VERTICAL RESILIENCE OF RAIL ATTACHMENT FOR TRACK WITH CONCRETE TIES
Stiffness of concrete tie track can be reduced by introduction of resilient pads under the rail; yet, if too much flexibility is introduced, there is danger of losing stability of the rail. Thus arises the problem of selecting optimal resilience of the pads. The system of the interaction of wheel and rail can be represented as a system with six degrees of freedom. Selection of values for the various parameters is quite complex. The author assumed the masses of various components taking part in the oscillation to be proportional to their deflection under a single concentrated force. It was concluded that: the reduction of joint stiffness for more universally used track reduces dynamic effect of wheel to rail action, reduces stresses in wheel and acceleration input to the car, the recommended value of stiffness is of the order of 100 x 10 to the third power Klg/cm, and the values of inertia force can be considered as a linear function of speed. INSTRUCTION GOVERNING THE SUPERELEVATION OF OUTER RAIL AND THE SPEED OF TRAINS ON CURVES
This specification for operations practice provides four superelevation tables: Table A gives the equilibrium elevation for various speeds on curves at which the overturning forces are balanced by the superelevation. Table B gives the

speed at which conventional passenger equipment will ride comfortably around a curve. Three additional inches of superelevation would be required for balance of overturning forces. Table C gives a modified speed which may be authorized for freight trains. The superelevation is between equilibrium and comfortable. Table D gives a maximum theoretically safe speed assuming a center of gravity at 98 inches above the rails. This table is not to be used for elevating track. It is for information only. Change in superelevation will follow the alignment spiral where possible. The rate of change of superelevation should not exceed 1/2" in 31' for speeds up to 50 mph or 3/8" in 31' for speeds over 50 mph.

REVIEW OF A RUSSIAN ARTICLE CONCERNING THEIR APPROACH TO TRACK DESIGN AND MAINTENANCE

Three means of reducing track maintenance are being instituted in Russia in order to counter the 30-60% reduction in productivity of gangs caused by heavy traffic. It is estimated that each kilogram of rail weight reduces cost of track maintenance by 1.4-1.6%. Therefore use of the lightest size P-43 is being discontinued. New standards of track design utilizing welded rail would reduce maintenance of way by 14-20%. A 5 cm. increase of depth of ballast in 20 x 10 to the 6th power ton/klm. areas reduces labor cost by 5-7% and an annual reduction of stone by 500,000 cubic meters. [Russian]

VEHICLE DYNAMICS AND WHEEL-RAIL INTERFACE PROBLEMS

This paper reviews problems of wheel-rail contact in terms of present knowledge of the conventional steel-on-steel system and on possibilities for research and innovation arising out of extensions to this present knowledge. Specific directions for research suggested are: experimental work on wheel-rail contact forces, followed by refinements of theory to include effects such as surface chemistry, surface roughness and unsteady motion; studies of new structural forms for wheels and rails which might yield a superior overall system design; investigation of the wear-vehicle dynamics feedback process for steel wheels on steel rails, particularly where there are radical changes in vehicle suspension design; and studies of various wheel-track kinematic and guidance systems to provide basic information for overall system design.

HOW HIGH CAN TRAIN SPEED BE INCREASED? A REVIEW OF PRESENT AND FUTURE

The effect of wave propagation in air and on the rail is discussed as a theoretical limit for train speed. As practical limits to speed, the deflection by the pantograph to the wire at point of contact is described. By this principle the critical speed of the New Tokaido Line (NTL) train has been calculated as 400 km/h. Adhesion force is plotted versus tractive resistance for a 12-car NTL train, which gives the limit to speed as 370 km/h. Vibration limits speed to 230 km/h on straight track due to passenger comfort. The problems concerning curved track are also briefly discussed.

DISCUSSION ON STRESSES IN RAILROAD TRACK

The inspection tests of rail-joints in track made for the purpose of learning the source of the wear of the joint bars and the rail, the places of wear, information bearing on the mutual interaction of the worn bars and rail when under load and when the bolts are newly tightened, and other information relating to the stability and maintenance of the rail-joints have given desirable information. The occurrence of high stresses in the unloaded worn joint bars in track due to the tightening of the bolts was found to be as great as 30,000 and 40,000 lb. per sq. in. and in a few cases as high as 60,000 lb. per sq. in. The stresses were fairly proportional to the amount of the lateral bending put into the bar by tightening the joints, measured from the loose condition. The instruments designed and built to facilitate the measurement of profiles and shapes and straightness of joint bars and rail and their position with respect to each other in the joint have proved satisfactory.

WHEEL, AXLE, AND RAIL STRESS PROBLEMS RELATED TO HIGHER CAPACITY CARS--PART IV-EFFECT ON RAIL

Those items that have been found advantageous in reducing shelling caused by higher capacity (85 to 100-ton) cars are wheel loads should be limited in proportion to wheel diameter. Higher strength material in the rail will greatly reduce shelling but not entirely eliminate it (under the wheel loading conditions existing with 70-ton capacity cars before the allowable load was increased 5%). Modified rail head contours in today's modern rail sections which approach the average worn wheel condition, have been helpful in reducing shelling. Rail lubrication on curves extends the rail life but results in the removal of more rails for shelling rather than abrasive wear.

LATERAL LOADING BETWEEN LOCOMOTIVE TRUCK WHEELS AND RAIL DUE TO CURVE NEGOTIATION

Curve-negotiation mechanics and forces resulting when locomotive trucks negotiate curves are well recognized. However, meaningful and reasonable prediction of forces resulting in service conditions has been limited. An

instrumented wheel-axle assembly was developed and used on 2,3, and 4-axle trucks to study the effect of creep and the transverse load reactions resulting between wheel and rail. Instrumentation was used to measure these forces and the reactions between axles and truck frame under operating conditions. Test results confirm predicted phenomena and indicate the effect of creep on resulting loads. This paper includes a brief and general review of curve-negotiation mechanics and presents the test results and their relation to the theoretical analysis.

THE TRANSPORTATION ENVIRONMENT

Rail shipping is compared to truck shipping. In both cases the over-the-road environment is characterized by a continuous low amplitude vibration with random and periodic shock type inputs superimposed. The basic periodic inputs are rail joints for rail transportation and expansion joints for highway transportation. The random inputs for rail transportation are road crossings, bridges, switches, railroad crossings and the like. For highway transportation, the random inputs are railroad crossings, bridges, pot holes, etc. The continuous low level input is what creates resonant damage to products. The shock inputs create the dented, crushed, and broken hinge type of damage. Both types occur in both modes. The environment is divided into natural frequencies of vibration, vertical accelerations, shock spectra, impact forces and lateral acceleration, the magnitude of which is displayed graphically.

JOINT DEFLECTION AND RAIL END BATTER ON 130 LB RAIL EMPLOYING UNCONVENTIONAL METHOD OF LAYING

The purpose of this test was to determine if rails matched and laid in a continuous stretch of track with ends in same position as when passing through the hot saws at the rail mill show less joint deflection and rail end batter than rails received from the mills and laid in the usual way. The matching and laying of rails for the test produced 92 joints where ends were matched due to different ingots and rail classification. Initial measurements of joint deflections and rail end batter were taken during May 1930, and these measurements were repeated at intervals over a period of eight years. The final inspection was made during May 1938. It was concluded that to load, identify, distribute and lay rail matched in the same order as rolled and hot sawed at the mill would unquestionably result in higher manufactoring and rail laying costs than now exist. The results of this test with a limited number of rails matched, compared with rails not matched, show no improvement over the usual method of shipping and laying rail.

A2 040254
COMPARISON OF RAIL ABRASION, END BATTER AND DEFLECTION FOR 130 LB., 131 LB., AND 152 LB. RAIL

Rail abrasion, and batter, and joint deflection measurements were made on 130 lb., 131 lb., and 152 lb. rail on adjacent stretches of track east of Tyrone, Pa. Various joint bars were employed. Maintenance cost records were also recorded for this stretch of track. Early measurements, particularly of joint deflection, gave large variations in deflections from joint to joint, and led to removing and measuring a considerable number of bars showing high and low joint deflection. The results of these measurements indicated a need for better mill inspection to control vertical camber and led to a more thorough control of camber ranges during manufacture. Also the initial use of the "Toeless" type of bar such as applied in this test indicated a pronounced tendency to "cocking" the bars during first application and led to development of the present yoke gauge now in general use for applying the "F" types of bars to prevent "cocking". The 152 lb. and 131 lb. "F" type bars in this test were badly cocked when first applied. In the joint deflection comparison a good showing is made by the 131 lb. rail (untreated) with the B-1 type bar (Plan 66194-B) both on tangent and sharp curves. As to rail end batter the 131 lb. (untreated) rail with B-1 bars also gives the least amount of batter on tangent and sharp curves after eliminating the 131 lb. (heat treated) rail from which it would be expected less batter would occur. For the various weights of rail (untreated) on curves the 152 lb. rail had an additional service of one year over 130 lb. rail and three-fourths year over 131 lb. rail before it was necessary to transpose the rail. Measurements of rail abrasion during the period of test shows a marked decrease in abrasion on both tangents and curves for the 152 lb. and 131 lb. rails over the 130 lb. rails all untreated. Maintenance costs have been largely affected by local conditions, particularly differences in drainage and in the new tie territory of 130 lb. rail previously mentioned.

PERFORMANCE OF CHROME PLATED SWITCH POINTS

Chromium plated switch points were tested to determine whether chromium plating will increase resistance to abrasive wear sufficiently to warrant the added cost. Six pairs of 18' 130 lb. switch points were chromium plated on wear surfaces for a length of about six feet from the point. The plating process was preceded by a careful polishing of the surfaces to be plated. The cost per switch point was $14.53. An examination by chemical test of all of these points very shortly after they were placed in service showed that the plating was entirely removed wherever the wheels had contacted the switch points. This failure of the plating doubtless occurred immediately after they were placed in service and was probably due to deformation of the steel underlying the plating causing the plating to fracture and separate from the steel.

BATTER TEST OF 151 LB. R.E. RAIL
This report covers a test of 151 lb. R.E. rail in which the base and lower portion of the web at the rail ends is cut square while the head and upper portion of the web is mitred, the change in angle of out taking place about the center of height of web. The mitre makes an angle of 60 degrees with the line of track. For the purpose of test the above rails were laid on the Pittsburgh Division in No. 1 Eastward Freight Track east and west of Ardara on April 27, 1935. For comparison, 67, 131 lb. X-Rails with ordinary square ends were laid at same time adjacent and west of the mitred rails on the same track. After one night's traffic had passed over the rail initial measurements of rail and batter were taken. It was concluded that insofar as rail end batter there is no advantage in the use of mitred end rails over ordinary square cut end rails as determined by batter measurements over a period of one year and-1/2 months service in heavy tonnage freight track.

RAIL ABRASION AND END BATTER OF CONTROL COOLED 131 LB. R.E. RAILS
This is a progress report showing results of rail abrasion and end batter of control cooled 131 lb. R.E. rails rolled and treated by various manufacturers and laid during 1935. The Illinois and Bethlehem rails were laid on the Middle division No. 4 westbound passenger tracks on tangent and 4 degrees 0" curve east and west of Lewistown, Pa. The Carnegie and Inland rails were laid on the Panhandle Division No. 1 eastbound passenger and freight track on tangents and curves ranging from 3 degrees 14' to 7 degrees o" west of Carnegie, Pa. It was found that for the tangent track the differences in both abrasion and batter as between thermal treated and ordinary hot bed cooled rails are hardness of the rail has resulted from the thremal treatment. The information for curve is not directly comparable on account of wide variations in curvature where measurements were obtained. There have been no transverse fissures or other failures in either the test or comparative rails during the three year period between measurements.

FINAL REPORT ON 131 LB., R.E. FERRO-TITANIUM RAIL TESTS NOS. 253 AND 300 CONDUCTED ON THE ALTONNA AND COLUMBUS DISTRICTS
It was the purpose of the tests to determine to what extent rail with ferro-titanium added would alleviate the presence of shatter cracks with ultimate formation of detail fractures or other kinds of failures. Also, to obtain information as to the service quality of the above rail by means of observations and measurements of wear and rail end batter. The ferro-titanium rail used in Tests Nos. 253 and 300 was rolled under standard specification C.E. 35-(b). It was concluded that there is no overall advantage, either in reduction of head wear or rail end batter, in the addition of ferro-titanium to rail steel. Shatter cracks have been eliminated in rail of normal composition by control cooling. There is no necessity for using rails of special composition for this purpose. While the reduction in flaking, often associated with the formation of shelly spots, was not marked, there may be justification in considering titanium along with higher silicon contact as an alloying element intended to reduce shelling. It is recommended that in the study of rail chemical composition intended to reduce shelling, consideration be given to titanium.

RAIL END WELDING BY FIVE DIFFERENT PROCESSES
At the time of this test, a two-flame or three-flame welding torch was being used. Since a single flame welding torch is currently in use, it was felt that a reinvestigation of the thermal effects on joint bar camber and rail joint profile was desirable. This report covers the reinvestigation of this matter. Fifty joints were welded prior to applicaton of reformed joint bars and fifty joints were welded after application of reformed joint bars on the tangent east of Bellwood, Pa. Welds were made with a single flame welding torch on 152-lb. P.S. rail and joint bars reformed 1/16" oversize were applied to the joints. The measurements of camber of the bar itself, taken with a straight edge with the bar removed from the rail and reported above, show an average loss of camber of .004" in bars where welding was done after bars were applied, and a corresponding loss of .001" where bars were applied after welding was completed. The net loss of .003" is so small that it might be considered insignificant, except that it is an average and obviously represents a considerably greater loss in some individual bars. It is concluded that better top of rail profiles across joints result where joint bars are changed (reformed bars applied) after welding. The damaging effect of welding after application of reformed bars is less with the single flame torch than it was with the two or three-flame torch.

JOINT BAR SHIMS
It was desired to determine by service test the possible merits, economy, and effectiveness of joint bar shims used with special machined joint bars for 130 lb PS 4-hole and 131 lb. RE 6-hole bars. Set up for the test comprised 200 joints, each constructed with two designs of shims at each location compared with reformed bars without shims to be used in same track and location adjacent to test material. The 4 hole 130 lb. shim joints used in this test have not shown merit, economy or effectiveness in producing improved joint conditions over ordinary joints with reformed bars used without shims. Other than the limited amount of information developed by the 6 hole 131 lb. shim joints included in the trial made in main track conclusive information from the standpoint of service effect is not available, however, it is believed the results would be comparable to those obtained with the 4 hole joints.

CONTROLLED BEARING JOINT BARS
The purpose of this test was to determine the efficiency and merit of controlled bearing bars of F-4 type with known vertical camber. The test was changed to include two stretches of 131 lb. F-7 joints and one stretch of 152 lb. F-3 joints. Test locations were as follows: Middle Division No. 4 Track; Middle Division No. 2 Track; and Panhandle Division No. 1 Track. All bars were installed in continuous stretches on light curves or tangent. All bars were to be furnished with vertical camber, not less than 0.015 inches nor more than 0.045 inches. Installation of test bars was made in connection with laying of new rail. Periodic wear and deflection measurements were made on C.B. and comparative bars. Measurements of joint wear and deflections were made periodically until January 1944. A table showing average inward movement of joint bars and differences in deflection of joints is attached. The record shows a slight advantage for the straight bar. The record of maintenance cost shows a small difference in favor of the straight bars. The record of deflection and joint bar take-up shows very slight differences, the balance being in favor of the straight bars. There appears to be no justification for the additional cost of the lateral deformation necessary. Based on the results of this test and of Test No. 391, it is concluded that the controlled bearing bar has no advantage over the straight bar and is in fact harmful in that it introduces higher rail web stresses.

FLAME STRAIGHTENING OF JOINT BARS
The purpose of this test was to determine the effect on joint bars of the flame straightening process and the relative economy and benefits to be obtained from flame straightening joint bars in track, as compared with the application of reformed bars. It was concluded that consistent results in flame straightening fit bars were hard to achieve. Some few joints were properly straightened with good results, but most of them were left with either too much or too little camber. It was recommended that no further application of flame straightened bars be made.

MILL END HARDENED RAIL OF VARIOUS MANUFACTURERS AND WEIGHTS OF 131 LB. AND 152 LB.
The purpose of this test was to compare Mill end-hardened rail with non-end-hardened rail of various mills, weights and sections. The test includes 131 RE rail and also 152 PS and PSM rail laid in track near Newport and Mt. Union, Pa., 1944. Records of mill practices with respect to end-hardening processes were obtained. Laboratory hardness records were compared with mill values. Measurements were taken of rail end batter, joint deflection, and out-to-out dimensions of joint bars. These measurements were repeated after one year's service, and after two year's service. This report is based on an analysis of the 1946 measurements after a service of 2 years. It was concluded that rails properly end-hardened may be expected to show a marked improvement in resistance to batter, and in resistance to chipping and spalling when compared with non-end-hardened rail. The air quench method shows better performance than the water quench process. The reduction in batter and chipping should result in longer life of rail, and in reduced expenditures for repairing rail ends by welding.

FASTENERS TEST REPORT
Effect of temperature decreases on experimental fasteners was determined in a series of field tests. One inch Huck fasteners did not provide adequate restraint to freeze conventional insulated joints, as movement occurred with a 30F drop in temperature. A similar test was conducted with 1.125 inch Huck fasteners. The holding capacity was adequate to a minimum temperature of plus 10F. Hi-flex structural adhesive was laboratory and field tested. Performance was satisfactory to minus 15F.

TEST 431--RAIL MODIFICATION
The test comprised modified rails applied on high side of 6 deg 00' curve in heavy tonnage territory. For the test rails 131 lb. No. 1 quality, open hearth high carbon steel were furnished. Performance of the rails in track was followed during 2 years service by occasional inspections, measurements of rail wear, and rail end batter. Carnegie rails with 10" head radius were heavily flaked but no shelling was evident, whereas, the Bethlehem rails with 14" head radius were shelling.

STRESS CORROSION OF RAIL WEB STEEL (STATIC)
The test included six rail joint segments containing one bolt hole with a bolt inserted to make the joint. It also included twenty steel specimens taken from rail steel which were subjected to static bending stresses. The twenty corrosion test specimens were tested after nearly twelve and one half years of exposure to the elements. The joint segments were tested approximately one month later. All of the test specimens were cleaned throughly and examined in the laboratory by Magnaflux and Magnaglow methods for the presence of corrosion cracks. While there was considerable pitting to be found, the laboratory examination disclosed no cracks in any of the specimens. This test shows that static stress combined with corrosion has little or no effect upon the development of cracks in rail web steel.

ARRANGEMENT OF RAIL ANCHORS ON TRACK HAVING MAJOR TRAFFIC IN ONE DIRECTION BUT SIGNALLED FOR MOVEMENT IN BOTH DIRECTIONS
The test consisted of two stretches, one at Metuchen on the New York Division and one at Edgewood on the Maryland Division. Each stretch was signalled for movement in both directions. Application of rail anchors in five different arrangements was made on new 155# rail. From experience gained in this test it may be concluded that six anchors with traffic are seldom sufficient on a main line track. With regard to reverse anchoring it may be concluded that two reverse anchors are sometimes, but not usually sufficient. Four reverse anchors appear to be sufficient in all cases. For track having major traffic in one direction but signalled for use in both directions, a minimum of 8 normal and 4 reverse anchors be used and that they be applied in the present conventional arrangement with reverse anchors being applied to the opposite side of normally anchored ties.

FLAME CLEANING OF RAILS
The purpose of this test was to determine the possible advantage, effectiveness, and economy in flame cleaning of rails before the application of grease at rail ends for protection against corrosion. The rail ends in four stretches of new rail totaling seven miles were flame cleaned before greasing. Inspection made at the time of application and after seven years' service revealed that air cleaning and flame cleaning were equally effective. Under the circumstances of this test no advantage is shown for flame cleaning which is considerably more expensive than the usual method.

SWITCHES WITH RAILS END HARDENED AT THE HEELS AND RAIL BOUND MANGANESE FROGS WITH TOE AND HEEL RAIL END HARDENED
The purpose of this test was to determine the practicability and economy of end hardening for heat treating rail ends on frogs and switch points. The test

included four frogs and two complete switches with treated rail ends, and two frogs and complete switches without treatment for comparison. There was no apparent advantage to be gained by end hardening or heat treating rail ends. Results of this test indicate that joint batter is not a governing factor in determining need for renewal of frogs and switches. Pending further development the end hardening of frogs and switch rails is not recommended.

140-LB. RAILS TO FINE GRAIN STEEL (ALUMINUM ADDED TO THE INGOT)
The purpose of this test was to determine if inherently fine-grain steel will resist shelling better than rails of ordinary steel. Frequent inspections of the test installation were made, and it was observed that the fine-grain and ordinary rails performed nearly alike. In 18 months' time the flaking and head checks were much in evidence, and after two years of service, head checking and flaking were well advanced. A derailment in November 1956 damaged three of the fine-grain rails. A previous laboratory examination of the rails had revealed that the fine grain steel had practically the same mechanical properties as the coarse grain steel as measured by tensile tests and Brinnel hardness. It was concluded that fine grain steel produced by addition of aluminum to the ingot as used in this test, offers no advantage for use in rails.

A2 040278
DETERMINATION OF PLASTIC FLOW IN RAIL HEAD
The purpose of the test was to determine the amount of plastic flow which takes place in the gauge corner of a rail on the high side of a curve under conditions which produce shelling. The rails were laid on the Bolivar Curve. At this location the track was laid with 140-lb., 1948 rail, which in August 1953, was showing flaking and light shelling. This is a 4-degree curve with 4-inches superelevation, authorized speed 45-mph, and carries moderate to heavy eastward freight traffic. Records kept in connection with another test indicate a tonnage of approximately 29,000,000 gross tons annually. The three test rails were installed August 17, 1953. Inspection September 12, 1955, showed light flaking on all three rails. On the high rail of curves there is a flow of metal at the top gauge corner of the rail toward the gauge side. This flow of metal extends to a depth of 1/4-inch to 3/8-inch below the rail surface. The magnitude of deformation is positive evidence of shear stresses well beyond the yield point of the steel.

A2 040279
RAIL WEB STRESSES IN HIGH SPEED TERRITORY
The purpose of the present test was to determine if possible the cause of frequent split web failures in the joint on 131-lb. RE rail on the Fort Wayne Division, and in 152-lb. PS rail on the New York Division. Web failures in 131-lb. and 152-lb. rail on the Fort Wayne and New York Divisions are adequately explained by the corrosion fatigue theory. The ocassional bolt hole failures in 133, 140, and 155-lb. rail are not readily explained. A 50% allowance for impact is justifiable based on measured wheel loads. Application of reformed bars changes stress distribution in the rail web and in many cases increases web stresses, accelerating rail web failure. Loose bolts and increase in rail end gaps increase rail web stress. The results of this test emphasize the need for protection of rail steel against corrosion, for maintaining standard bolt tension, a good fit between bars and rail, and good surface through joints.

AREA DESIGN OF RAIL BOUND MANGANESE FROG
For test purposes 4 AREA design #10 rail bound frogs were installed in main track in comparison with 3 PRR Standard rail bound frogs. At each of the three locations both types of frogs were placed in track having similar traffic conditions. A record of first cost, service performance and maintenance difficulties was kept for each location. It was concluded that the AREA design Rail Bound Frog will give longer service and be more economical than the PRR Standard Frog. Therefore it was recommended that the PRR Standard for Rail Bound Manganese Frogs be modified to include the basic AREA design at the heel of the frog which includes the 7" spread of the casting and the support and design of the heel rails.

ALLOY STEEL RAIL (CHROME-VANADIUM OR "CV")
The CV rail was laid in October 1953, in connection with regular rail renewals. The location was selected because it was one where moderate shelling had developed in the previous 131-lb. rail over a period of about 11 years. A total of 47 CV rails were laid--16 on the low side and 31 on the high side of the curve. Measurements of gauge superelevation, ordinates and rail head wear were made. A final inspection of CV rail was made on October 29, 1959, at which time 30 CV rails remained in track. There was no indication of shelling, although, some flaking was noted on the CV rail, and there was no indication of rail and defects. The results of this test have shown the CV alloy steel of the composition used to be unreliable. Its good wearing qualities and superior resistance to shelling are over-shadowed by its poor resistance to impact.

FLAME HARDENED AND HEAT TREATED STOCK RAILS
Flame hardened and heat treated stock rails were installed at locations where the open hearth stock rail had shown short life due to excessive wear, primarily flange wear. Flame hardening and heat treating produced a Brinell hardness on the rail head of approximately 350. Both the flame hardened and heat treated stock rails gave better performance than the open hearth stock rail; however, the flame hardening process resulted in considerable vertical distortion of the stock rail, as much as five feet in 60-ft. As a result, this type of hardening was discontinued. While this test was installed initially to investigate the reduction in flange wear, the use of heat treated stock rails to date and the results of heat treated rails used for other purposes indicate that they provide greatly increased life and reduced maintenance as compared with ordinary stock rails where crushing and plastic flow cause frequent renewal.

FLAME HARDENED VS HEAT TREATED AND MANGANESE CROSSINGS
The purpose of this test was to determine the relative value from a service point of view of flame hardened crossings, as compared with heat treated and

manganese crossings. Two flame hardened, one heat treated and one maganese crossings were installed on new timber supports in a two over two track crossings, making an angle of 71 degrees 38'. All crossings were interchangeable. These crossings were installed on May 2, 1953. On the September 8, 1954, inspection it was found that excessive batter on one of the flame hardened crossings made renewal necessary. Initial cost, maintenance required, as well as service life indicate a preference for the heat treated crossing over the flame hardened.

FOUR BOLTS VERSUS SIX BOLTS IN JOINT BARS FOR 155-LB., 140-LB., AND 133-LB. RAILS--JOINT BARS TO BE STANDARD LENGTH

Four different punchings of bars with compatible rail drillings were compared at three test locations. All the bars used were of standard length and design, the only difference being the hole location. The test was laid out in such a manner that measurements of batter and deflection of joints could be obtained on both tangent and curved track. The curve was 1 degree 52" in the portion of the 140-lb. test rail with AREA drilling, four hole special drilling, PRR standard drilling, and PRR standard with second hole from each end omitted was laid on tangent track only. There is no material difference in profile or in maintenance cost among the various combinations tested. The four hole bars tested will adequately fasten the rail, but the saving realized by elimination of two bolts would not be enough to justify the expense of the change of standard.

A2 040287
FIELD END HARDENING OF RAIL BY THE AIR REDUCTION CO. METHOD

Two and seven-tenths miles of 140-lb. PS rail, laid in No. 3 track were utilized for this test. End hardening rail in track was completed on June 18, 1953 in conjunction with the laying of new 140-lb. PS rail. A total of 279 joints were hardened at a cost of $0.39 per joint. The high temperatures necessary for the end hardening process had a damaging effect on the No-Ox-Id protective coating applied to the rail web in the joint area. The heat treatment caused an average increase in Brinell hardness of about 50 points. A visual inspection of the test stretch in 1959 confirmed previous observations that mill end hardened rail was more resistant to impact and had fewer battered joints than did either of the other two types. In view of the fact that mill end hardened rail is now available from all mills serving the Pennsylvania Railroad there is no advantage to be gained from end hardening new rail in the field, except as indicated above for cut ends in continuous welded rail.

RUBBER TIE PADS UNDER CROSSING FROGS

The purpose of this test was to determine if rail abrasion pads applied between tie plates and crossing frogs and anchor seal pads applied between timber and tie plates in railroad crossings would result in reduction of noise, improved riding conditons, reduced maintenance, and increased life of frogs and timber foundations. The test locations are in heavy-tonnage tracks and in high speed territory. The frogs at Valparaiso developed considerable batter and tread wear after a very short period in track. Chipping and cracking of the castings was observed within six months. The pads were in long enough to determine that they did not have sufficient rigidity to withstand the large forces to which they were subjected. Both anchor seal and rail abrasion pads were deformed and torn. The crossings in both tracks at Orrville have given satisfactory service. There has been little difference in maintenance required for the crossings with and without pads. There was no significant reduction in noise to be realized from the use of pads. The use of tie pads will prevent tie plate penetration into crossing timbers.

SWITCH POINT GUARDS

The test was begun with Bethlehem Steel Co. guards, but was later expanded to include guards manufactured by the Q. and C. Co. and American Brake Shoe Co. All three types of guards have been quite effective in reducing flange wear at the point of the switch rail. At each location, switch point life has been more than doubled. The Racor and Q. and C. types require some maintenance in that the bolts through the stock rail should be kept tight. Original cost and installation cost of the Bethlehem Steel Co. type is greater. Under certain conditions the wheels have a tendency to climb up the guarding face. In view of this climbing action these guards should be used only in yards or at slow speed locations. The switch point guards should not be used where L-6 and P-5 locomotives are operated.

A.A.R.--DESIGNED INSULATING JOINT

The joint was built up from a new 115-lb. R.E. joint bar. A layer of neoprene rubber was vulcanized to the fishing surfaces of the bar and at the same time to a 1/16" sheet of steel previously formed to 132-lb. R.E. bar fishing surface contour. Two neoprene coated tie plates were used to support the joint on the ties. The test 132-lb. R.E. insulating joint was installed on July 2, 1959. An inspection of the joint on 7-9-59 showed that the joint bars were performing satisfactorily. The nut locks used with the bolts were obviously defective, since four of the six had failed. The neoprene was separating from the steel plates at the top of the end posts. The standard insulation test revealed no current leakage. Neither the scraping of the bolts nor the peeling of the neoprene should in any way affect the effective performance of the test joint.

A2 040292
INVESTIGATION OF RAIL HEAD HARDNESS

Transverse rail head specimens were taken from three pieces of rail, 131-lb., 140-lb., and 155-lb. sections received for examination of failure. Hardness readings were taken from the running surface toward the interior of the rail head for a distance of approximately 1/2 inch. The hardness on the gauge side was usually maximum at 1/16 inch to 3/32 inch below the running surface, with slightly lower hardness between this point and the surface of the rail head. It is concluded that where rails have experienced sufficient traffic under heavy loads to develop approximately 1/8 inch head wear the hardened metal resulting from cold work extends 1/8" to 3/16" below the surface with a maximum hardness at a depth of 1/16" to 3/32". Rail grinding to a depth of .007" to .010" should cause no anxiety with respect to loss of surface hardness with such rails.

RAIL ANCHOR RESISTANCE IN TRACK
Six panels of track were tested at two locations. Resistance to rail anchors was developed by applying a longitudinal load to the end of each rail in a panel of track; this load was transmitted through rail anchors and ties to ballast. The load was applied by means of two hydraulic jacks and manually operated hydraulic pump. The panels at Lewistown having every tie anchored failed at a total load of 32,000 pounds while the panel having alternative ties anchored failed at 29,000 poinds. Panels at Parkersburg having every tie anchored failed at an average total load of 20,000 pounds while the panels having alternate ties anchored failed at an average total load of 18,000 pounds. Actual resistance to longitudinal movement, per panel, depends on type and quality of track structure.

EFFECT ON RAIL OF KERSHAW TRACK LINER
Since this is the first track lining machine to operate on an impact principle, some question of doubt had been raised as to the possible effects of this impact on the rail under adverse conditions. As a practical test the machine was first used at a temperature of plus 30 degrees F. on curved yard track laid with 1903 100-lb. rail. It was used in attempting to line a yard track laid with 85-lb. rail with a rail temperature of plus 10 degrees F. an atmospheric temperature of approximately 0 degree F. In both cases the track was full of cinder ballast, frozen solid. Ties were spaced 23 inches apart and were in good condition. In the practical test the Mershaw Track Liner did not break or visibly kink either 85-lb. or 100-lb. rail under the very adverse conditions of the test. However, the track structure was weakened and track gauge spread 1/12 in. after five to eight impacts of the ram.

THERMITE WELDING PRACTICES OF RAIL IN THE UNITED STATES
The alumino-thermic welding method for joining the ribbons has become practical. Improved thermite welding methods have been introduced which produced rail joints meeting the quality of electic-flash butt-welded rail joints and oxyacetylene pressure butt welded rail joints. The alumino-thermic or thermite reaction is a strongly exothermic self-propagating reaction, where finely divided aluminum reacts with a metal oxide. A mixture of aluminum and iron oxide produces sufficient heat to weld steel, the filler metal being produced in the reaction. The reaction takes place at 5,000 F and produces a filler metal at 3,5000 F which, in entering the rail gap, welds and fuses the rail ends. This filler metal is pure iron with a low hardness, which has to be enriched with alloys and high carbon steel to produce a rail-quality filler metal.

JOINT BARS 152 LB F-3 AND 131 LB F-7 WITH VARIOUS RANGES OF UPWARD VERTICAL CAMBER
The purpose of these tests was to determine the effect with respect to service and maintenance labor of joint bars of various camber in heavy tonnage tracks. The test included application of bars with 4 ranges of camber in various joints applied in service at selected locations. Periodical measurements were made of joint deflection, rail end batter and out to out take up of joint bars; records of maintenance work and cracked or broken bars were obtained during a period of more than 3 years service. The best results require rails straight or with an upward sweep at the ends and bars of camber .030" to .060". It is recommended that if and when all mills produce rails with the desired end condition, the specification for joint bars be changed to provide for limits of .030" to .060" vertical camber.

RAIL LAID WITHOUT EXPANSION ALLOWANCE VS. RAIL LAID WITH NORMAL EXPANSION ALLOWANCE
The purpose of this test is to determine by service test the practicability and advantages of laying end hardened rail without expansion allowance and with joints "frozen", as a means of reducing rail end impact and noise, and rail end batter. The design and laying of the test track is described. Walking inspections and observations of the test during the recording of field data have indicated superior surface and rail end condition of the tight rail as compared with the standard. Riding the Aero Train, which was noticeably noisy, showed a lower level of joint noise on the tight rail. The joints in the tight rail have lost less camber than those in the standard rail. During nine year's service it has been determined that rail laid without expansion offers reduction in joint bar wear and reduction in loss of joint camber as well as a better maintained track for equal expenditure.

R.M.C. PLASTIC RAIL JOINT PACKING WITH VERMICULITE BASE
R.M.C. Plastic Rail Joints Packing is a cake composed of vermiculite impregnated with an asphalt oil and rust inhibitors. It is placed at the end rail behind the joint bar for the purpose of lubricating and protecting the joint. No-Ox-Id "A" is a rust inhibiting grease used for the same purpose. Comparison was made of these two substances by applying them to alternate 10 joint stretches. While the damage to rail ends by corrosion fatigue, which was found in so many cases with the original R.M.C. packing, does not seem

to be repeated with the Vermiculite packing, there is no evidence that the overall protection is superior to that given with No-Ox-Id "A". The protection to the rail end in most cases appears to be inferior. Since rail web failures have been reduced in new rail designs, and since there was a lack of apparent benefit from the use of packing, the use of packing was abandoned.

78-FOOT RAIL VS 39-FOOT RAIL

The economies resulting from the use of 78-foot rail as compared with conventional 39-foot rail was studied. Test stretches were installed at three locations. Each location included one mile of track laid with 78-foot rail and one mile of track laid with 39-foot rail. Test results indicate that there has been a saving by the use of 78-foot rail. There should be an increase in savings credited to 78-foot rail when the need for reformed bars develops. Relatively larger joint gaps on the 78-foot rail as compared to the 39-foot rail have not as yet shown an appreciable effect on rail end batter or surfacing costs. End hardening of rail has apparently prevented excessive batter. The additional rail anchors applied to the test stretches in 1954, have been successful in preventing further accumulation of wide joint gaps in the 78-foot rail, and have also prevented welds from moving into tie plate areas.

REPAIR OF CAST MANGANESE GUARD RAILS BY ELECTRIC ARC PROCESS

The purpose of the test was to determine the economy and practicability of repairing worn or cracked cast manganese guard rails by building them up with electric arc welding. The 130-lb. P.S. guard rails were placed in "South Interlocking" at Altoona, Pa., in very severe service locations. The 131 R.E. guard rails were placed in a ladder track at the west end of Antis Yard, Altoona, Pa. After 2.5 years service, all guard rails have given satisfactory service at the locations they were applied. The 130 P.S. guard rails at "South Interlocking" are showing heavy wear, while the 131 R.E. at the west end at Antis Yard are showing relatively light wear and are in good condition. From the results of this test, it is concluded that the building up to worn cast manganese guard rails, by use of electric arc welding, is practical and economical.

A COMPUTER STUDY OF DYNAMIC LOADS CAUSED BY VEHICLE-TRACK INTERACTION

Computer analyses of vehicle and track are producing enlightening results regarding actual dynamic loads and the manner in which various parameters of vehicle and track structure affect these loads. Using this information, it is possible to decide more intelligently how to alleviate the high wheel-rail stresses caused by today's unique traffic and track conditions. Possible solutions range from better track maintenance to different wheel rail geometries to changes in stiffness and damping of trucks and the track structure itself.

DYNAMIC MEASUREMENT OF RAIL PROFILE AND RELATED LOCOMOTIVE TRUCK MOTIONS

The profile of the railroad track on which a railway vehicle operates represents an input into the vehicle. This input is due to vertical and lateral rail irregularities and can cause dynamic loads that result in excessive damage or wear and tear on vehicle components and on the track itself. In order to study the dynamic operation of rail vehicles, it is necessary to know the profile of the track on which they operate. Since the unloaded profile of the rail can vary significantly from the loaded condition, it is the loaded-rail profile that must be known. This paper presents a method developed by the authors' company for the rapid measurement of the loaded-rail profile and includes some typical rail profiles and related truck motions resulting from these profiles. The instrumentation resulting from this work appears to have immediate application in day-to-day railroad operation and in high-speed rail transportation studies.

THE EFFECTS OF JUMBO (HEAVY AND HIGH CUBE) CARS ON THE M OF W EXPENSES

Studies research and field observations show that the heavier wheel loads imposed on the rail today cause higher rates of rail failures, severe flaking, spalling, pitting and shelling. Track geometry also deteriorates faster. The two remedies are stronger rail material and stiffer track. But these are quite costly and economically not always possible. Instead, it is more likely that the movement of heavy loads will be continued on the present track at the expense of higher maintenance costs. This paper presents estimates and approximations with regard to the magnitude of the penalty M of W departments must pay in the area of track maintenance as a result of operating jumbo cars.

QUALITY OF RAILS AND MEANS OF GUARANTEEING IT--FALLING WEIGHT TESTS AND DEFINITION TESTS (1ST AND 2ND SERIES OF TESTS)

The main object of these tests--was to define and to standardize the conditions of use of the falling weight tests laid-down in UIC Leaflets 860-1-0 and 860-2-0, for the acceptance of rails of current quality and rails of nontreated steel of a quality resistant to wear. It was concluded that a falling weight test, irrespective of its type, is not representative of the fatigue behavior of rails in the track, but it was considered advisable to retain for the time being, such a test on complete pieces of rail, to make it possible to detect and eliminate brittle rails with a large degree of probable success and to maintain each rail production within a truly characteristic and correct scatter range.

A2 040414
QUALITY OF RAILS AND MEANS OF GUARANTEEING IT--CONDITIONS OF USE FOR TECHNICAL SPECIFICATION UIC 860-1 CONCERNING: DIMENSIONAL TOLERANCES, FALLING WEIGHT TEST, TENSILS TEST-PIECE, DETECTION OF PIPING

The conditions of application of UIC Specification No. 860-1 were investigated relative to dimensional tolerance, falling weight test, tensile test piece, and detection of piping. Initially, rail tolerance measurements indicated that the majority of mill-produced rails were not acceptable, but if specified tolerances were strictly adhered to, it was felt the price of rail would increase greatly. Since users were reasonably satisfied with currently produced rail, the tolerance applicable to web thickness, inclination, and openings of the fishing angles were relaxed. When UIC Specification No 860-1 was initiated in 1954, it constituted the first step towards the standardization of the falling weight test. The Committee now offers a choice between two methods of carrying out the falling weight test; one method involves two successive blows applied to the test pieces rolled from a certain number of ingots, the other involves one blow and is applied to test pieces rolled from every ingot. Because of the nature of the steel used for wear-resisting rails, the corresponding UIC Specification 860-2 has been drafted to include a tensile test piece of 10 mm diameter. The Committee to propose the standardization of the 10 mm diameter test piece. One result of this decision is that the minimum elongation will have to be raised from 12 to 14% in the case of ordinary rails. This test has been found to be not very accurate and of limited interest, since in reality it only permitted the revelation of piping in the rail without offering the possibility of its true appreciation. The Committee therefore sought another test for inspection purposes which would reveal piping in an indisputable manner. After considerable research, they have decided on a test which consists of the examination of the polished slice of rail intended for the macrographic (sulpher print) test.

TECHNICAL AND ECONOMICAL STUDY OF TESTED TYPES OF CONCRETE SLEEPERS. BEHAVIOUR OF ORE TEST SECTIONS. (2ND OBSERVATION PERIOD 1965-1966). EFFECTS AND DERAILMENTS ON CONCRETE SLEEPERS

This report examines train derailments on concrete sleepered track. It is based on 40 derailment reports furnished by 8 European Administrations. It was that reinforced concrete sleepers have a certain degree of fragility and the damage observed in case of derailments, caused by the impact of derailed wheels, is generally considerable. It has, however, become apparent that the presence of concrete sleepers has never led to the derailment of axles, which would not have been derailed in the case of wooden sleepers. The repair involves more work than that in wooden-sleepered tracks and the resumption of the traffic at reduced speed often takes more time.

A2 040416
BEHAVIOUR OF THE METAL OF RAILS AND WHEELS IN THE CONTACT ZONE-RESIDUAL STRESSES IN THE RAIL (CONTINUED) STUDY OF THE WORK-HARDENED ZONE

This report contains the results of measurements taken to study the work-hardening caused by traffic, and more especially the changes in the residual stresses in the rails near the running tread which constitute an important factor in the study of rail fatigue phenomena. About 5 mm below the surface the work-hardening is very large, and the rail is the center of a hydrostatic pressure zone extending down to a depth of approximately 10 mm, this then changing into a tensile one with a maximum at about 15 mm. This may explain why the fatigue cracks (of the kidney-shaped flaw type) tend to originate at a depth of 10 to 20 mm but do not develop in the upper highly compressed zone. Furthermore, the residual-stress fields vary from one section of the rail to another, probably as a result of the oscillations of the wheel-loads due to short-wave rail corrugations.

A2 040417
BEHAVIOUR OF THE STEEL AT THE POINT OF RAIL-WHEEL CONTACT- INTRODUCTORY STUDY ON THE CAUSES OF SHELLING CRACKS IN RAILS

This report reviews pertinent literature on the subject of shelling cracks in rail head. From the research conducted at the University of Illinois it is concluded that shelling cracks in rail heads are primarily due to fatigue under repeated rolling action. Obvious methods of reducing the development of shelling cracks would be to reduce wheel loads on the rails, to use larger diameter wheels or to use stronger rail steels. Future research should be directed towards the closing of the gap between standard fatigue data and the fatigue phenomenon as it occurs under contact stresses due to rolling action. At the moment, the prime difficulty in correlating tensile or torsion and rolling contact fatigue data stems from insufficient knowledge of stress distributions modified with respect to elastic theory by plastic deformation.

A2 040418
PROBLEMS OF INTERACTION OF VEHICLES AND TRACK--WORN PROFILES OF RAIL HEADS AND WHEEL TYRES

As a result of a large number of tests it has been proved that service wear on wheel tires and rail heads leads to definite profiles. These worn profiles are to a large degree independent of the initial profiles of tires and rail heads. In the worn condition the profiles maintain their form and are not subject to any further change. The worn profiles are characterized by good mutual conformity and thus by little increase in wear. The worn profile of tires results in a shortening of the wave length of the periodical wheel set motions (hunting) in the track clearance. It was concluded that to wear new profiles of rail heads and tires should be adapted as much as possible to the worn profile. The use of special wheel tire profiles promise no lasting influence on the riding quality of vehicles. Therefore other design measures on the vehicles should be preferred to control the hunting motion.

SERVICE AND DETECTED FAILURES OF BUTT-WELDED RAIL JOINTS

During the period 14 service and detected failures of butt-welded rail joints were submitted for examination to the AAR Research Center. Macrographic and Microscopic examinations of the welds and of both rails adjacent to the joint were made. Since the majority of the butt welding rail in the United States is done by means of the electric flash process, the failures reported in Table 1 are predominantly in the welds produced by this process. Because of the thermal shock produced by this process in the relatively short heated portions at the ends of the rail, failures occur in rails with heavy segregation or fish tail which, before welding were in a homogeneous state, but opened into a discontinuity during the welding.

INVESTIGATION OF SERVICE AND DETECTED BUTT-WELDED RAIL JOINT FAILURES
In the period between October 1, 1965, and October 1, 1966, sixteen failures, service and detected, in butt-welded rail joints were submitted to the Association of American Railroads Research Center for a metallurgical examination. To date, the investigation has been completed on 9 of these 16 failures, in two oxyacetylene pressure butt weld: It is believed that a result of improper welding practice. Failure in an electric-flash butt weld was attributed to the presence of an electrode burn introduced during the welding process. In other electric-flash butt welds it was disclosed that the rail ends were cropped with a petrogen torch and that the time between cutting and welding ranged from a few days to several weeks. This time lapse is of concern because of the incipient cracks that may form and further develop on subsequent heating operations. A second possible cause for these failures is that the amount of rail cropped from the ends of these secondhand rails was insufficient to remove existing bolt-hole cracks that extend back into the web. In still other electric-flash butt welds, heavy segregation patterns were found.

ROLLING-LOAD AND SLOW-BEND TEST RESULTS OF BUTT-WELDED RAIL JOINTS
In the period from October 1, 1965, to October 1,1966, sixteen rolling load tests and six slow bend tests were conducted on butt-welded rail joints at the Association of American Railroads Research Center. The joints were made by the thermite (Thermex Metallurgical, Exomet and Orgotherm), submerged-arc and oxyacetylene pressure-butt-welding process. The rolling-load tests were made on a 12-in-stroke rolling-load machine. Welded specimens were tested for various reasons including: (1) to determine the quality of the submerged-arc-welded rail joints, (2) to evaluate 115-lb thermite welded rail joints made by the Exomet process, (3) to determine the seriousness of making butt welds from rails with hairline cracks of (pipe) in the web. (4) to investigate the possible detrimental effects of a collar that was not removed from an Orgotherm thermite welded rail joint. The slow bend tests were made with the rail resting on supports 4 ft. apart and loaded at 2 points, one on each side of and 6 in. from the weld. These tests were made with the rail base down, thereby subjecting the head to a compressive stress and the base to a tension stress. For satisfactory service performance a minimum of 1.5 in. of deflection and 140,000 psi modulus of rupture are being used as tentative criteria for oxyacetylene and electric-flash pressure butt welds. A summary of the slow bend test results is provided.

BUTT WELD FAILURES
A record of failures in various types of butt-welded rail is presented and briefly analyzed. On the basis of failures per 100 weld years, the failure rates for the oxyacetylene pressure butt welds and electric flash pressure butt welds are low, and about the same, for new rail. It should be noted, however, that the average service period of the oxyacetylene pressure butt welds is 68 percent longer than that of the electric-flash pressure butt welds. For relay rail, the performance of the oxyacetylene pressure weld is somewhat better than that of the electric-flash pressure weld. The failure rate in thermite welds is substantially higher than that for either of the two pressure processes.

EVALUATION OF LINDE'S EXPERIMENTAL 936-89 WIRE FOR BATTERED RAIL END BUILD UP USE
An investigation to evaluate Linde's experimental 936-89 cored wire for rail end build up was conducted based on rolling-load test results, hardness survey results and a metallurgical examination to determine the quality of the weld. Information supplied by Linde relating to the welding procedure indicates that prior to welding, all joints were preheated to 700 F. A Tempil stick was used to determine the preheat temperature. Immediately following the preheat the joints were welded using 425 amperes, 27 volts. Sample rail joint were resurfaced at the butt edge to bring the deposit closer to the edge. These welded, battered rail end sample joints were subjected to rolling-load testing in the 12-in-stroke rolling-load machine. Testing of one sample was discontinued after the joint had been subjected to 4,002,200 cycles in the rolling-load machine because of excessive batter. Testing specimen 154 C was subjected to 2,000,000 cycles in the rolling-load machine. This test was discontinued because of a failure, originally starting as a progressive-type failure from a bolt hole, and later resulting in a head and web separation when the bolts were tightened to a desired tension. Speciments cut from joint 154 A show a normal heat pattern and good weld-metal deposit penetration. A good weld-metal deposit penetration was noted.

INVESTIGATION OF INSULATED RAIL JOINTS
A comprehensive investigation was undertaken to determine the most appropriate and significant laboratory testing procedure for evaluating the merits of insulated rail joints. The investigation decided upon consisted of three phases. First, a new 3M plastic insulated joint for 136 RE rail was instrumented with strain gages to measure the flexural strains developed in the top and bottom of the two bars at midlength and 6 in each way from midlength. Since the strain would be zero at the bar ends, this gave five points along the length of the bar to establish the shape of the bending moment curve. These bars were then placed in main-line track on the Santa Fe. and measurements were taken of joint bar flexural strains developed under a number of passing trains, including passenger and freight. In the second phase of the investigation, another pair of the same type of 3M plastic joint was similarly instrumented with strain gages and placed in a rolling-load machine in the laboratory. Increments of loading were applied, and it was found that a wheel load of 15,000 lb. gave the same range of flexural strain in the bars at midlength as the maximum range measured in the track installation. The third phase of the investigation is a laboratory study with the objective of determining the effectiveness of different designs of insulated joint to support the rail ends and minimize joint tie tamping requirements. It would be expected that the more flexible the insulated joint, the more load would be thrown on to the supporting ties and more frequent tamping would be required. Accordingly, two lengths of 132 RE rail, each 10 ft long were supported in a special laboratory setup under a hydraulic loading machine on 11 ties plates spaced 20 apart. Two load cells were placed between the rail base and each tie plate to measure each tie reaction. Results were not avilable at the time of this publications.

RAIL CROPPING USING THE OXYGEN-GASOLINE (PETROGEN) CUTTING TORCH

Hardness checks of the cropped area revealed excess cementite and a hardened heat-affected zone. This method of cropping rail for oxyacetylene pressure butt welding is not recommended unless the cementite and heat-affected area is removed by other means. Because of the large quantity of metal removed (washed-out) during the electric-flash butt-welding process, cropping by an oxygen-gaoline torch may be acceptable, but if cementite becomes entrapped in the weld interface during the welding process, a weld failure may result. If cementite becomes entrapped in a weld produced by a thermite welding process, it will act as a stress raiser which promotes fatigue failure. In rail torch-cut for application of joint bars, the presence of cementite on the rail faces may promote head and web separations.

RAIL CROPPING BY THE WET ABRASIVE CUTTING METHOD USING A 26-IN. N.C.G. NO. 310 CUT-OFF WHEEL

Photomicrographs reveal the depths of transformed (untempered martensite) metal to vary from 0.017 to 0.024 inches for the three rails which were cropped by the wet abrasive cutting method. This layer would wash out during electric-flash butt welding. Tests will need to be performed to determine the effect of this layer on rails welded by oxyacetylene welding.

INVESTIGATION OF SERVICE AND DETECTED BUTT WELDED RAIL JOINT FAILURES

In the period between October 1, 1966, and October 1, 1967, there were seven service and no detected failures in butt welded rail joints investigated by the metallurgical laboratory of the AAR. A summary of these service failures is tabulated. Investigation 136-22 involved an electric flash butt welded joint that failed in service. The rails used in the fabrication of this joint were 112-lb RE sections rolled July 1942. This failure could be attributed to an entrapment introduced during the welding process. Investigation 136-25 involved a rail, part of a continuous welded string, that failed in service. This rail was identified as a 140-lb PS section rolled in 1959. This failure can be attributed to these electrode burns which were introduced during the welding process. Investigation 136-27A, B, and C involved three electric flash butt welded joints that failed in service. The rails used in the fabrication of these joints were 132-lb RE sections rolled in August 1965. These electric flash butt weld failures can be attributed to pipe and heavy segregration. Investigation 136-31 involved an Orgotherm thermite welded rail joint that failed in service. The rails used in the fabrication of this joint were 115-lb RE sections rolled in June 1966. This failure could be attributed to the presence of a martensite formation that resulted from a heavy grinding of the thermite weld collar after the weld metal had cooled. Investigation 136-34 involved an electric flash butt welded joint that failed in service. The rails used in the fabrication of this joint were 136-lb RE sections rolled in 1967. This failure could be attributed to the presence of this cementite.

RESULTS OF ROLLING-LOAD AND SLOW-BEND TESTS OF BUTT WELDED RAIL JOINTS

In the period between October 1, 1966 and October 1, 1967, 22 rolling-load tests were conducted on butt welded rail joints but no slow-bend tests were conducted. These butt welded rail joints were made by the oxyacetylene and electric flash butt welding process. The rolling-load tests were made on a 12-in-stroke rolling-load machine. Investigation 214 (samples A through F) was conducted to determine the seriousness of hairline cracks (segregation and pipe) on oxyacetylene pressure butt weld quality. Five of the six joints with stood 2,000,000 cycles of repeated loadings without failure, which is considered a run-out, and one joint (214E) failed after 897,100 cycles. A macroscopic examination made on transverse sections cut from the end of each rail prior to welding indicates that this failure originated from a fishtail. Investigation 220 (samples A through F) is a continuation of the problem presented in investigation 214 but was conducted to determine the effects of hairline cracks on joints from rails of heavier sections. It was found that fatigue of the failed specimens originated in the fillet between the head and web and can be attributed to a shear drag introduced while removing the weld upset. Investigation 226 (samples A and B) was conducted to evaluate two electric flash butt welded joints from which the upset metal had been ground from the top and sides of the head and bottom and sides of the base but not removed from the web. An examination of the fracture surface to determine the fracture mechanics indicates that this failure originated in the fillets between the web and upset metal. Investigation 230 (samples A and B) was conduced to evaluate oxyacetylene pressure butt welded joints made with a new type of welding head. Joint 230A failed after 33,500 cycles of repeated loading and joint 230B withstood the 2,000,000 cycle minimum requirement without failure. This failure can be attributed to the lack of fusion at the weld interface.

PROGRESS REPORT ON ANCHORAGE OF CONTINUOUS WELDED RAIL

Measurements were made on a test installation for the study of rail anchorage for continuous welded rail. The purpose was to obtain data on (1) the effect of train movements on rail anchorage forces (static before and after) and (2) the relation between rail anchorage force and tie movement. This installation was on tangent track with 115 RE continuous welded rail. All weight bars were loosened for the first train to obtain zero readings and a 100-lb force was applied to eastbound anchors (anchors to restrain easterly rail movement). All westbound anchors had the bolts adjusted to just be in contact. The joint gap and rail temperature were measured periodically. Also, the rail position lengthwise of the track was measured at each of 7 test locations. These measurements were then repeated after each of four trains had passed to show the change that had been effected by the train passage. Tests were also made to determine the resistance or force required to move the ties in the ballast. Specific results from the various tests are presented in several tables. Truck housing dynamic recording equipment was driven to the test site and information was recorded under all trains during a two-day period. The recording equipment consisted of 12-carrier amplifiers and a direct writing oscillograph. Ten channels recorded the longitudinal rail forces exerted through rail anchors to the weigh bars on the ties. The remaining two channels, connected to extensometers, were used to measure the longitudinal movement of the rail and tie with respect to the reference pipe.

REPEATED SHOCK TEST OF RAILWAY TRACK
By means of a repeated shock tester for track, the dynamic properties are studied of the test track. Test tracks were selected one on a wooden tie section and the other on a concrete tie section. There were laid 50 kg PS rails, wooden ties without tie-plates or pre-stressed concrete ties with a spacing of 60 cm. Ballast was crushed stone with a depth of 25 cm and a shoulder width of 35 cm. Before every test the ballast was tamped. To know the pressure on rails, bending stress was measured. Displacement of rail depression was calculated on the data of measurements by the velocity vibrometer. Dynamic force upon rails was calculated on the data of rail bending stress. This force exceeds the centrifugal force under 1400 to 1900 rpm and this is considered to be caused through resonance.

TRACK TOOLS
This committee is making a study of the following subjects: Snap-on Ratchet Track Wrench. The committee suggested that it be designed as a double-end socket wrench having a thin-wall socket with a single-action ratchet in one direction. The ratchet should be fitted around the center of the double-end socket where the handle will engage it. There have been a number of failures of aluminum track jacks. Therefore, a canvass is being conducted. From the data received, a study will be made to determine necessary changes in design, metallurgy, specifications, etc., to correct the situation. An investigation will be made on the use of lightweight metals for the AREA track level and gauge. Wear limit of striking and cutting tools. A study will be made on the economy of reclaiming tools that have worn down to the specified wear limit.

STANDARDIZATION OF TRACKWORK PLANS
This committee submits the following report of progress in connection with the standardization of trackwork plans. Plans for five new standard turnouts were submitted and approved for recommended practice. Also published and issued for inclusion in the Manual were the various other AREA plans incorporating revisions in switch details. A study was made of the method used in calculating the recommended maximum speeds of trains through level turnouts. The AAR research staff made a study as a result of this investigation on standardization of turnouts. The formula developed by them used the angle of impingement at the point of switch, and an experimentally determined maximum lateral acceleration for comfortable riding, to develop the permissible speed through the switch. Speeds calculated by this method were compared to the recommended speeds now in the Manual and were found to be similar. Revision of a plan covering swtich stands was recommended.

DESIGN OF TIE PLATES
This is a final report, on the service test in which seven designs of tie plates for the rail base of 6 in. were subjected to 379 million gross tons of traffic. The test results indicate good uniformity in plate cutting under the 14-in. and 14 3/4-in. plates on the inner rail of the 6-deg curve, but that the 14 3/4-in. plates with 1/2-in. eccentricity had the best performance on the outer rail. The 13-in. plates have performed reasonably well and should be adequate, particularly under medium traffic or with 5 1/2-in. base rail. The 12-in. plate is indicated to be inferior for heavy traffic, particularly on the curve and tangent with softwood ties.

INVESTIGATION OF FAILURES OF WELDED RAILS
Six failed welds were sent to this laboratory for evaluation. One electric-flash butt weld failed after about two years in service because of a fatigue fracture starting at near midheight of the rail web at a small ball of the molted sparks which ordinarily fly away as the rails are being heated but which in this case became trapped in the weld. Another electric-flash butt weld had also been in service about two years when it failed because of a fatigue fracture starting in the rail web about 3/4 in above the rail base. These two failures can be attributed to a combination of three circumstances: High tensile stresses due to cold weather. Stress concentration at the small imperfections in the welds. Stress concentration due to the flash under the rail bases. Four additional failures are described. Eleven bend test results are reported.

THE PROBLEMS OF HIGH SPEED TRANSPORT ON FRENCH RAILROADS
Speed increases to 125 miles/hour has had hardly any influence on the cost price per kilometre of the locomotive-coach-track ensemble. Design features for trucks to permit the speed increase are discussed. High-speed adhesion test results are shown, indicating where slipping begins. High speed requires great power The amount of this power varies, for a given speed with the geometrical dimesnions of the train. As the length of the train plays an important part, it is preferable that the whole length should be available to passengers. Current collection test results are shown as a function of speed.

EXPERIMENTS ON THE SETTING OF RAILWAY BALLAST UNDER REPETITION OF LOAD
Four types of ballast were laid a top 30 cm layer entirely composed of standard crushed stone; upper 20 cm composed of crushed stone and lower

10 cm of standard screened gravel; upper 10 cm of crushed stone and lower 20 cm of screened gravel; and 30 cm entirely composed of screened gravel. Comparison between the Grade 1 crushed stone with size distribution as produced and the one with size distribution modified by screening to 30 to 50 mm indicated that the setting rate of the ballast composed of the latter was 21% slower than that of the one of the former. Comparison between the wooden and the concrete ties used in the experiment with reference to both types of ballast revealed that the ballast setting under concrete ties was 50% less than under wooden ones. A ballast of screened gravel with coarse sand fillings was compared with the one of the same material minus sand. It was found that the setting rate of the former was very much slower than that of the latter; it means that good stability will be gained if the cavities are well filled.

LATERAL BALLAST RESISTANCE AND STABILITY OF TRACK IN EARTHQUAKE
The behavior of the railway track in earthquake was studied through experiment and theoretical analysis. The experiment was performed with real tracks in the RC-box placed on the vibrational table of 5 times 5 sq m in dimensions. The conclusions are as follows: against the earthquake acceleration with which railway structures are designed, 83% of the static lateral ballast resistance of track is maintained in the track on the Shin Kansen and 78% in the track with PC-ties and crushed stone ballast on the narrow gauge lines. The long weld rail track holds the safety factor at least 1.15 for the buckling due to temperature rise in the earthquake with the same acceleration mentioned above.

A2 040559
TRACK STRUCTURE FOR HIGH SPEED RUNNING
Numerous experiments on gradual growth of track irregularities show that the vibration with very large acceleration of the track, which occurs by the shock of running wheels, brings an extreme reduction of load bearing power of the ballast, and that the ballast surface suffers settlement under train loads. The amount of ballast settlement is proportional to the load, the number of repetition and the acceleration of ballast vibration, and the acceleration increases proportionally to the train speed. By using 70 kg rails, with sleepers wider by 20% than the present ones and rubber pads having one half of the present coefficient of spring; the track destruction caused by the same train load becomes 35% of that of the present standard track. By decreasing spring coefficient of one. The method of fastening a rail elastically to a vibration becomes as small as 40% of that of the present one. The method of fastening a real elastically to a sleeper using rubber pads and metallic springs has already been standard for a concrete sleeper, but as the action of load at the portion of fastening was not hitherto known well, the design should be regarded as rather empirical.

PHYSICAL TESTS OF NORMALIZED AND NOT-NORMALIZED OXYACETYLENE PRESSURE-BUTT-WELDED 115 RE RAIL
The welds were made using three 39-ft rails, according to the normal procedure with the exception of not normalizing eight of the welds. The rolling-load tests were made using 48,000-lb and 60,000-lb wheel loads. The data indicate that all the failures produced in the rolling-load tests were from causes other than the effects of normalizing or not normalizing. The slow bend test of two normalized and two not-normalized oxyacetylene pressure butt-welded rails made. The results indicate a trend toward greater load, energy absorption and deflection in favor of the not-normalized tests. The drop tests of two normalized and two not-normalized oxyacetylene pressure but-welded rails were conducted. Again no significant difference can be found in the data for the normalized compared with the not-normalized welds.

BONDING OF RAILS
The strength in static bending of rails bonded by conventional brazing or by a unique brazing technique involving the use of fiber metal shims ranges up to a maximum tensile fiber stress at failure of 71,800 psi. Work to date has been done using mild steel fiber metal shims, with and without copper foil on either side of the shim to supply molten filler metal. Since this technique yielded a joint strength as high as 63,900 psi, the superior technique of employing rail steel fiber metal shims preimpregnated with copper could yield strengths comparable to those of pressure-welded rail.

ROLLING-LOAD-TEST RESULTS OF WELDED ENGINE-WHEEL BURNS ON RAIL SUPPLIED BY THE SEABOARD AIR LINE RAILROAD
The oxyacetylene-welding method is the standard procedure for repairing wheel burns. Two welds of this type were prepared as controls. Eight engine-wheel burns were then welded by means of the electric-arc method. The first six welds were made on 115-lb RE rail and the last four welds were made on 132-lb RE rail. In this type of test 2,000,000 cycles without failure are considered a run-out. All of the welds were checked ultrasonically for defects. The oxyacetylene welds had the best results, in that one ran to 2,000,000 cycles without a failure and the other ran to 589,000 cycles, failing from a detected inclusion. The electric-arc welds failed prematurely at 49,000 to 159,000 cycles. The microscipic examination of fractures revealed taht a sharp line of demarcation between the weld metal and rail metal existed as well as very fine porosity on the interface. This porosity in all of the electric-arc welds was the cause of the failure. The microsocpic porosity in the interface could not be detected ultrasonically whereas the indication of the inclusion was very definite.

TESTS OF ELECTRIC FLASH BUTT-WELDED RAILS
This paper describes rolling-load tests and physical tests of specimens of 131 and 130-lb electric flash butt-welded rails which were undertaken to determine if stress relief treatment would be necessary. The 131-lb. rail was set up for rolling-load tests of weld 73 in. in a 33-in. stroke rolling-load machine. The second rolling-load test was made on weld 52 in the 131-lb. rail, which was supplied with all the flash metal ground off except under the rail base. 1. The first two-rolling load tests that failed at a bolt hole and stress raiser on the rail webs emphasize the damaging effects of such conditions. 2. The rolling-load tests which ran over 2,000,000 cycles with 60,000-lb. wheel load without failure, are considered very satisfactory for welded rails. 3. The bend tests of 132-lb rails gave higher tests than unwelded 131-lb. rails, and as high as any previously tested rail welds. 4. Some of the physical tests indicate that the welds which were not stress relieved were slightly stronger than the stress relieved welds. However, the difference is negligible and no conclusions on this subject should be based on tests of only two welds.

DESIGN OF TIE PLATES
This report consists of (1) a progress report on the service tests of seven designs of tie plates for the rail base width of 5-1/2 in. and (2) the results of a field test in which the magnitude and eccentricity of tie plate loads in tangent track under diesel and steam power were measured with calibrated dynamometer tie plates. In the service tests, it was found that the 13-in. length plates as compared with the 11-in. designs on the 4-deg. curve effected a greater reduction in plate cutting than would be expected from the inverse ratio of the plate lengths. Excluding the 3170 plate with the pressed circular rail seat, and bottom, the shape of the rail seat of the other 11-in. designs had no important influence as to the amount of plate cutting. So far, the 3170 designs of tie plate, which has approximately 10 percent more area than the 7-3/4 in. by 11 in plates, has shown no superiority for reducing plate cutting. The tie plate load tests showed that swinging ties resulted in an average increase in tie plate loads of 4000 lb. for the steam locomotives, as compared with approximately 5000 lb. for the diesel locomotives. The individual tie plate loads measured under the diesels were more uniform in magnitude than for the medium weight Mikado locomotives. The steam locomotives produced higher individual tie plate loads than those of the diesels.

RESISTANCE TO WARPING OF CONTINUOUSLY WELDED OLD AND NEW RAILS
This paper uses computational methods for calculation of track stability to examine the feasibility of welding the rails of older types of permanent way. It also examines the problem of warping of new, continuously welded rail, and the problem of whether very heavy rails (S64, S55) can be subjected to continuous welding in view of the fact that they employ light fastenings. The general results of these investigations can be summed up as follows: 1. Because of their particularly great moment of inertia, heavy rails can be continuously welded even when laid with simple, non-rigid fastenings. 2. With medium-heavy and light type of rails, the type of sleepering and the ballast cross-section have an important bearing on the resistance to warping. In such cases, it is advisable to examine, before the welding takes place, the safety against warping in accordance with local conditions, and to determine the minimum temperature at which the rails may be laid. 3. Because of the rail wear, the safety against warping increases to some extent with the age of the continuously welded track. It is therefore possible to accept a certain amount of slackness in the rail fastenings and a consequent reduction in the frame rigidity of the track.

TRACK ANALYSIS
In the present paper an attempt has been made to create the physical based for an objective assessment of the quality of railway track. For this purpose, the damage occasioned by faults in the geometric position of the track has been reduced to the universally applicable notion of 'detrimental energy' which is, in its turn, based on the detrimental integral exclusively derived from the geometry of the track. The definition of these novel notions is made possible by classifying the faults as subcritical, critical or super-critical depending on the period length of the oscillations caused by them. This leads to a coherent evaluation system which is largely founded on physical facts, lends itself to automation by means of modern computers, and furnishes directly applicable data not only for short-term maintenance programmes (marking of danger spots) but also for long-term renewal programmes (quality assessment of entire sections of track). The necessary computing techniques are outlined in their logical set-up.

FIELD EVALUATION OF 130 LB PS 39 FT. ROLLED RAIL
It was the purpose of the test to determine by service if Briquetted Sponge Iron Scrap used in the manufacture of steel rail instead of the usual steel scrap would develop any advantage or superiority from the standpoint of wear or other service conditions. The rails were laid alternating five special and five ordinary rails on the outer and inner sides of curve. After a service of 13 months and immediately before removal from track measurements of head wear were taken on 12 special and 12 comparative rails (6 high and 6 low) around the curve. This test has shown considerable increased wear on an 8 deg. 00' curve in heavy traffic territory for 130 lb. PS open-hearth rail manufactured with Briquetted Sponge Iron Scrap compared with same weight and process rail manufactured by regular products which include Scrap Steel.

ROADBED STABILIZATION SOIL PROBLEMS IN RAILWAY TRANSPORTATION ENGINEERING
In this paper soil problems are examined in terms of the cut and fill of line changes, in the daylighting of tunnels and in the performance of track. Included are planning remedial construction to preclude landslides, geometry studies for daylighting tunnels, design of new cut slopes including those in the proximity of abandoned coal workings, fill design in new construction effects of water content of borrow materials on compaction, and planning and control of waste areas.

EIGHTH PROGRESS REPORT OF THE ROLLING LOAD TESTS OF JOINT BARS
Twelve tests of 133 RE head contact 36-in. bars averaged 509,200 cycles. Twelve tests of 115 RE head free 36-in. bars averaged 1,462,450 cycles. Five of the joints ran to 2,000,000 cycles with no failure. Micrographs, taken on all failed bars, revealed decarburized bar surfaces to varying depths up to 0.024 in. No clearly defined correlation between cycles for failure and depth of decarburization was apparent. Brinell and tensile tests on 12 of 100 failed bars from service indicated higher hardness reading near the surface of the bars than at the center of the head. Ten of the 12 bars tested failed to meet the specifications of 100,000 psi, minimum tensile strength and 11 fell short of the 70,000 psi minimum yield point.

RAIL FRACTURES RESULTING FROM ENGINE WHEEL BURNS, INCLUDING EFFECT OF REPAIRING SUCH BURNS BY OXYACETYLENE OR ELECTRIC WELDING
Twenty-one specimens were artificially burned with the wheel rotating at a speed of 15 mph, the rails being applied to the moving surface of the wheel for 3-sec. intervals. The burns produced by this method were approximately 1-1/2 in. wide by 2-1/2 in. long and appeared to be quite uniform in nature. A tabulation of the rolling-load tests completed on these specimens up to the present time is shown. Up to the present time no explanation can be offered for the difference in fatigue life due to the location of the built-up metal on the engine burn. Tests have not progressed far enough to lead to any conclusions.

SERVICE TESTS OF MANGANESE CROSSINGS
The report covers the comparative tests of designs of solid manganese steel crossing frogs at McCook, Illinois, the tests of manganese insert and solid manganese crossings on structural steel and longitudinal timber supports, and tests of crossing frog bolt tension. Some of the designs included in the tests are more resistant to the development of fatigue cracks than others, but in none were the developed stresses low enough relative to the fatigue strength of the manganese steel to give the service life under heavy traffic that should be expected. Four railroad crossings were installed in the double-track main lines of the Indiana Harbor Belt Railroad and the Chicago and Western Indiana Railroad. The structural steel T-beam support was placed under one each of the solid manganese and insert crossings and the other two crossings are carried on longitudinal bolted crossing timbers. The inspection made in 1947, after approximately one year's service, showed all castings in the four crossings to be in good condition with no-flangeway cracks. A plan of the flangeways of the four crossings showing the flangeway cracks as found on May 7, 1948 is presented. The extent of the cracks was about the same, regardless of kind of support, for the two types of crossings.

RAIL FAILURES RESULTING FROM ENGINE WHEEL BURNS, INCLUDING EFFECT OF REPAIRING SUCH BURNS BY OXYACETYLENE OR ELECTRIC WELDING
Service failures of repaired burns have been negligible. One railroad reports that of 500,000 burns repaired in the last 8 years only 6 service or detected failures of welded engine burns have occurred. Benefits derived from welding repair are: elimination of undesirable microstructure and quench cracks; which serve as potential stress raisers or reduce the fatigue strength of the rail steel elimination of low spots on the rail surface; and building up of engine burns permits recovery of much rail for main line use which would otherwise be scrapped or consigned to secondary service.

CROSSING FROG BOLT TENSION TESTS
To determine the characteristics required of spring washers for use with turnout and crossing frogs, field observations have included measurements on a bolted heat-treated rail crossing in high-speed territory, and on this type of crossing together with a manganese insert, and a solid manganese type in slow-speed territory. For each service period, the bolts were initially set to a tension of approximately 40,000 lb. Loss in bolt tension was not due to the nuts backing off. Loss of tension is evidently due to wear. The rate of bolt tension loss was found to be considerably more on the bolted rail type of construction than on either the manganese insert or solid manganese types of crossing. The high reaction types of spring washers have shown better ability to maintain bolt tension over the test period than the low reaction types. The shock load or dynamic variation in the bolt tension under traffic was measured. Two series of tests were conducted; one with 40,000 lb initial tension, the other with 25,000 lb tension. The bolt tension tests are continuing.

A2 040829
DISCUSSION ON "THE ENGINEERING ASPECTS OF HIGH-SPEED TRAINS" (1) MOTIVE POWER: (2) PASSENGER ROLLING STOCK; (3) BRAKING AND SIGNALLING; (4) PERMANENT WAY
This paper surveys the engineering aspects of high-speed trains in terms of motive power, passenger rolling stock, braking and signaling, and permanent way. In developing high-speed trains there is clearly a need to examine all aspects of vehicle performance on the track, and also a need to subject every item of traction equipment to the closest secrutiny to ensure that it is suitable for onerous high-speed duties. The car of the future will probably be lower and smoother, and with smaller windows than present-day cars. It will be pressurized and adjacent body ends will be closer to incorporate peripheral coupling and improve passenger access. It will also cost more. A basic consideration in obtaining the best brake performance of high-speed

trains is the maximum braking retardation. When high retardations are used and as the maximum speed of trains increases from about 100 mph to 120 mph (or even 150 mph) two problems of braking which become increasingly important are adhesion and heat dissipation. Both necessitate modifications to present braking practice when higher speed stops are to be made. It is generally agreed that at high speeds some form of cab signaling is essential, and systems in use vary from the relatively simple A.W.S. as used in this country to apparatus which starts, controls, and stops the train automatically. There is every justification to believe that, from the point of construction, modern track would be quite suitable for speeds up to 160 mph--possibly more--where it is straight or flat-curved.

RAIL DESIGN AND SERVICE MEASUREMENT OF RAIL WEB STRESSES OUTSIDE OF JOINT

The report on rail design deals primarily with the revisions of design to improve the strength in the upper web fillet of the rail to better resist the high range of stress that occurs on curved track on the gauge side at this location. The work described on rail design in the report was occasioned by the occurrence of web failures in the 131 lb. RE rail section on the low rail of curves after considerable traffic had been carried and there had been a reduction in height of section because of rail wear. The cause of split web failures (head and web separations) in 131 RE rail has been found to be corrosion fatigue. Laboratory and service stress measurements have demonstrated that this section develops high stresses in the upper web fillet gauge side, on the low rail of sharp curves. Based on practical experience, mathematical theory, and laboratory and service tests using modern strain measuring equipment, the 140 PS rail section has been developed to retain all the desirable characteristics of the 131 RE section and eliminate its weaknesses. The report contains a detailed drawing of the 140 PS rail section developed from this research and which is now known as the 140 RE rail section, having been adopted by the American Railway Engineering Association as a standard standard section. A detailed drawing of the 133 PS section and of the 155 PS section which were developed from this research are also included in the report.

THERMIT WELDED RAILS, FULL FUSION PROCESS

The purpose of the test was to determine the strength and safety of Thermit welded rails (Full Fusion Process). Eight specimens of 131 lb. RE rail 8 ft. long, including a Thermit weld at the center, were provided for laboratory tests. For comparative purposes, eight similar specimens, including an Oxweld pressure weld, were furnished for test. All specimens were 131 lb. RE rail. Three specimens of each kind of weld were tested head down, and three specimens, head up, under the drop test machine. One specimen of each type of weld was tested head up and one head down, under static load, under the million pound testing machine. Results of the drop tests and static tests and of the hardness survey are shown on attached tabulated statements. Every Thermit welded rail broke with the first drop under the drop test machine, even though in one case with the rail tested head up the drop was reduced from 59" to 6" and the energy from 44,000 ft. pounds to 4500 ft. pounds. The Oxweld specimens each withstood the first and second blows with the full 44,000 ft. pounds energy. On the static test the Thermit rail tested head up broke at 262,000 pounds load on a 48" span, and the Thermit rail tested head down broke at 251,000 pounds load. The Oxweld specimen tested head down broke at 375,000 pounds with a square break directly through the weld. The Oxweld specimen tested head up did not break with a load of 375,000 pounds. The strength of the Thermit full fusion weld as determined by these tests does not approach the strength of a full section rail or that of a bolted joint. The grain structure is coarse, the fractures are brittle, indicating the probability that failures in service might be sudden and without warning.

ON THE PERFORMANCE OF THE RAIL FASTENING DEVICE FOR THE SHARP-CURVED, STEEP-GRADED TRACK

In order to examine the performance of rail fastening device Type 6 designed for PC sleepers used in the sharp-curved, steep-graded section where a severe load condition is assumed, and to make clear the distribution of train load on sharp curve, the lateral wheel force and wheel load, stress of spring clip and rail inclination angle were measured in the field test. These measured results were used for the examination of the fatigue limit of spring clip, the relationship between the lateral wheel force and stress of string clip and the distribution of lateral wheel force.

NUMERICAL CALCULATION AND APPROXIMATE FORMULA OF BUCKLING STRENGTH OF TRACK

In 1967, the adoption of 60 kg rail in the track of the Sanyo Shin Kansen was determined. For this determination, it was considered that the temperature difference corresponding to the buckling strength of the track with this rail would not be different so far from that of the track with 50 T rail. To confirm this, the authors made the calculation program of the buckling strength of track and computed this for every rail in Japan including the new 60 kg rail. Through the investigation of calculated results, it was found that there would be simple approximate formula to calculate the buckling strength of track. This paper contains the calculating method of the buckling strength, calculated results, the composition of the approximate formula and its application.

RESILIENT RAIL

Design and experimental results of a Resilient Rail developed for the mitigation of vibration and noise under train operation are summarized. The paper is divided into three parts, Part 1 treating the design, performance, durability test and field test of the Resilient Rail on revenue lines; Part 2 the noise-abating effect of this rail; and Part 3 the qualitative examination of anti-vibration rubber employed in 9 revenue line test. It is concluded that the Resilient Rail has been adequately designed; the metallic parts and anti-vibration rubber possess ample strength; the Resilient Rail can reduce the noise by about 4 phons (A) on elevated tracks or bridges; and also a vibration-abating effect can be counted on.

SP WORKS INSULATED JOINTS INTO RAIL WELDING
Southern Pacific has adopted an approach to insulated joints in welded rail that involves the prefabrication of a bonded insulated joint between two 39 foot rails and the subsequent welding of the resulting 78 foot rail into welded strings at the welding plant. The insulated joints are assembled using an epoxy resin and Huck fasteners, and the epoxy is allowed to set for about 12 hours, after which the insulating value is tested with an Ohmmeter. The 78 foot rail must be backed into the welding machine. Such incorporation of the insulated joint into the welded rail string requires pre-planning the location of the insulated joints in the welded rail strings, and careful attention to the loading diagram when loading and unloading the welded rail train. The loading diagram is placed in a container at the loading end of the welded rail train.

RETAINING GAUGE ON CURVES: THE L&N APPROACH
Louisville and Nashville has found that powerful diesel units with three axle trucks cause problems with holding gauge on curves. L&N launched three point plan: a laboratory study, use of gauge-measuring devices, and new standards for tie-plate sizes and spiking patterns for curves. Use of a common tie-plate for 100 lb and 132 lb rail meant that the 132 lb rail base covered one of the spike holes on the gauge side. To help prevent rail overturning under those conditions, a compression clip anchor was used in place of the spike on curves. L&N has adopted a new 18 inch tie-plate for problem curves. Diesel locomotive truck side thrust was suspected as a source of wide gauge on curves, so a gauge sensing device was mounted on a locomotive truck. Tests confirmed the rail moved outward under dynamic loading. Measuring devices attached to the rails also confirmed movement. A pickup truck equipped for rail/highway operation was also equipped with gauge recording instruments. On heavy-tonnage routes, curves of 5 degrees or more or troublesome curves get the new 18 inch tie-plate. Three line spikes are now used on the outer rail of the curve, with one screw spike in the hold down holes on either side of the rail. Still another technique being tried is the use of washer head screw spikes which are driven as line spikes.

A similar article on the L&N approach to curve problems appeared in Railway Track and Structures, V69, N1, January 1973.

A2 043365
STUDY OF ACTIVE VIBRATION ISOLATION SYSTEMS FOR SEVERE GROUND TRANSPORTATION ENVIRONMENTS
An investigation is conducted to evaluate the application of active mechanisms for the protection of equipment and/or personnel from the severe dynamic inputs characteristic of ground transportation vehicles. For the purposes of the study, dynamic loads and isolation system performance are defined in terms of the maximum expected vertical excitations associated with the suspension system of high speed ground transportation vehicles, and conservative levels of allowable passenger acceleration. Selected configurations employ available hardware, and consist of a static load support fluidic spring in parallel with a 0.2 Hz resonant frequency electrohydraulic isolator, which: a) provides the desired degree of isolation from both discrete frequency and broad-band vibration excitations; and b) limits the payload deflections to within plus or minus 6 inches under conditions of combined vibratory and transient dynamic loads. Rigid and flexible payloads of 1,000 3,000 and 10,000 pounds per isolator are considered. The response of the selected isolation systems is presented in terms of absolute and relative transmissibility; payload acceleration; and relative displacement between the payload and the source of excitation for the vibratory, transient, and combined excitations. In all cases the effect of increasing the payload weight by twenty percent is shown. The results indicate that the selected active isolation systems are capable of protecting a range of payloads from severe vibratory and transient dynamic loads. Systems stability, estimates of flow and power requirements, system weight, reliability, and failsafe criteria considerations are shown. Recommendations are made regarding extension of the techniques to provide isolation in the combined vertical and lateral directions. (Author)

AUTOMATIC SUBMERGED-SLAG WELDING OF RAIL
The procedure of submerged-slag welding--a new automatic fusion welding of rails in the field--is described in this paper. The optimum wire compositions and welding conditions are determined in relation to micro hot cracking in HAZ, and the mechanical properties of welded rails are examined. Finally, the results of investigations of rails welded by a trial "welding car" are discussed. Based on the favourable results obtained of using this welding machine, it is expected to realize the full automatic welding of rails in the field in the near future.

TIE REPLACEMENT PROGRAM
The demand for track materials varies directly with the financial state of the railroads. The demand for wood ties has recently slackened off so that tie producers have no incentive for R&D, lessening production efficiency and putting a squeeze on profits. The market for other lumber products and the availability of a concrete tie substitute have also considerably weakened the wood tie market. Concrete ties are more stable and lower in price due to steadier cost trends of sand, gravel, and cement, and also a lower labor to material cost ratio. Performance studies comparing concrete and wood ties have favored the former. In an economic evaluation of discounted cash flow equations and cost drains, concrete ties are favored again.

FATIGUE BEHAVIOR OF WELDED BEAMS
The fatigue behavior of welded steel beams is evaluated by using the fracture-mechanics concepts of stable crack growth. A fracture-mechanics model for cracks originating from the pores in the web-to-flange fillet weld is developed. Estimates of the stress-intensity factor are made that numerically describe the initial flaw condition. With the final crack size known, a theoretical crack-growth equation was derived from the fatigue test data of the welded beams. The derived relationship compares well with actual crack-growth measurements on a welded beam and available data from crack-growth specimens. The regime of crack growth, where most of the time is spent growing a fatigue crack in a structural element, is shown

to correspond to growth rates below 10 to the minus 6 power in. per cycle. Few experimental crack-growth data are available at this level. It is concluded that the fracture-mechanics concepts can be used to analyze fatigue behavior and to rationally evaluate the major variables that influence the fatigue life of welded beams.

MAINTENANCE OF WAY AND THE INFORMATION EXPLOSION

Maintenance of way activities have traditionally been subjected to budget restrictions, in part because it has been difficult to document and quantify the real cost of deferred track maintenance. Southern is using the computer to produce studies and reports on maintenance of way programs. The key elements are a group of data bases or master files containing essential information. Probably the most important is the Track Characteristic Master. Southern's Research C r R-1 provides key information on track conditions. A second file contains all pertinent details on derailments. Correlation of the derailment file with the track characteristic master produced a sensitivity index of defect types as a predictor of derailments. Southern is completing a System-wide anchor and double spiking program with standards based on traffic density, degree of curvature, and grade. The best way to determine when rail should be relaid and when track should be retied and surfaced is by measuring rail and track condition. R-1 car findings cause adjustment in maintenance schedules. Southern is pursuing an equally aggressive role with respect to rail defects and rail failures. The most recent addition to the data bases is the bridge file. Track programs have been correlated for efficiency.

CN SEEKS MORE STABLE TRACK

With the increase in traffic and the advent of six-axle diesel locomotives and 100-ton cars, CN has been experiencing some difficulty with conventional track...in maintaining line and gage, in accelerated rail wear, and in corrugation. The new 'track structure test' encompasses the overall function of the structure rather than specific components. It involves continuous welded RE high silicon rail, fastened accurately to prestressed monolithic concrete ties that are restrained by well tamped and drained crushed rock ballast. The test site was selected to include heavy trains, six-axle locomotives, and downgrades and sharp curvature. The results are intended to provide guidance in writing an improved track specification. Total tonnage moved in 1971 amounted to 31 million gross tons. The ties were made in England. The fastening used is the Pandrol 601 A clip. Details of the installation process under traffic are given. Three different tie spacings were used.

MAJOR M/W ACTIVITIES TO STAY AT HIGH LEVEL IN 1973

The Class 1 railroads laid 685,000 tons of new rail in renewal in 1972, which is 6.5% higher than the 643,321 tons laid in 1971. Although renewal of ties represented a decline of 4.8% compared to 1971, tie renewal for 1972 exceeded 20 million for only the second time in 15 years. Looking ahead to the next 12 months, it is estimated that the Class 1 railroads will install 730,000 short tons of new rails in existing track in 1973, which will be an increase of 45,000 tons, or 6.6% compared to 1972. The estimate of tie renewal in the Class 1 railroads is that 19,500,000 new crossties will be installed in existing tracks in 1973, which is a reduction of 900,000 ties, or 4.4% compared with 1972. The question of whether, and to what extent, M/W activities are being influenced today by the FRA Track Safety Standards, is answered by "not much". The fact is that railroad management has become convinced of the need to spend more on the tracks and structures.

RESEARCH: THE ANSWER TO TRACK PROBLEMS

The FRA Track Safety Standards have now been established and the railroads must bring all their tracks into compliance and continue to maintain them to these standards, or reduce operating speeds to the lower track classification levels. The Research and Test Department of the AAR, under Dr. Bill Harris' administration and in cooperation with member railroads, the RPI, individual manufacturers and other agencies, has many major research projects under way, studying the adequacy of design and material specifications for tank cars, equipment components, as well as a

special committee assigned to study rail specifications and chemistry. The most promising of these projects, from a track standpoint, however, is the track-train dynamic study. The results to be derived from these research programs will not only make it possible for the railroads to meet the transportation demands of the future, but will make it possible for them to do so at a lower cost, not the least of it is the cost of maintaining the track and roadbed.

HOW I'D MECHANIZE A 5000-MILE RAILROAD--FROM SCRATCH
The assignment is to come up with a blueprint for mechanizing the maintenance-of-way operations of a 5,000-mile railroad, the hypothetical Ft. Knox & Denver Mint R.R. Three assumptions are made: the railroad runs through a thousand miles of changing climate and terrain with 3,000 mile of light-traffic branch lines and 2,000 miles of medium to heavy mainlines, all in good condition, and there are three major yards and many lesser ones--the railroad has money--and, fantastically enough, it has no maintenance machinery. There are at least two ways to attempt a national solution of the problem: one is to find one or more railways with similar conditions and use their machine fleets as models, the other is to develop a fleet consist by independent means. This is the method selected by the author. Details are given of the equipment fleet he would assemble, including three tables: (1) Rail gang equipment; (2) Tie gang equipment, and (3) Equipment for bridge gangs, switch gangs and special purposes.

MODERN PERMANENT WAY
Heavier loads, higher speeds, and a greater concern for safety are creating a greater emphasis on railroad track structure. Yet the number of current books on railroad track is indeed small. This book is an attempt to present a modern treatment of track and its components in the English language. Although the author it associated with the Indian Railways, the book is pertinent to American practice, and contains many references to specific American practices. The book covers rails, ties, fasteners, ballast, soils, track assembly, track maintenance and track modernization. It also covers concrete ties, welded rail, and high speed track.

EFFECT OF FLAT WHEELS ON TRACK AND EQUIPMENT
Under present AAR rules governing removal of flat wheels, flat spots are limited to 2-1/2 in. length for one slid flat and 2 in. each for adjoining spots on freight car wheels and 1 in. on passenger car wheels. These limitations have been established from the experience and judgment of those concerned with the operation and maintenance of equipment and track. To date mathematical solutions to evaluate the impact effects from flat spots have not been adequate. Until recent years, instruments of sufficiently high frequency response to accurately measure the rapid stress changes have not been available. Tests made on the New York, New Haven, and Hartford RR. in 1942 established the characteristics required for reliable instrumentation. Suitable stress measuring instruments were obtained and a comprehensive test program to determine the effects of flat spots on both the track and equipment was conducted on the Chicago & North Western Railway during the summer of 1947. A special test train was used consisting of a locomotive, a passenger car carrying the measuring and recording instruments for the measurements on the test car, and a flat test car having a flat wheel and loaded with rails.

This report was prepared by the Joint Committee on Relation Between Track and Equipment.

FOR M/W, A BIGGER SHARE OF THE DOLLAR
For more than ten years both rail and tie renewals have traced a generally upward curve and for the next twelve months the rail-renewal curve is expected to continue upward. Tie renewals are projected to decline slightly but tie insertions in 1973 will be at a higher level than in 1972. In spite of the increases of recent years, tie renewals are running short of actual needs and insertion of new rails are running far below requirements. Apparently the FRA Track Safety Standards have had little effect so far on M/W programs. There seems to be a trend towards performing more spot work on track as opposed to out-of-face work and towards the use of insulated rail joints and new and improved M/W machines; and an effort is being made to determine the cause of cracks in concrete ties shortly after they are inserted.

AERIAL STRUCTURE AND RAIL SUPPORT METHODS REPORT NO 11
A series of tests was run for BART to evaluate the ability of rail fasteners to maintain electrical isolation, reduce noise levels, and provide safety and economy; and to determine their suitability for use on advanced design concrete aerial structures. The evaluation of several types of concrete ties and the results of tests on a new concept in the installation of rail fasteners and associated hardware on concrete aerial structures are included. Investigation showed that a new concept of track support was required for aerial structures and subways; further, it was realized that the fastener chosen for use on the aerial structures can also be used on the underground portions of the rapid transit system, a fact which will limit the types of rail fasteners needed for the system. Subsequent studies, therefore, are geared to the choice of a fastener suitable for use on aerial structures. On aerial structures rail fasteners must be simple enough for one man to assemble with hand-carried tools. The fastener must remain stable under the application of a 15,000-pound wheel load and must be capable of holding a longitudinal force of approximately 2,000 pounds of 3,000,000 cycles of loading in a test machine. Other criteria for fasteners of rail and aerial structures are listed. The "second pour" technique, which still requires further development, is to be used in installing track fasteners on concrete surfaces in order to

guarantee that the anchor bolts will not come in direct contact with reinforcing steel. Indications from test results indicate that concrete ties are safe and economical and perform well under the type of transit loadings expected in the BARTD system.

HOW TRACKMEN COMBAT UNIT TRAIN DAMAGE
Unit trains may have cheered up the job of top management by boosting freight revenues. But they have brought little sunshine into the lives of track engineers who are having to cope with a whole new set of track problems created by day-to-day running of high-axle-load unit trains. British Railways, for instance, says that substantially higher track maintenance costs are a direct result of today's higher speeds and heavier axles which demand better track and more repair time. Deutsche Bundesbahn makes virtually the same comment. But both DB and BR, operating almost entirely over continuous welded rail (cwr) and concrete sleepers on main lines, have a relatively easy time of it compared with a number of US railroads which are operating regular 100-ton wagon unit train consists over jointed track laid on timber sleepers.

CONTINUOUSLY SUPPORTED RAIL SUBJECTED TO AN AXIAL FORCE AND A MOVING LOAD
The recent practice of welding railroad rails to each other suggests that considerable axial compression forces may be induced in the rails because of a rise in temperature. This in turn may reduce the critical velocity for the track to the range of operational velocities of modern high-speed trains. The purpose of the paper is to demonstrate that this is indeed a possibility.

RAILWAY TRACK DESIGN, CONSTRUCTION, MAINTENANCE AND RENEWAL OF PERMANENT WAY
The multiplicity of operations involved in the construction and maintenance of Railway Track or Permanent Way, requires from those entrusted with these works, a thorough knowledge not only of the most efficient methods for modern loads and speeds, but also of the underlying principles of design. The methods of construction, of renewal, and of improvement of track have been described in detail, and the measures to be adopted in emergencies have been explained. The theory and practice of the intricate subject of Points and Crossings has been dealt with concisely in two chapters, and complete proofs have been given for all formulae. The manufacture, tests and treatment of materials used, and their capabilities and limitations, have been explained. Subjects such as Signalling and Interlocking, and Bridge Maintenance, with which a trackman is intimately connected, have also been dealt with briefly. Modern tendencies have been indicated in the discussion of every aspect of track work, and frequent comparisons have been made with track practice abroad, particularly in the United States of America, as the type there is similar to the Indian track.

EFFECT OF BALLAST CONDITIONS ON TRACK STABILITY
It is shown how installation of long-welded rail on Europe's principal trunk routes has created problems of track stability caused by the presence of thermal stresses in the track, affected by local climatic conditions. The measurements obtained by the tests conducted at the Technical University in Munich, West Germany showed that the lateral resistance is greatest when the track has settled under traffic. After tamping combined with a rise of 2 to 3 cm, the lateral resistance decreases by approximately 70%.

THE EFFECT OF SURFACE FILMS ON FATIGUE CRACK INITIATION
The suppression of fatigue crack initiation by surface films can be viewed in terms of two mechanisms: (1) protection against environmental attack, and (2) suppression of surface plasticity. These two mechanisms are described in detail. Environmental protection requires a flawless coating which is impermeable to the active component of the environment and resistant to fracture under repeated cyclic strain. Suppression of plasticity requires a film with an elastic modulus greater than the substrate metal. The stiffer coating repels dislocations from the surface and suppresses the development of slip bands and crack initiation. (Author)

EVALUATION OF THE BRITTLE FRACTURE OF RAILS [SPRODBRUCHABSCHATZUNG AN SCHIENEN]
The testing of rails provided for in the technical specifications of the railways (and particularly the UIC) gives incomplete information concerning the behaviour of rails subjected to certain frequent stresses in service, such as the effect of impacts caused by flats on the wheel treads. The author's purpose is to establish more satisfactory criteria for evaluation purposes, taking into account the triaxial character of the pressure in the rails by making use of the Schnadt diagram covering the index of the capacity of plastic deformation of the steel in relation to the pressures to which it is subjected. The above article contains an account of the work carried out by the author in order to establish characteristic parameters of the risk of brittle fractures of the rails in relation to a coefficient covering eventual cracks, or grooves, in the rail surface, as well as the temperature, the load, and the speed, and numerical formulae are provided covering the German State Railway's S 49 rails. [German]

M/W PRODUCTIVITY: "GOOD MACHINES ARE NO GOOD STANDING IDLE"
Machines that will perform work better, faster and with fewer men are one way to greater productivity in the maintenance-of-way department--but not the only one. Maybe it's not even the most important means of making the most effective use of the M/W dollar. Certainly, it's important for a railroad to have the latest machines for maintaining track. But the interests of productivity are not being served if this equipment speeds a good part of the working hours sitting idle because trained personnel is lacking for making repairs when breakdowns occur. Neither are the interests of optimum productivity being served if price or cost is put ahead of durability in the purchase of materials or in the conduct of work.

SLEEPERS--A WIDE-AWAKE APPROACH TO TRACK PROBLEMS
In the early days of railroad development, few problems were encountered in the provision of cross ties; mainly they were extracted from nearby forests. As railroad development in South Africa picked up after World War I, indigenous sources of timber became inadequate and recourse was had to the import of hardwood cross ties from Australia, Rhodesia and the Far East. The development locally of concrete cross tie manufactere was a logical development after the Second World War and now home-made cross ties dominate the railroad scene pretty well throughout Southern Africa. Steel cross ties, concrete cross ties, and cross ties and rail failures are discussed.

CONCRETE TIES
This specification is intended to provide necessary guidance in the design, manufacture and use of concrete ties and their components for main line standard gage railway track systems. The specification contains minimum performance requirements of components for concrete tie railway track based on a variety of permissible tie spacings and ballast depths. Track constructed of tie and fastener components meeting the specifications applicable to the anticipated usage should be expected to give satisfactory performance under current AAR-approved maximum axle loads. The specification covers materials, physical dimensions, and structural strength of prestressed monoblock and prestressed and conventionally reinforced two-block concrete ties. In addition, longitudinal and lateral load restraint requirements as well as the electrical performance requirements of rail fastener and tie combinations are given. Laboratory tests for the determination of the suitability of new designs are specified, as are necessary quality-control procedure during manufacture. The specification does not cover techniques nor equipment for the manufacture of concrete ties or fastenings. Where current specifications or recommended practices of other technical societies, such as the American Society for Testing and Materials or the American Concrete Institute, are appropriate, they are made part of this specification by reference.

PROBLEMS OF TRACK MAINTENANCE FOR HIGH SPEED
The replacement of steam by diesel and electric traction, high speeds, axles carrying a weight of 25 t on rail and very heavy merry-go-round trains, place more severe strain on the permanent way. This position is made manifest, inter alia, by the duplication of rail cracks and ruptures since 1960, and necessitates the revision of the track building and maintenance standards. The author reviews the research and activities carried out, with this object, through modification of the track and vehicles. The article contains a review of a number of special problems--pollution of the ballast by mud seeping through, the frittering away of the ballast, the poor holding qualities of the rail fastenings, joints, and the organization of the maintenance sites.

TECHNICAL ASPECT OF HIGH-SPEED TRAIN OPERATION: TRACK AND ELECTRIC INSTALLATIONS ON HIGH-SPEED LINES [L'ASPECT TECHNIQUE DES GRANDES VITESSES: LA VOIE ET LES INSTALLATIONS ELECTRIQUES DES LIGNES A GRANDE VITESSE]
The problems raised by trains travelling at 260-300 km/h are related essentially to vehicle operating stability and track stability, and have been substantially solved at the present time. Without going into the details of calculations, these problems are discussed along with the results of theoretical studies and tests. The techniques and approaches used can, for the most part, be regarded as operational today. The speed of the wheel-rail system is certainly not limited to 300 km/h: faster trains would raise economic as well as technical problems. In spite of the efforts made to raise speeds on existing lines, it is not possible to exceed 200 km/h on these lines, owing to the infrastructure which dates back to the last century, except on short stretches where high-speed tests have been conducted. The design of the infrastructure and superstructure (track, signalling and catenaries) of new allowing train speeds of 300 km/h is described in the article along with the engineering studies which have been making increasingly greater use of data processing techniques. PROBLEMS OF CONSTRUCTION OF PERMANENT WAY OUTLAYS FOR INTRODUCTION OF HIGH-SPEED PASSENGER TRAINS
The main requirements for the reconstruction of permanent way outlays of existing railways when high-speed passenger trains are introduced, depend on the following factors: 1. Level of maximum speeds of passenger trains; 2. Level of maximum speeds of freight trains; 3. Number of passenger and freight trains and their weights; 4. Parameters of existing permanent way outlays; 5. Economical expediency of expenditure for the reconstruction of the outlay for the given railway section to ensure the required speed as compared with reduced speed as a variant.

ON THE STABILITY OF THE RAILROAD TRACK IN THE VERTICAL PLANE
The report reviews and discusses various aspects of railroad track buckling in the vertical plane. Buckling tests of straight tracks are reviewed first. A review of the published analyses on vertical track buckling reveals that they may be grouped into two main categories. In one category, the authors assume that the track is an elastic beam which is continuously supported by a Winkler base, before as well as during buckling. In the other group, the authors assume that the track is a beam of uniform weight, which rests on a 'rigid' base and that the buckling load is reached when part of the track lifts itself off the base. To clarify the validity of some of the assumptions made, two simple models which represent the assumptions made are studied first. This is followed by a review of the literature. A TRACK CURVATURE MEASURING SYSTEM AND ITS APPLICATION

A track curvature measuring system has been designed and installed in the Department of Transportation's rail test car by ENSCO, Inc. The system employs an inertial rate-of-turn gyroscope to measure the yaw rate of the car, an axle-driven tachometer to measure speed, and velocity transducers to measure the relative motions between the car and the trucks. An analog circuit receives these inputs and performs the curvature computation. The system is capable of making continuous curvature measurement at any speed greater than 3 mph at either direction of travel. The system performance and various applications of the data are demonstrated. Schemes for detecting undesirable superelevation and curvature mismatches are discussed.

A2 051536
APPLICATION OF GUIDEWAY ROUGHNESS POWER SPECTRAL DENSITY AS A MANAGEMENT TOOL

Ground surface vehicles such as trucks or railway cars can be considered as mechanical systems suspended on vibrating wheels. The source of vibrational energy is the roughness in the roadway or the guideway. A portion of the vibrational energy is transmitted through the vehicle suspension system and to the passengers or lading inside the vehicle. The magnitude of the transmitted energy and its frequency content depend on the roughness of the surface, the speed of the vehicle, and the mechanical characteristics of the suspension system. If the roads and guideways are categorized by the Power Spectral Density (PSD) of their surface roughness, the amount of vibrational energy can be predicted if the speed and the characteristics of the vehicle suspension system are known. Conversely, if a safe limit of the vibration has been established for a particular lading, management can render a cost effective decision on guideway maintenance, speed practices, and vehicle design from knowledge of the PSD characteristics of a proposed route.

FRACTURE MECHANICS--ONLY A THEORY?

Fracture Mechanics, a new branch of the fields "Material Research" and "Theory of Strength of Materials" has during the last 5 years been introduced into the European Technical Literature. This branch deals with research on non-deformed brittle fractures in high tensile materials. Suitable functions have been established for different shapes of cracks but these functions include only the tension in the undisturbed zone and the shape of cracks, and it is thus possible to detect the stress intensity at the tip of the crack. The critical stress intensity during spontaneous crack widening (i.e. at failure of the test specimen or the structural member) is concurrently the material characteristic. This offers the possibility to calculate the allowable crack dimensions in structural members. So far the method is still limited to materials of ideal elasticity, i.e. to brittle materials, but there is reason to hope that it can be expanded to more common tough materials. [German]

STRESSES TO WHICH THE TRACK, THE BALLAST, AND THE SUBGRADE ARE SUBJECT, UNDER THE ACTION OF MOVING LOADS [SOLLICITATIONS DE LA VOIE, DU BALLAST ET DE LA PLATE-FORME SOUS L'ACTION DES CHARGES ROULANTES.]

The above article contains a synthesis of the research carried out by ORE D 71 Committee. Details are shown, in a condensed form, of the partial results set out in the 12 reports prepared by that Committee. So far as concerns research into the stresses to which the fastenings and sleepers are subjected, additional information is provided, showing the present concerning the studies carried out by the SNCF, after the general report had been drawn up. Progress effected in the field of the extensometric technique enables certain pressures to be more clearly established, and the use to be avoided of corrective coefficients, or empirical formulae, for the study of the rheological characteristics of the ballast and the subgrade. These investigations are carried out within the framework of research into the interaction between the track and the vehicle, and the optimum equipment of the conventional track. [French]

TRACK WITHOUT BALLAST [LA VOIE FERREE SANS BALLAST]

Non-ballasted track is a necessity from the point of view of a reduction in the cost of maintenance on main lines, and particularly in tunnels, and on underground railways. The constitution of non-ballasted track, i.e. continuously welded rails on RS concrete sleepers on continuous reinforced concrete slabs, with resilient sleeper pads placed between, resolves the problems of the transmission of the pressures to the track formation, the damping of the vibrations, the permanency of the track geometry, and, therefore maintenance. It is of advantage to make use of lightweight aggregates for the continuous reinforced slab, principally because of the small modulus of elasticity of the lightweight concrete. [French]

TECHNICAL PROBLEMS CONCERNING HIGH-SPEED TRANSPORT [TECHNISCHE PROBLEME DES SCHNELLVERKEHRS]

Based on the operating programme, and the problems of high-speed rail transport, details are shown of high-speed passenger coaches, and goods wagons. Solutions to tractive and braking problems are then discussed. Details are also shown of the effects of high-speeds on the layout, and deformation, of the track. Based on the terms "dependability" and "security", a description is given of a data-processing system. Finally, the authors deal with the necessity of research and development. [German]

WHAT BENEFITS FROM BALLAST COMPACTION?

An answer is sought through a research program undertaken jointly by the Federal Railroad Administration and five large railroads. A factor behind the undertaking is the reasoning that the disturbance of the ballast that takes

place during a track-surfacing operation has the effect of diminishing the restraint offered by the ballast to lateral and longitudinal movement of the track.

AUSTRALIA HOLDS AN INTERNATIONAL CONGRESS ON SLEEPERS
Thirty papers presented in Sydney in August cover fully technical matters relating to timber sleepers against an Australian background but concrete and steel tend to figure in the presentation as equipments still in the development stage and are little discussed. Nevertheless, if the balance between prime and labour costs changes and the long-life of concrete outweighs its cost disadvantage, timber will take second place in Australia and New Zealand.

JOINT BARS-DESIGN SPECIFICATIONS AND SERVICE TESTS INCLUDING INSULATED JOINTS AND COMPROMISE JOINTS
Various tests and application procedures of joints are discussed. Insulated joints, glued joints, web-contact joint bars, Huck fasteners, and joints with structural adhesives are studied in service tests, both in the laboratory and in field installations. The field installations are varied in location. Static stresses in rail and dynamic stresses in rail joint are studied in connection with field installations Huck fasteners. Among the conclusions are: 1)service tests of redesigned vulcabond insulated joints showed much chipping and flaking off; 2) Huck fasteners on polyurethane insulated joints were in satisfactory condition after two to twelve months installation; 3) Huck fasteners in standard head-free toeless angle bars would not satisfactorily restrain rail movement.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Part one of this report discusses a laboratory investigation of 132-pound rail made from vacuum degassed steel. The purpose of this investigation is to determine whether rails made from vacuum degassed steel and air cooled are comparable in properties with rail steel produced by currently common practices. The manufacturing process and test specimens are described. Rolling load tests, drop tests, slow bend tests, Charpy impact tests, hardness tests, and chemical analysis are performed. Macroscopic and microscopic examinations and physical property determinations are examined. The properties of vacuum degassed steel rails without controlled cooling were comparable to those manufactured by conventional techniques. Part two is a report on a field inspection of vacuum degassed steel rail on the Norfolk & Western Railway. Slight curve wear was noted in the high side rails, and slight rail wear was noted on the low side rails. No shelling or head checking was noted.

RAIL FAILURE STATISTICS COVERING (A) ALL FAILURES (B) TRANSVERSE FISSURES (C) PERFORMANCE OF CONTROL-COOLED RAIL
This report of rail failure statistics covers all failures, transverse fissures, and performance of control-cooled rail. Mill performance with regard to service failures is discussed. Statistics for both accumulated service failures and detected number of defects are given. No additional transverse fissure failures in control-cooled rail were reported in 1971 indicating that good quality control and mill practices have been followed in the manufacture of this rail to avoid shatter cracks. The low incidence of rail failure from welded engine burns indicates that practice of welding these burns is showing good service performance. Butt weld failures are tabulated.

SOME ASPECTS OF SERVICE DEVELOPMENTS IN RAIL-HEAD METAL
Service developments in rail-head metal characterized by the presence of white etching regions have been studied. After the development of microstructural white-etching regions resulting from traction and adhesion conditions, spalling begins as a result of trains passing repeatedly over these hard and increasingly brittle areas. White-etching regions on a car-dumper hoop rail resulted from impact during loading and unloading of the dumper, because these areas were in contact with mating guide wheels in the normal load and unload positions of the car dumper. White-etching also results from the effects of repeated loads on the vertical face of non-end-hardened bolted rail. A rolling-contact fatigue test concludes that rail steels have longer life at lower maximum static contact stress levels than at higher stress levels.

STRESS DISTRIBUTION IN THE PERMANENT WAY DUE TO HEAVY AXLE LOADS AND HIGH SPEEDS
The stress distribution in the rail head near the contact surface between rail and wheel with heavy axle loads at high speeds is discussed. An experimental investigation of the stress distribution was performed. Tensile bending stresses in the rail head and rail foot, and lateral forces are discussed. In Germany a test track of prefabricated concrete slab was constructed, and the measurements taken showed that scattering of stresses in the rail foot were small and did not vary with the driving speed.

THE THERMAL ELONGATION OF RAILS ON ELASTIC MOUNTINGS
Elongation and contraction of rails due to temperature changes is a primary factor affecting the variation in length of rails and their associated strains and stresses. This report considers thermal elongation in conjunction with the longitudinal elasticity of rail fastenings. The sequence of longitudinal loads on elastic rail mountings and the thermal elongation involving rail creep are mathematically presented. Numerical values worked out on a study of the Delft Viaduct show that the assumption of continuous distribution of rail mounting resistance provides a workable theory by which thermal elongation of rail systems can be effectively analyzed.

AAR STUDIES OF BUTT WELDED RAIL JOINTS
The purpose of this study was to obtain a correlation between defects shown by radiographs of thermit butt welds in track and results obtained in rolling-load tests in the laboratory. Thermit welds in the Canadian National Railway and the Denver & Rio Grande Western Railroad were evaluated. The Research Center's repeated load tests did not correspond exactly to service conditions. More study is needed on the effectiveness of the radiographic examination technique in determining if thermit welds contain defects that would seriously impair their serviceability in track.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL METHODS FOR THEIR PREVENTION
This report is in two parts. Part one presents the causes of shelly spots and head checks in rail. Samples of these service defects were analyzed and then duplicated at the Association of American Railroads Research Center. Results showed that they were stress induced microstructural changes, not foreign material attributable to manufacturing practice. Part two presents a summary of the test using fully heat-treated rails and alloy rails installed on curves with shelly histories. Changes in rail design were included in this test. For fully heat-treated rails wear on the low side rails was relatively less than on the high side rails. Use of high silicon rails was also tested. Chipping was noted in both the high-silicon and regular rails where bond wires had been attached by welding.

EFFECT OF LUBRICATION IN PREVENTING FROZEN RAIL JOINTS AND RETARDING CORROSION OF RAIL AND FASTENINGS
The effect of lubrication is investigated in preventing frozen rail joints and retarding corrosion of rail and fastenings on a five-mile service test of North Western's eastward main track, relaid with 78-ft butt-welded 115 RE rail in 1957. Four of the five miles were sprayed out-of-face; the other mile, the control, had no protection until July, 1962, when special compounds or paints were applied to some of the welds after flame cleaning and wire brushing. Applications of metal preservatives are described for each mile of test track, indicating where corrosion was minimized. It is concluded that the spray and brush coats of Texaco 55 and NO-OX-ID provide the best protection against corrosion of rail and fastenings.

RESULTS OF ROLLING-LOAD AND SLOW-BEND TEST OF BUTT-WELDED RAIL JOINTS
Results of rolling-load and slow-bend tests of butt-welded rail joints are reported. Welding methods include submerged arc, thermit process, and oxyacetylene pressure process with abrasive-wheel-cut weld faces and with variations in upset pressure and Btu input. Welds with magnaflux and ultrasonic indications of defects are also included in tests. It is noted that results, particularly results of submerged arc process, represent initial work on developments needing considerable further refinement. Results on thermit welds are representative of the results obtained in previous test of such welds, except those made by the Southern Railway, which show results meeting the standards established by tests of oxyacetylene pressure butt welds and flash butt welds for the first time. Investigations of welds with magnaflux and ultrasonic indications indicate a lack of uniformity existing in judging these indications at the inspection stations.

DESCRIPTION OF FLAME-HARDENING OF RAIL BY THE UNION PACIFIC RAILROAD, AND PHYSICAL AND METALLURGICAL TEST RESULTS
The process of flame-hardening of rail is described, and physical and metallurgical test results are presented. Rolling-load, drop, and slow-bend tests are performed on the treated rail. After an 8-hour flame-hardening process, no detrimental effects occur under the rolling-load tests for shelling; rail also conforms to accepted straightness with relatively inexpensive equipment. Since a superior fully heat-treated rail is unavailable economically to the railroads, the data described indicate a usable product for a relatively low cost.

RAIL END BATTER; CAUSES AND REMEDIES
Causes and remedies of rail end batter are discussed. Four rail joints of 131 RE section with a 0.040-in. batter are welded, using the semi-automatic wire feed method with a modified 4560 wire electrode and gas shielding eliminated. A 700 F preheat and 1100 F post heat are produced with a propane heater. Rail joints are subjected to rolling-load tests. Results are presented of rolling-load tests of four rail joint assemblies, built up with Haynes Stellite modified 4560 wire electrode. It is noted that batter ranges from 0.006 in. to 0.016 in. on joints 69 A and 69 C that ran to 5,000,000 cycles. Hardness obtained on a standard BHN tester on the parent rail metal that was work hardened and on the weld metal before and after work hardening is reported. It is noted that the trend of spalled rail ends with a BHN range of 481-564 before work hardening and 512-600 after work hardening occurs, and that the spalling occurs about 1-1/2 in. away from the rail ends where the porosity is the heaviest.

LENGTH OF TRANSITION SPIRALS-A REVIEW OF RESEARCH REPORT ER-37
A review of research report ER-37 is made to discuss length of transition spirals on curves. It is noted that existing methods and formulas provide spirals of adequate length when the work is carefully done, although situations still exist where a road has neglected to reline curves to provide spirals of desirable length and where the elevation runs out on the tangent, producing an undesirable sensation on the curve. A different principle is introduced into the calculation of spiral length, the principle that lateral acceleration should vary uniformly from zero on the tangent to a maximum on the full curve, and that the rate of change of lateral acceleration should be limited rather than limiting the rate of change of elevation. Formulas are elaborated, and their use results in new line construction, reconstruction of existing line, or setting up higher speed passenger service.

RAIL SLIPPAGE TESTS-CONCRETE TIES
Tests are conducted to determine rail slippage for concrete ties, using the fastenings to check the slippage resistance anticipated in the design calculations. Test procedure is described and results are presented. It is noted that the values of rail slippage resistance for the AAR design clips for the Type E tie are generally more than the 2000 lb minimum for 5000 lb bolt tension, except those with vibration, which are only about 1000 lb. It is concluded that the measurements of rail slippage resistance obtained agrees reasonably well with those anticipated in the design of the fastening for the AAR Type E prestressed concrete tie. It is believed that a range of bolt tension between 10,000 and 5000 lb should be maintained with AAR clips until such time as service experience indicates that a change in these limits is warranted.

A2 052317
INSULATED RAIL JOINT DEVELOPMENT AND RESEARCH
An effort to design rail joint insulation capable of resisting high compressive and abrasive forces that develop between rails and joint bars was presented. A protective steel armor bonded to the insulation in the joint bars was selected as the best method to protect the insulation. Rolling-load tests were run on seven types of insulated joint bars, including the VulcaBond joint designed by the AAR. The rolling-load tests gave good comparative data on the action of the joints in flexure and the fatigue life in flexure. The VulcaBond joint had the smallest deflection. A standard armoured continuous type was next lowest, and the plastic joint had the greatest. The fiber-glass joints were the best of the plastic type tested, but had considerably greater deflections than the VulcaBond or continuous type and a lesser life in fatigue. The VulcaBond joints were installed on track in several railroads. Several weaknesses were found and remedied or eliminated. However, the bushings need further strengthening.

RAIL WEAR TESTS ON THE ST. LOUIS-SAN FRANCISCO RAILWAY
Two curves on the St. Louis-San Francisco Railway were selected for rail wear tests. The section having a slightly lower rate of wear in past service

was not lubricated. The other curve had a "Meco" single rail lubrication using graphite grease at the far end of its two curves. The effectiveness of the lubrication was gaged by taking rail profiles at various intervals of time. These profiles show the amount of steel worn from the heads of the rail gage. Elevation and curvature of the high rail were measured at each point where a profile was taken. Seven sets of profiles were taken of the rails undergoing the tests. The profiles show significantly less wear on the curve with the track lubricator than on the curve with no lubrication. The effectiveness of molybdenum-disulphide was tested as a rail lubricant. Its application showed less wear rate. These service tests definitely show that track lubricators are effective and can double the life of the outer rail in the presence of heavy sanding.

SERVICE TEST OF SOLID MANGANESE STEEL CROSSING FROGS WITH PRESTRESSED CONCRETE SUPPORT VERSUS TIMBERS
An inspection of a service installation of a prestressed concrete crossing support is presented. The crossing had been given normal maintenance during the service period. At the end of the first winter the concrete was performing much better than the timbers, with very little vertical movement during traffic. After heavy rainfall the wet subgrade condition resulted in vertical moving of timbers double that of the concrete. A concrete corner was broken off at the point of failure in one of the post-tensioning rods, but there was no evidence of further distress due to reduction of effective rods from six to five. No cause for the break was found. A record of maintenance costs was not kept.

ENGINEERING ASPECTS OF CURRENT RAIL SECTIONS
This investigation of the engineering aspects of current rail sections falls into four phases. 1) Flexural Stiffness and Strength--The additional stiffness as indicated by the moment of inertia and strength as indicated by the section modulus of the 106 CF&I, 119 CF&I and 136 CF&I sections are increased approximately in proportion to the additional amount of metal provided in these sections. 2) Shape of Head Contour--Measurements indicate the rolled contour of the 115 RE and 132 RE sections fit the worn wheel contour better than the 119 CR&I and 136 CF&I sections. Better service performance as to the development of shelling is concerned can be expected from them. Narrowing of the rail head decreases the radius of hollowing of worn car wheels with resultant increase in wheel contact pressures and internal direct stresses and shearing stresses within the rail head. 3) Depth of Rail Head--Increased depth of rail head in the CF&I sections provides additional metal for vertical head wear. Measurements of actual vertical head wear as related to traffic and traffic densities indicate the present RE sections have adequate depth of head to provide a full usable life of the rail. 4) Localized Web and Fillet Stresses--Measurements indicate that upper fillet stresses in the web are reduced with the CF&I sections as compared to corresponding RE sections.

A2 052334
SERVICE PERFORMANCE AND ECONOMICS OF 78-FT RAIL; SPECIFICATIONS FOR 78-FT RAIL
The service test of rail laid in 78-ft lengths on the Illinois Central Railroad was covered in this progress report. The prime purpose of the test was the determination of adequate arrangement of rail anchors to control rail creepage better, and to obtain an improved rail gap uniformity. Winter gaps were measured before adjustment of the gaps was made. The average of summer gaps in the two test sections was not materially changed by the adjustment of gaps in the winter, except for one rail. The joints in this rail that would not close at high temperatures, before adjustment, now have summer gaps comparable to other joints measured. The anchorage, alternate ties boxed, in the test mile will give satisfactory results with 78-ft rail provided it is laid with expansion required to have it tight at 85 deg. Because joint slippage resistance is required to keep the joints from opening too much in the winter, especially in 78-ft rail, it is important that the track bolts be retightened frequently. In proposing expansion of the use of 78-ft rail a table is provided.

SUBSTITUTES FOR WOOD TIES
This progress report on substitutes for wood ties includes information on ties used in European countries, progress in prestressed concrete railroad ties, and work done in the AAR Research Laboratory. Metal and reinforced concrete sleepers (ties) have been used in France. The metal sleepers gave good results with light traffic, but could not be used on high-speed and circuited tracks. Concrete ties supplementing wooden ones were advantageous because their reported service life was from 30 to 40 years. The AAR Research Laboratory used three different rail designs on standard and lightweight aggregates. Lime-rock aggregate ties could not sustain loads imposed in heavy-duty travel. Bolts extending completely through concrete ties with rail clips were the most satisfactory rail fastenings.

SERVICE TESTS OF DESIGNS OF MANGANESE-STEEL CASTINGS IN CROSSINGS AT MC COOK, ILL
This report covers the service test of the last remaining test casting in the double-track lines of the Baltimore & Ohio Chicago Terminal Railroad and the Atchison, Topeka & Santa Fe Railway at Mc Cook, Ill. The two U. S. Steel solid pedestal castings showed that the depth-hardened frog was in service 0.8 year longer and carried 56 million more gross tons of traffic than the unhardened casting. Both depth-hardened castings were in service 26 months before the first welding of the battered tread corners a compared to the 18 months for the USS unhardened casting. The greater service life of the Rampo deepened-flangeway design than that of the USS solid pedestal type castings indicates some advantages for the more flexible casting. The USS casting with rigid support of tread corners also developed the higher receiving flangeway fillet stresses. All of the test castings were those used in the end position with a height of 6 1/4 inches to match 110 RE rail and an intersection angle of 75 degrees 48 minutes.

A2 052359
PRESTRESSED CONCRETE TIES
A new design of prestressed concrete ties by the AAR is the subject of this discussion. Two different types of fastenings were used with this tie to determine the type of fastening to be ultimately used. The design calls for clip bolts to be tightened to 10,000 lb. tension, which will give a good grip on the rail and prevent rail creep. Two types of tests to determine the flexural strength of the ties were performed; repeated load and static tests. The concrete tie was more securely held in the tests. In a test installation clips were used to hold the rail down. It concludes that a potential of 50-year track could be realized through the utilization of this type of prestressed concrete tie.

WHEEL LOAD, WHEEL DIAMETER AND RAIL DAMAGE
The dual study of wheel load, wheel diameter and rail damage is presented. It is concluded that formulas derived from earlier studies should be applied to today's situations for worn wheel on worn rail. A report on shelly rail reviews previously gathered information before discussing a recommendation that a limitation be placed on wheel loads for diesel and turbine locomotives. The recommended limit for wheel loads is 800-lb per inch of diameter. The study concludes that shelly rail stress increases in proportion to the cube root of the load; the life of the rail up until the time failure occurs decreases very sharply for any small increase in stress.

STATIC AND FATIGUE TESTS ON PRESTRESSED CONCRETE RAILWAY SLABS
The fatigue properties of prestressed pretensioned concrete railway slabs are discussed. A theoretical study of the fatigue resistance of such members is first presented, followed by a description of laboratory tests on six beams. Test results are discussed and interpreted. The theory of fatigue failure is based on three diagrams including a failure envelope based on a limited amount of fatigue test data on prestressing strands and a diagram of the fatigue characteristics of plain concrete. The two failure envelopes are combined with curves expressing the moment-stress relationship for a given beam. The investigator is able to predict the critical loading. It is concluded that the test results check reasonably well with the critical fatigue loads predicted on the basis of the stated theory of fatigue failure.

PREVENTION OF DAMAGE RESULTING FROM BRINE DRIPPINGS ON TRACK AND STRUCTURES
Prevention of damage resulting from brine drippings on track and structures is discussed in an attempt to find non-toxic brine corrosion inhibitors for use in refrigerator car bunkers. Features of inhibitors for brine corrosion are cited, and tie plate corrosion resistance is also discussed. Copper bearing steel is evaluated, and rail corrosion in tunnels is investigated. It is noted that variation in concentrations of elements such as copper, nickel, and chromium contribute nothing toward increasing the resistance of the steel against liquid brine drippings.

HOLD-DOWN FASTENINGS FOR TIE PLATES, INCLUDING PADS UNDER PLATES-THEIR EFFECT ON TIE WEAR
Study is made of hold-down fastenings for tie plates, including pads under plates, and their effect on tie wear is investigated, related to tie life, regaging and readzing curves. Economic factors of hold-down fastenings are also considered. Tests are conducted, and progress of test, including additions and revisions, is reported. It is noted that a number of tie pads still in use are no longer considered satisfactory for use. Topics discussed include maintenance of hold-down fastenings, gage of test curves, general inspection, tie coatings, repeated load tests of tie pads, and economic studies.

SERVICE TESTS OF VARIOUS TYPES OF JOINT BARS
Report is made of two service tests of joint bars for 115 RE and 132 RE rail. Service test installations are described, and test data is presented. It is concluded after 10 years of service that the test sections show good performance with little difference except that the 4-hole bars show slightly more difference in the level at the 1/4-inch points of the rail ends. The long-toe bars on the Santa Fe continue to show a slight tendency toward developing cracks in the spike slits, although the progression is slow.

RECENT DEVELOPMENTS AFFECTING RAIL SECTION
Report is made of measurements of the actual loss in height due to wear of rail being removed from main line tangent track during 1957. Data is furnished for rail section, year rolled, approximate annual traffic density in gross tons, measured height of rail to the nearest 1/32-inch at the mid-width of the rail and away from rail end batter or wheel burns, and the loss in height of rail. Twenty railroads with annual traffic of 20 MGT or more furnish data from a measured location. It is noted that if rail head wear on main line tangent track follows the mean curve for traffic densities, then for varying traffic densities and a total rail life in its original tangent position varying from 150 to 500 MGT of traffic, the total head wear is expected to vary from 0.100 to 0.140-inch for the conditions tabulated.

A2 052389
SERVICE PERFORMANCE AND ECONOMICS OF 78-FT RAIL, SPECIFICATIONS FOR 78-FT RAIL
Tests and measurements made on two service installations of 78-ft rail were presented. The purpose of the tests on the Chicago & North-Western and the Pennsylvania Railroad was to determine if the presence of greater joint gaps on the 78-ft rail would create an increase in cost of maintaining the remaining joints, thereby reducing benefits due to the elimination of one half of the joints. Measurements show no outstanding difference between the 78-ft rail and the 39-ft rail at the Chicago and Northwestern site. At the Pennsylvania Railroad site measurements show pull-in of 78-ft rail to be almost identical to that of 39-ft rail. Joint gap measurements on the Illinois Central reveal that rail anchorage of 22 alternate ties boxed per 78-ft rail has given a more satisfactory rail gap uniformity than in earlier tests.

A2 052391
DESIGN OF TIE PLATES
This report on the design of tie plates is presented in two parts. Part one presented the evaluation of seven designs of tie plates. Tie abrasion, tie plate bending, and gage of track were the factors used to evaluate the service wear

of the tie plates. The evaluation period of 13 years was not long enough to develop the advantage of longer plates. No permanent bending developed in the thinner plates. The plates with ribbed bottoms act as a retardant to gage widening, but show an increase in cutting the tie. The outer rail on the 6-degree curve is the chief maintenance problem as to wear of rail, ties and gage widening. Part two presents a final report on tie plate bending on a curve of the Illinois Central Railroad. It is concluded that the AREA plan thicknesses for plates for the 5 1/2 inch rail base is sufficient for a satisfactory service life, except where there is severe brine corrosion and heavy traffic density amounting to more than 18 million tons per year.

METHODS OF HEAT TREATMENT, INCLUDING FLAME HARDENING OF BOLTED RAIL FROGS AND SPLIT SWITCHES, TOGETHER WITH METHODS OF REPAIR BY WELDING
Methods of heat treatment are discussed, including flame hardening of bolted rail frogs and split switches, together with methods of repair by welding. Report includes welding techniques and metallurgical examination of experimental laboratory welds, and a description of service tests of simulated crossing units at Mannheim, Illinois. Recommended welding procedures for the service test units are made. Maintenance of tread corners is investigated, and measurements of rail wear and batter, and Brinell hardness are conducted during the entire service period. It is concluded that in the flame-hardened group, the Ramapo units had the lowest average number, receiving corner batter of 57 percent of the control units. The Cleveland units of the heat-treated group had the lowest average value of receiving corner batter of 37 percent of the control units. Average increases in Brinell hardness readings due to cold rolling and work hardening of the normal rail and the tread corners are tabulated.

CURVE WEAR WITH DIESEL LOCOMOTIVES ON THE BESSEMER AND LAKE ERIE RAILROAD
A series of test runs were made to obtain definite information on the amount of rail curve wear produced by diesel locomotives relative to that produced by the remainder of the train. A second series of tests was made for the purpose of relating the effectiveness of flange oilers on the locomotive and rail lubricators in the track in controlling the amount of curve wear. Instrumentation consisted of a box to catch metal abraided by diesel units from the track and a motion picture camera to photograph the passing wheel flange on the high rail. The tests show that although the rate of rail and wheel wear with a diesel unit is greater than for a heavily loaded freight car, the greater amount of rail wear is due to the train rather than the diesel units. Rail and wheel flange wear on curved track can be practically eliminated by lubrication with either flange oilers on the diesel units or rail lubricators in track, or a combination of the two.

A2 052427
STRESS CONCENTRATION IN BUILT-UP STRUCTURAL MEMBERS
This report covers a description and analysis of tests made to determine stress concentrations in plates in the vicinity of rivet or bolt holes under varying conditions of pitch, gage, edge distance, bearing and clamping force. Measurements of strains with SR-4 strain gages and the methods of photoelasicity were the two test procedures employed in the investigation. The items investigated by each of these methods and the results are as follows. Stress concentrations at the sides of open holes in plates will vary within relatively small limits if the conventional spacing of 3 hole diameters and edge distances of 1 1/2 diameters is maintained. Stress concentrations at the sides of holes with pins in bearing in double shear will be higher than for open holes. Plates connected by pins bearing in double shear will be higher than for open holes. Plates connected by pins bearing in single shear have stresses at the sides of the holes 20 to 40 or more times the average stress on the gross section of the plate when load is applied centrally with respect to width of plate. In joints connected by high clamping bolts, the stresses inside the hole produced by clamping applied through washer only are compressive. In correlating the magnitudes of stress concentrations with the results of fatigue tests on typical specimens it can be concluded that elastic stress concentration is a valid criterion for establishing the fatigue strength of fabricated structural members. Appendix I presents a qualitative explanation of stress concentration and change of direction of stress path or trajectory.

A2 052433
EFFECT OF LUBRICATION IN PREVENTING FROZEN RAIL JOINTS
Rail joint lubrication service tests on the Illinois Central Railroad and the Chicago, Burlington and Quincy Railroad were covered. Various types of lubricants or rust preventatives and methods of application were tested to determine more satisfactory and lasting treatment of rail joints and to prevent stripped joints and damaging corrosion during the life of the joint bars. A description of the test installations was given. Test measurements and data were described for the Illinois Central installation. No important conclusions as to the relative effectiveness of the rust preventatives were justified for this service test of one year. It was evident that the heat in the joint left from the rail end-hardening was detrimental to most of the sections greased with a brush coat. In tests on the Burlington rail joint gap and joint bar pull-in measurements were taken. Inspection of dismantled joints was performed. It was concluded that in general the several kinds of lubricants were not effective in reducing joint wear or pull-in to a significant amount. The greatest benefit derived from these was in the arresting of corrosion and the prevention of hard rust slabs forming in the lower rail fillets at the ends of the joint bars.

RAIL END BATTER; CAUSES AND REMEDIES
Testing of various methods of building up rail ends by welding was explored. Nine railroads and one contract welder were invited to weld 50 joints each, using the procedures in use on their own railroads. Seven of the panels were welded by the oxyacetylene process, three panels by the d.c. electric arc process, and one panel by the a.c. electric arc process. A record was made of the net time required by the welder and helper to do the welding, and the amount of welding rod, oxygen and acetylene or gasoline used. The procedure on each panel was presented. The following conclusions were reached. 1) Satisfactory welding can be done by either the oxyacetylene or electric arc process. 2) The cost of labor and fuel is higher for the oxyacetylene process than for the electric arc. 3) The investment in equipment for the oxyacetylene process is less than that for the electric arc process. 4) The cost of reconditioning rail ends by heating and forging is nearly the same as that for building up by welding by the oxyacetylene process. 5) There is no advantage of multiflame oxyacetylene tips. 6) The rail should be preheated before electric welding. 7) Grinding produces a better surface than finishing by forging. 8) The skill of the welder is a very important factor.

RECENT DEVELOPMENTS AFFECTING RAIL SECTION
This report presented two studies in corrosion fatigue of rail web steel. Two fatigue tests with corrosion using tap water as the corrosion medium were performed. Tests from the University of Illinois showed very little reduction in the endurance limit as obtained without corrosion. Duplicate tests performed at the Pennsylvania Railroad Laboratory at Altoona, Pa. resulted in a greater reduction in the endurance limit than that of the original at the University of Illinois. It was concluded that the Altoona tap water was more corrosive than the Urbana tap water which accounted for the difference of results, and therefore,, no further modification of the corrosion procedure was done. Results of the Altoona test could readily be interpreted as corrosion fatigue due to the severity of the corrosion present during the tests. A curve concluded fatigue with and without corrosion was present. It showed that where corrosion is present it becomes a practical impossibility to so design a rail and the rail joint as to prevent failure from corrosion fatigue. In summary it was felt that sufficient proof had been offered that rail web failures in the joint do occur from corrosion fatigue, and that the fatigue life of rail web steel can be sufficiently reduced by corrosion fatigue to account for these failures.

TEST RESULTS ON RELATION OF IMPACT TO SPEED
Test results on relation of impact to speed are reported to support the proposed Article 107 of the Rules for Rating Existing Iron and Steel Bridges. It is noted that a study of short span steel bridges 20 to 40 ft. long and deck plate girder spans 40 to 130 ft. long subjected to live loads with or without hammer blow indicates that the reduction of impact as a result of speed should occur at 40 mph or less, rather than synchronous speed or less as was proposed in 1947 for spans longer than 50 ft. The value of 40 mph was selected as the maximum practical speed where allowable reduction in impact might be permitted since rolling equipment without hammer blow has no synchronous speed. It is noted that some values of total impact on truss spans approximately 120-150 ft. long, subjected to equipment with hammer blow, receive more impact than is provided by Article 206 of the Specifications for Steel Railway Bridges. The character of the reduction equation for truss spans subjected to rolling equipment with hammer blow is consistent with the data.

REPORT ON SERVICE TEST OF SOLID MANGANESE CROSSINGS FROGS AT MCCOOK, ILLINOIS
Service tests of solid manganese crossing frogs at McCook, Illinois, are reported. Stress measurements are covered in the flangeways and at other significant stress areas of five different designs of manganese castings placed in the crossings of the Baltimore & Ohio Chicago Terminal Railroad and the Atchinson, Topeka & Santa Fe Railway. Service tests include tests of the original design of casting by Taylor-Wharton and the Carnegie-Illinois casting. It is concluded that some of the designs included in the tests are more resistant to the development of fatigue cracks than others, but in none were the developed stresses low enough relative to the fatigue strength of the manganese steel to give the service life under heavy traffic that should be expected, and efforts to further reduce these stresses are recommended.

HOLD-DOWN FASTENINGS FOR TIE PLATES, INCLUDING ELASTIC PADS UNDER PLATES; THEIR EFFECT ON TIE WEAR
Study is made of hold-down fastenings for tie plates, including elastic pads under plates, and their effect on tie wear, in an effort to extend the service life of ties and save cost. Service tests are reported to determine, from periodical measurement of tie plate penetration, track gage, curvature, cross levels and other observations, the relative effectiveness and economy of the several types of hold-down fastenings and tie pads, as to reduction in mechanical wear of ties and the maintaining of good track gage on curves. Initial gage measurements for original construction were taken in November 1974 and checked in August 1948; readings for the 1948 construction were taken on October, 1948. It is noted that when gage widening occurred, its cause was undetermined, but forthcoming tests will determine if the pads were a major contributing factor to the gage widening. Generally the gage in most test sections on the long curve held well. Tie plate penetration measurements are taken, but in many instances a tie plate does not become finally seated in one year.

QUALITY OF RAILS AND MEANS OF GUARANTEEING IT. PROPOSALS CONCERNING THE 6TH EDITION OF TECHNICAL SPECIFICATION 860-0 GOVERNING THE SUPPLY OF VIGNOLE (FLAT-BOTTOM) RAILS OF NON-TREATED STEEL
At the request of the 7th UIC Commission, the D 45 Specialist Committee has been charged with studying the dimensional tolerances of rails with a metric weight greater than 60 kg. As the administrations made increasing use of heavy rails it become necessary to include in Technical Specification 860-0 for the supply of Vignole (flat-bottom) rails of non-treated steel, the maximum permissible dimensional tolerances for these heavy rails. Having regard to the results of the tests already carried out within the scope of its programme of work and the experience gained by its members, the D 45 Specialist Committee deemed it advisable not to limit its investigations merely to the problem of dimensional tolerances, but to examine the whole specification at the same time, and to group into one report all the amendments and additions which it intended making to the existing text. The most important amendments concern marking, freedom from defects, dimensional tolerances, and certain acceptance and guarantee conditions. The wording of the texts at present in force and of the texts proposed to the 7th UIC Commission have been completed by remarks explaining or justifying the decisions of the D 45 Specialist Committee.

BEHAVIOR OF THE METAL OF RAILS AND WHEELS IN THE CONTACT ZONE. EXPERIMENTAL STUDIES: 1) WORK-HARDENING SPEED WITH THE EMS 60 MACHINE (ADDITIONAL MEASUREMENTS), 2) RESIDUAL STRESSES IN HARD-GRADE STEEL RAILS (ADDITIONAL MEASUREMENTS) 3) CHECKING OF FATIGUE CRITERION PROPOSED BY MR. DANG VAN
This report is in three parts: 1) Work-hardening speed examined with the EMS 60 machine: The development of the two principal residual stresses produced on the running surface of rails made of different grades of steel has been studied as a function of the repeated passages of a loaded wheel. It has been shown that this development ceases at about approximately 1 million cycles. 2) Residual stresses in hard-grade steel: These stresses have been measured inside 2 rails of hard-grade steel, one new and the other work-hardened in service. The use of the rail in the track produces severe longitudinal and transverse compressive stresses at the surface. The stress field is affected strongly throughout the height of the rail-head. 3) Checking of fatigue criterion proposed by Mr. Dang Van: The fatigue limits of a rail steel have been determined for different cases of stressing. The results have enabled the validity of the fatigue criterion proposed by Mr. Dang Van (see Report C 53/RP 7) to be confirmed.

OPTIMUM ADAPTATION OF THE CONVENTIONAL TRACK TO FUTURE TRAFFIC. STUDY OF THE CHANGE IN THE TRACK LEVEL AS A FUNCTION OF THE TRAFFIC AND OF THE TRACK COMPONENTS (FIRST RESULTS OF LABORATORY AND SITE TESTS)

The report deals with the change in the longitudinal level of conventional tracks under the effect of operating loads. Tests have been carried out in the laboratory and on actual sites on differently equipped tracks, with a view to defining the influence of the various track component parameters. The discovered evolution law of defects has shown that the reduction in sleeper spacing and of crib and shoulder consolidation exert a rather clear influence. It has also become apparent that the quality of the maintenance operations exerts a very large influence. These findings should however be treated with caution. The influence of the inertia of the rail, the thickness of the rail pads, the types of sleepers and the conditions of the formation and of the ballast, will be accurately defined later.

AN ANALOG-DIGITAL METHOD OF DETERMINING VERTICAL TRACK IRREGULARITIES AS THE EXCITATION OF A RAIL VEHICLE'S VERTICAL OSCILLATIONS

Unknown dynamic parameters of the track have been obtained by statistical calculations. The parameters are used to design an analog-system to determinate a "substitute vertical track irregularity" as an excitation of vertical vehicle oscillations for the accepted model of the track. The signal recorded on the magnetic tape may also be used for an analog study of the vertical vibrations of other vehicles. The computations have been based on the correlation function method.

OPTIMIZATION OF THE LAYOUT AND OF THE RE-ALIGNMENT OF THE LAYOUT OF CURVED TRACK

This study is devoted to problems in connection with the layout of railway tracks in curves, the "versine method" currently employed on the SNCF being the sole method considered. These problems involved are of two types and concern: (1) the re-alignment of the layout during track maintenance operations: it is a case here of the correction of layout defects due to the passage of trains and not involving important track shifting; (2) detailed modification of the layout: it is a case here of the modification of the layout of a curve carried out in particular with a view to an increase in the running speed, combined, possibly, with a fault-correction. The solution of these two problems is obtained with the help of linear programming: it gives the track-shifts and the future versines and superelevations at each reference point on the site in taking into account one or more optimization criteria. The results are presented in the form of a list accompanied by a diagram supplied by a curve-plotter and giving versines and superelevations as a function of the curvilinear abscissa. The first type of problem has now been solved, both for simple curves and for curves with successive arcs. The calculation program concerning the second type of problem is in the course of being perfected and finalized.

STANDARDIZATION OF POINTS AND CROSSINGS. DIVERGING TURNOUTS FOR SPEEDS OF 100 TO 200 KM/H AND ABOVE--GENERAL DESIGN--EXPERIENCE ACQUIRED BY CERTAIN ADMINISTRATIONS

This report gives a summary of the experiences already gained by the Railway Administrations in the matter of switches and crossings for speeds between 100 and 160 km/h on the diverging route. To begin with are discussed the general characteristics of the guide lines within which the figures indicated are based essentially on the conclusions of Committee D 72. The trials already carried out and those yet to be undertaken should permit the establishment of the essential parameters; acceptable cant deficiency, form of transition, design of switch toe, slope of entry for check rails ets. Bordering on these trials of turnouts of standard design, which embrace the range of speed up to 220 km/h on the divergind route, the trials with movable nose crossings intended to eliminate gaps in the running lines, are equally provided for.

OPTIMUM ADAPTION OF THE CONVENTIONAL TRACK TO FUTURE TRAFFIC. RHEOLOGICAL PROPERTIES OF THE TRACK
The laboratory tests carried out with a view to determining the dynamic modulus of elasticity of the ballast and described in the present report show that, from the point of view of vibratory phenomena, the real behaviour of the track can be simulated on the small test rig. The vibrations of the track have been analysed in the frequency range comprised between 20 and 90 Hz and it has been established that the use of sleepers of different types affects the modulus of elasticity and the position of the resonance peaks. It has thus been possible to show that heavy sleepers are better suited for high speeds.

STATISTICAL CHARACTERIZATIONS OF RAILWAY TRACK BEHAVIOR
Absolute space curve data of railway track, representing the vertical and lateral perturbations of both running rails, was collected and analyzed. A variety of track is studied, including high speed versus yard, bolted versus continuous welded rail (CWR), and old versus new construction. Analytical techniques include Signal Averaging, Analysis of Variances, and Correlation analysis. As a result, it is concluded that railway track is characterized by a pure Markovian process, a periodic process, and a periodically modulated random process.

THE IN-TRACK TREATMENT OF THE RAIL RUNNING SURFACE ON THE NETWORK OF THE GERMAN FEDERAL RAILWAYS (DB)
The running speeds of passenger trains and express goods trains have constantly increased over the last few years. Particularly on main lines, electrification has led to the use of heavy electric locomotives with high axle loads and starting accelerations. For safety, economy and riding comfort in these conditions, a good track seating is essential. The Author deals with the need for regular grinding of rail heads on railway tracks, for which purpose the German Federal Railways have employed the "Speno" rail-grinding train since 1968. Its design, use and results obtained are described here.

THE CANCER OF MAINTENANCE DEFERRAL
During the past 20 years there has been a marked decline in the quality of tracks expecially among the bankrupt railways. On the basis of a 37-year tie life, a railroad should install 80-90 ties per mile per year. Yet in 1972 PC installed 61. The Southern Railway presently has one of the best track maintenance programs in the U.S. and one of the highest maintenance-of-way ratios (percentage of operating revenue devoted to M/W. work) at 16.9. Continuous welded rail is also an important M/W project on the Southern. These programs typify the Southern as the prosperous railway of the South, Southwest and West.

A2 054681
SANTA FE'S WELDED RAIL PLANT AIMS AT LOW COST PRODUCTION
The use of continuous welded rail is producing big savings for railroads. If those savings are to be maximized, large investments are required, at least on the major roads, to provide installations and equipment that will make it possible to produce CWR from both new and secondhand rail at minimum cost. Santa Fe's new centralized rail welding plant at Amarillo, Tex., to be dedicated on May 14, provides an example of how this line of reasoning works out in practice. On about 30 acres of land alongside its main line, Santa Fe has created a double-line rail butt-welding complex designed to produce approximately five miles of butt-welded rail daily in two eight-hour shifts the year around.

A2 054692
THE EFFECT OF TRACK AND VEHICLE PARAMETERS ON WHEEL/RAIL VERTICAL DYNAMIC FORCES
The railway track and vehicle combination comprises heavy rigid wheels running on heavy rails. Imperfections in either will give rise to dynamic effects which increase with speed. These will supplement the contact forces which, on perfect track with perfect wheels, are basically the static wheel loads. The commercial necessity for higher speeds and greater axle loads has been established and this historical trend will probably continue. Forces and stresses will therefore become more severe unless technical progress is made in track and vehicle design. In this context, close co-operation between the Civil and the Mechanical Engineer is essential. Track must have a high standard of alignment and level and maintenance quality must be improved as far as practicable. The forces that the rails and track structure will withstand must also be specified. New vehicles, particularly those for high speed operation or with heavy axle loads, must not generate excessive track forces.

TESTS ON A NEW TYPE OF CONCRETE SLEEPER [VERSUCHE MIT NEUARTIGEN BETONSCHWELLEN]
The sleeper in question is 2.4 m long with short crosswise projections on either side below the rail. The problem was to find a solution to track side-slip, especially in small radius curves, when the rails are welded in long sections. The OBB have carried out comparative tests in the laboratory and on the track with the new sleeper and with the standard concrete sleeper (BE 14) in extended 2.6 m form. Although the experiments have still to be completed, it is already clear that the stability of the new sleeper is greater. However a cost benefit analysis still has to be drawn up before the OBB can come to a decision over this sleeper.

A2 054782
THE BEHAVIOUR OF RAILS IN RELATION TO THEIR CONDITIONS OF USE
The principal rail failure statistics of 5 Administrations have been analysed with a view to determining the respective influence of the different features involved in the behaviour of rails in service. Some recommendations are proposed concerning the choice of rail-section as a function of the traffic, the grade and quality of the rail steel and the construction of rail joints. The problems raised by welds in continuously welded rails, by the substructure and by the environment are also mentioned. It seems that the rail withdrawals for fatigue defects increase proportionally with the total traffic load on the one hand with the cube of the average axle-load on the other.

Restrictions on the use of this document are contained in the explanatory material.

MODEL STUDY FOR VERTICAL TRACK BUCKLING
A study is presented of two models which represent the mechanism of vertical buckling of a track when subjected to a mechanical or to a thermal compression force, respectively. The postbuckling equilibrium curves and their stability are discussed and a stability criterion is defined. The effect of various track model parameters, upon the buckling load or buckling temperature, is shown. Graphs reveal that the range of safe compression forces for the mechanically compressed structure is much smaller than the range of the safe forces due to constrained thermal expansions; indicating a possible explanation why in the tests in which the compression forces are induced by jacks the track buckles predominantly in the vertical plane, whereas when the track is compressed by constrained thermal expansions it exhibits mainly horizontal buckling modes. It was found that the buckling loads, or temperatures, obtained from a linearized analysis have no relevance to the actual values obtained from a nonlinear analysis; the difference in results being substantial for buckling temperatures.

A2 057500
THE USE OF HEAVY MACHINERY FOR TRACK MAINTENANCE
Mechanisation of track maintenance with heavy machinery enables the following operations to be carried out mechanically: longitudinal and transverse levelling of the track; realignment of the track; levelling of the ballast. To these operations we must now add the tamping of the spaces between sleepers, in the case of long welded track. This mechanisation, which began with track levelling followed by realignment, has now reached a level of quality superior to the similar operation carried out manually. In addition, particularly in countries where labour is expensive, this mechanisation enables track maintenance costs to be reduced.

OBB TRIES OUT LUGGED SLEEPERS ON SMALL RADIUS CURVES
Because of problems of transverse displacement and buckling, Austrian Federal Railways (OBB), like most other European railways, limits the installation of continuously-welded rail on concrete sleepers to curved track with a radius of not less than 450 m. In Austria, however, this limitation affects between 30 and 40 per cent of OBB's mileage and there is economic pressure to solve these problems so that the advantages of long-welded rail can be extended to routes with curves of smaller radius. OBB has therefore developed two new monobloc concrete sleepers with this in mind.

KANSAS CITY SOUTHERN MAKES TIE RENEWALS WITH SMALL MACHINE
To an increasing extent, tie renewals are being made on the Kansas City Southern with a relatively small machine, known as the Section Gang Machine, which can be moved to and from the track by a few men. The number of attachments designed to increase the versatility now include the tie renewer, spike hammer, spike puller, lag screw bolter, tie drill and concrete breaker. Ease of handling, versatility of attachments and convenience of transporting it give the Section Gang Machine a good performance rating by KCS.

RECIPE FOR REHABILITATION
Two articles discuss the problems of bad track and deferred maintenance and some possible solutions. Because of the bad track some people are suggesting that the government take over the track to maintain it and let the companies pay a user fee to operate over the rails. The Transportation Act of 1974 would provide loans that could be used for track maintenance. CONRAIL is another proposed solution to the problems. New equipment is making maintenance-of-way work faster and cheaper but problems are developing with material shortages, especially ties.

18,000 TONNE ORE TRAINS IN AUSTRALIA
Over its seven-year existence, northwestern Australia's Hamersley Iron Railway has handled steadily increasing iron ore traffic until its gross tonnage reached an estimated 57.6 million during 1974. This 388-km high-capacity railroad is confronted with special problems of geographical isolation, harsh climate and high-growth rate. While in original design all equipment and track were based on US standards, as time passes, more European practices are introduced. The railroad is already studying new car designs and ultimately may consider doubletracking and other means of increasing capacity.

DEVELOPMENT OF TRACK BALLAST MAT
As a result of tests on the New Tokaido Line, aimed at developing speeds to 250 km/h, the laying of rubber mats under the ballast was conceived. Used automobile tires, ground and heat moulded into mats, have proven effective in preventing the pulverization of the NT Line ballast. The cost of track maintenance was reduced and noise and vibration suppressed. It has been decided to totally adopt the ballast mat in the tracks of the nationwide Shin Kansen network and it is possible also on the narrow-gauge lines.

EXPERIMENTAL TESTS ON VIBRATION-PROOF TRACKS AND THEIR EFFECTS
To minimize vibrations and noise from subway operation under a primarily residential area, a new line incorporated test sections of rubber mats under crushed-stone ballast, neoprene strips in a cast concrete roadbed, and vibration-proof asphalt concrete under crushed stone. The mats proved most effective but would invite greater settling of the track, complicating maintenance. The concrete slab, while more expensive, would minimize maintenance but would be costly to restore once performance had deteriorated. The vibration-proof asphalt concrete was not effective.

ASSESSMENT OF DESIGN TOOLS AND CRITERIA FOR URBAN RAIL TRACK STRUCTURES. VOLUME I. AT-GRADE TIE-BALLAST TRACK
The report presents the results of a critical review of the technical factors which govern the design and performance of at-grade tie-ballast track for urban rail systems. The assessment of current design practice is based on a review of the literature and discussions with experienced track design personnel. The evaluation includes design loads and the criteria for selecting rail size, tie size and spacing, ballast depth, and subgrade parameters. The major track problems identified were rail joints, rail wear and noise on curves, rail fasteners, and rail corrugation. Detailed technical evaluations were made to determine those areas where the track design procedures are inadequate. The report includes detailed information for the engineering design of track and recommendations for both short and long-range program plans for future research pertaining to the improvement of track performance.

ASSESSMENT OF DESIGN TOOLS AND CRITERIA FOR URBAN RAIL TRACK STRUCTURES. VOLUME II. AT-GRADE SLAB TRACK
This report presents the results of a critical review of the technical factors which govern the design and performance of at-grade slab track for urban rail systems. The assessment of current design practices is based on a review of the literature and discussions with experienced track design personnel. The evaluation includes descriptions of slab structures now in use in four countries, followed by review of design and analysis procedures used to characterize the subgrade and its support characteristics; the reinforced concrete slab itself, and the subgrade-support system. With a few exceptions, most of the work reported in the literature is based on highway or runway applications, where the mechanism of load transfer into the slab is completely different than in a rail support slab. Further research on the mechanisms of load transfer from rail fasteners into a reinforced concrete slab is needed, and the newly developed finite element approach appears well-suited.

RAILROAD ACCIDENT REPORT: CHICAGO, BURLINGTON AND QUINCY RAILROAD COMPANY TRAIN 64 AND TRAIN 824 DERAILMENT AND COLLISION WITH TANK CAR EXPLOSION CRETE, NEBRASKA, FEBRUARY 18, 1969
At about 6:30 a.m., on February 18, 1969, Chicago, Burlington, and Quincy Train No. 64 derailed the 72nd to the 90th cars, inclusive, at a turnout located on the spiral of a 2 degree curve as the train was entering Crete, Nebraska, at a speed of about 52 miles per hour. The derailed cars struck standing cars on a siding south of the main track and the cars of train 824 standing on a track north of the main track. A tank car in train 824 was completely fractured on impact with the derailed cars which released the lading of 29,200 gallons of anhydrous ammonia into the atmosphere. A gas cloud was formed which blanketed the surrounding area for a considerable time due to the weather conditions. Three trespassers riding on train 64 were killed as a result of the derailment and six people were killed and 53 were injured as a result of exposure to the cloud of ammonia. The Safety Board determined that the derailment was caused by the movement of a rail of the turnout due to lateral forces produced by the locomotive as it moved over track alignment and surface deficiencies of the track. The complete fracture of the tank car on impact was contributed to by the brittleness of the steel of the car caused by the low ambient temperature.

MEAN STRESS EFFECTS ON FATIGUE CRACK GROWTH AND FAILURE IN A RAIL STEEL
Over a limited range, the effect of mean stress has been studied on fatigue crack propagation and on the critical fatigue crack size associated with sudden fast fracture in center-notched plate specimens of a rail steel under pulsating loading. The results have been presented in terms of the stress intensity factor range K and the ratio R of the minimum to maximum stress. Increasing R was found to both accelerate cracking and reduce the critical crack size at instability. The data have been correlated with three crack growth equations currently used in the literature and it was found that the equation of Forman et al. relating crack growth rate to K and R gave the best fit. This equation was used to predict life in the finite range of the S-N curve. Fractographic examination revealed that the fracture surfaces were complex and a number of fracture modes contributed to cracking.

A UNITED STATES RAIL TRUST FUND; PRESCRIPTION FOR MODERN RAIL TRANSPORTATION
The Governor of Pennsylvania, aided by the Office of State Planning and Development and funded by two Federal agencies, has proposed a Rail Trust Fund of $12 to $13 billion for grants to all U.S. railroads for improvements in track, yards and other facilities over a six-year period. Like the Highway Trust Fund, users would pay the costs. Every railroad would collect and pay into the fund a 5% surcharge on freight revenues. These funds would pay off government-backed obligations financed over 30 years. Rehabilitation of road and track would require almost $7 billion; electrification, $3.2 billion; modernization and expansion of fixed facilities, $1.9 billion; modernization of yards, $900 million. Lower operating costs would result.
Prepared with Federal Financial assistance provided by the Department of Housing and Urban Affairs, Appalachian Regional Commission and Department of Commerce.

TRACK PRACTICES IN THE USSR
A six-man tour sponsored by the Department of Transportation made an 11-day tour of Soviet railroads to give them a look at track problems and practices in the USSR. In this first of two installments, the team of engineers and researchers reports on use of concrete ties and continuous welded rail. Track practices are largely determined by the heavy traffic densities of major routes. The goal is to do as much maintenance work in the shortest possible time, achieved by going to massive, high-production machines wherever possible. Much use is made of prefabricated track panels to speed this process. Various specialized machines are described.

JOINING AND HARDFACING OF RAILS, POINTS AND CROSSINGS USING MANUAL METAL-ARC WELDING ON THE SWEDISH RAILWAYS
Since 1967, the Swedish State Railways track office and the ESAB Central Research Laboratories has been developing a suitable technique and filler materials for rail welding. The first task was to reduce maintenance costs for track material by hard surfacing and joining of rail ends and crossings and later also points. The second phase was to further develop a technique and a backing material for the joining of rails by means of manual mold welding. The aim was to obtain such high quality in welds that the technique would be approved without any limitations.

DIRECTIONS IN TRACK STRUCTURE RESEARCH
This paper presents a survey of contemporary problems in track structure technology and the programs of research and development addressing these problems. It reports current and anticipated investigations into aspects of the service environment of railroad track structures, the mechanics of track structure degradation, the fatigue and fracture of rails, the development of rational design and maintenance techniques, the improvement of track components, and the development of non-conventional, low maintenance track structures for application to high speed high density service. Efforts involved with both the fundamentals of track mechanics, and the design of improved structures for urban rapid transit applications, as well as mainline railroad use are included.
Contributed by the Applied Mechanics Division of the American Society of Mechanical Engineers for presentation at the winter Annual Meeting, 17-22 November 1974, New York, New York.

LATERAL BUCKLING OF TRACK
The stability of this track against lateral buckling is afforded by flexural resistance of the track frame consisting of rails and sleepers and the ballast resistance. An attempt has been made to analyse the resistance offered by sleeper fastenings and represent the same in terms of virtual forces acting on the rails. The energy method has been used for calculating the buckling force, the shape of buckled track has been assumed as a triangle with elastic hinges at the ends. The lateral ballast resistance has been assumed to be constant irrespective of the deflection of buckled track. The present method is simple in calculation and can easily take into account the change in buckling load due to partial or complete loss of lateral ballast resistance of a few sleepers. The effect of various maintenance practices as per Indian Railways Long welded Rails Manual on the safety margin against lateral buckling has also been calculated.

A BIBLIOGRAPHY ON THE DESIGN AND PERFORMANCE OF RAIL TRACK STRUCTURES
This bibliography was prepared as part of the Rail Supporting Technology Program being sponsored by the Rail Programs Branch of the Urban Mass Transportation Administration. It is based on the reference material that was used to evaluate the technical factors which govern the design and performance of at-grade track structures for urban rail systems. While most of the reference material that has been included is directly related to track used for railroad, rail rapid transit and light rail transportation, there are some additional references on related topics such as rail vehicle dynamics, soil mechanics, stress analysis, etc. However, this bibliography does not include a comprehensive review of these related topics. This survey includes much of the published literature on track design, track loading, ballast,

wood and concrete cross ties, rail and rail fasteners. It also includes considerable material on track problems such as rail wear corrugation, rail defects, rail joints and track degradation. The formal literature search for this bibliography covered the time period from about 1963 to 1973. The principal sources were the National Technical Information Service (NTIS) file of government reports, Engineering Index, and the Applied Science and Technology Index. Earlier references were identified from the Railroad Research Information Service (RRIS) computerized data base and bibliographies prepared by the RRIS and the Association of American Railroads.

Individual abstracts from this bibliography have been selected under RRIS numbers 072794-072851.

SANTA FE INSTALLS CONCRETE TIE TESTS
Four out-of-face service installations at widely scattered points on system include various types of prestressed mono-block ties as well as different types of fastenings. The fifth installation tests concrete ties on a one-for-one basis. Details of the several test installations, each identified by its location, are described.

INVESTIGATION OF THE FORMATION OF CORRUGATIONS IN RAILS ON SELECTED TEST TRACKS UNDER CONDITIONS OF ORDINARY TRAFFIC
This is an evaluation of a large amount of data collected on two tracks since 1951 and 1958, respectively. Emphasis was on determining the behavior of different steels as a function of composition, melting practice, and treatment after rolling. Examples of findings are that increasing tensile strength and nitrogen content increase corrugations, increasing Mn and Si decrease the defect. [German]

A2 072822
DESIGN OF CONVENTIONAL RAIL TRACK FOUNDATIONS
Measurements of the distribution of vertical stress in the subgrade for given depths of ballast, track structural configurations and loading conditions are described. The mean maximum vertical stress in the subgrade can be predicted with reasonable accuracy by simple elastic theory. The results of laboratory work in which samples of soil were subjected to repeated triaxial loading are presented. For the cohesive soils tested a level of stress was found above which repeated applications of load caused large permanent deformations and below which permanent deformations were small and terminating. Based on these findings a method of track foundation design is developed in which the depth of ballast required to prevent excessive deformation of the subgrade can be predicted from the results of a simple laboratory repeated load test and a knowledge of the traffic loading to be carried. Small decreases in construction depth from the design depth produce large increases in deformation rate while large increases in construction depth over the design depth produce little return in terms of reduced rates of deformation. The proposed design procedure produces construction depths that are apparently close to the optimum for the fine grained soils so far investigated.

M/W EFFICIENCY ON UNION PACIFIC
The best yardstick in measuring the success of a maintenance policy is to compare the quality of the track and roadbed structure, with the maintenance cost, based upon the tonnage of traffic and the speed. Charts are updated each year to compare UP maintenance-of-way operating expenses with those of six other major railroads which have comparable traffic volumes, operating conditions, and so forth. Equipment is updated each year with the latest generation of equipment available, without over- mechanizing. The quality of day-to-day track-maintenance work that is done between the periods of out-of-face heavy program work has more to do to insure the best track conditions at the lowest over-all cost than any other single factor. Section gangs are assigned over the entire railroad to do the day-to-day maintenance work. The section forces mark the bad ties. The number of ties marked in each area is tabulated before the annual tie-gang program is established. UP M/W department is having a problem getting adequate on-track time for its mechanized track gangs engaged in out-of-face work. The only solution to the problem is to maintain close communication with operating department people to get just as much time on the track as possible. UP is a relative newcomer in the use of continuous welded rail. The road has firm rules governing the heating or cooling of the long strings. By vibrating the rail at the same time that it was being heated or cooled, frictional resistance is overcome and the rail is permitted to expand or contract the desired amount at the end of the string. Another area of pioneering for UP is in the use of glued or bonded insulated and closure joints between CWR strings. UP hopes to purchase a self-propelled car capable of testing track at 35 to 45 mph.

CONTACT VIBRATIONS
When a wheel rolls on a rail with a randomly wavy surface, the random waviness gives rise to a displacement input to the wheel and rail with a significant high-frequency (f greater than 100 HZ) spectral content. This displacement input excites the contact resonance of the system, wherein the mass of the wheel and an "equivalent mass" of the rail vibrate on the nonlinear contact spring. The purpose of the paper is to develop an analytical model for these high-frequency contact vibrations. The wheel is assumed to undergo only rigid-body motions, apart from the localized elastic deformation near the contact region. The rail is modeled as an infinite beam on a continuous, point-reacting foundation. With the rail roughness being assumed to be a locally stationary, Gaussian random process, a complete solution is presented to the linearized problem. Three phenomena of interest are investigated in detail: plastic deformation, loss of contact, and the formation of corrugations on the rail. The effects of various wheel and rail parameters on these phenomena are explored.

DYNAMIC TRACK COMPLIANCE
Analytical expressions for vertical and lateral track compliance are obtained from the solution of a beam on a visco-elastic foundation model. The equivalent foundation parameters were derived from the theory for a mass on a viscoelastic halfspace. The dependence of the overall track stiffness, damping, and natural frequency on the rail, tie, and roadbed parameters are evaluated. Upper and lower bounds for the overall track properties are obtained for existing types of at-grade track structures. A distinct advantage of the approach described is that it results in estimates for the effective damping due to both radiation of energy into the roadbed and energy loss due to internal soil friction. The damping due to internal friction can generally be neglected compared with the radiation damping.

PRELIMINARY SPECIFICATION FOR CONCRETE CROSS TIES (AND FASTENINGS)
This specification is intended to provide necessary guidance in the design, manufacture and use of concrete tie railroad track systems and their components. The specification contains minimum performance requirements of components of concrete tie railway track based on a variety of permissible tie spacings and ballast depths. Track constructed of tie and fastener components meeting the specifications applicable to the anticipated usage should be expected to give satisfactory performance under current AAR-approved maximum axle loads. The specification covers materials, physical dimensions, and structural strength of prestressed monoblock and prestressed and conventionally reinforced two-block concrete ties. In addition, longitudinal and lateral load restraint requirements as well as the electrical performance of rail fastener and tie combinations are given. Laboratory tests for the determination of the suitability of new designs are specified, as are necessary quality-control procedures during manufacture. The specification does not cover techniques nor equipment for the manufacture of concrete ties or fastenings. Where current specifications or recommended practices of other technical societies, such as the American Society for Testing and Materials or the American Concrete Institute, are appropriate, they are made part of this specification.

STUDY OF NEW TRACK STRUCTURE DESIGNS
The effect of an abrupt change in the elastic foundation properties upon the motion of a high speed vehicle is investigated in detail in this study. Limiting allowable accelerations are chosen as the criteria for riding quality. The study indicates that there is a likelihood of encountering a variety of elastic soil combinations which can seriously deteriorate the riding qualities of a rail vehicle on conventional track. As remedial measures, two alternatives are considered to improve the quality of ride; one by improving the rigidity of the track structure by means of providing a track structure utilizing narrow vertical walls embedded in the subsoil, and the other by carefully compacting the foundation soil to minimize local variations. A study is also made to evaluate the relative economics of the alternatives.

WELDED RAIL ON BRIDGES
In a quarter-mile length of welded rail movement due to changes in temperature is confined to the 8 rail lengths at each end, with no movement taking place in the 21 rails in the center section. The action of welded rail on bridges is probably not too much different than that of jointed rail because of the resistance to slippage of rail ends in the joint bars. Consequently, the anchorage being used for jointed rail may be useful as a guide. On ballasted deck bridges, welded rail could be used and anchored in the manner used for open track and no consideration need be given to locating the rail joints off the bridge. On open-deck vaiduct spans, anchor every tie for 200 ft each side of any rail joint that falls on the span with two rail spring clips and elsewhere anchor alternate ties with two clips. On open-deck truss spans, box-anchor each tie in the open track for 200 ft at each end of the span. For spans up to 250 ft it would probably be satisfactory to use no anchors on the bridge except for perhaps two rail lengths at the fixed end and leave the span free to expand and contract at the expansion end. On Open-deck bridges, the welded rail could be used on timber, concrete or steel-beam trestles for any length of bridge with the same anchor pattern as used on open track if the rail joints fall 200 ft off of the bridge.

RAILWAYS OF SOUTHERN AFRICA--TRACK PROBLEMS AND SOME SOLUTIONS
In track, South African Railways has followed closely the western European concept--concrete sleepers, good elastic fastenings, with a high ballast standard using continuously welded rail. All aspects of track design, particularly rail and sleeper fastenings, must be designed to reduce maintenance. The author notes that what might appear to be a costly initial design often turns out to be a cost saver in the long run. It is concluded that track design validates the fundamental axiom of engineering: that the closer the design approaches the limit of the strength of the material, the shorter the life of the product.

WELDING OF AUSTENITIC MANAGANESE STEEL--SOME EXPERIMENTS INCLUDING A WELDING OF CROSSINGS
This report, a supplement to previous papers, includes three sections on the welding of austenitic manganese steel. First the effects of silicon and phosphorus in the base metal on cracking suceptibility of welds are compared and discussed, based on slit-type and angle-expanding-type (modified Murex-type) cracking tests. Then the manual and automatic gas shielded arc welding of manganese steel to carbon steel is described. Finally the properties of a sort of delayed cracking observed in a 16 Mn, 16 Cr type weld metal and its prevention, which are applicable to the welding of manganese steel crossing frogs to carbon steel rails are investigated. The welds have shown good performance in a field test.

DEVELOPMENT OF "BALLAST-MAT"
To realize the commercial operation of 250 km/h on the Shin-Kansen network, the "Ballast-mat" which gives more elasticity to the track on elevated structures or tunnels was developed. The process of the development is here introduced through the construction of the ballast-mat, a field test, vibrogir tests, a follow-up examination and material tests in a laboratory. During the process, it became clear that the ballast-mat greatly contributes to the reduction of the cost for track maintenance, the prevention of the pulverization of ballast and the suppression of noise and vibration.

STUDY ON EMBANKMENT FOR CONCRETE SLAB TRACK UPON FLEXIBLE PAVEMENT--REINFORCED EMBANKMENT WITH NET
To construct concrete slab track and assure minimum maintenance, it is necessary to have a densely compacted embankment, taking into account the specific nature of the fill material and the structure. An embankment reinforced with nets of polyethylene has been developed to achieve this. The nets are laid horizontally at 20-cm intervals throughout the fill slope shoulders. The tensile strength of the net allows the heavy compacting vehicle to transverse the shoulder of each layer of the fill safely. Tests showed the embankment was compacted densely throughout--even at the slope surface.

DRILL-LIME TREATMENT OF SHALLOW RAILWAY SUBGRADE FAILURES IN EXPANSIVE CLAYS
This report deals with a method of stabilizing roadbed by applying hydrated lime to holes drilled in the subgrade which Southern Railway has been utilizing. With some 80 locations treated, the results after a few months were encouraging. While it is too soon to evaluate permanent results, it appears that the drill-lime application may offer relief to areas having the following combination of features: 1) Expansive clays responding to lime treatment; 2) Track areas having shallow ballast sections; and 3) Shallow subgrade failures.

This article is also contained in "A Bibliography on the Design and Performance of Rail Track Structures", Sept. 1974, #072794.

MANY NEW APPLICATIONS FOR 'NON-CLOGGING' SNOW SWITCH
A special switch based on the stub principle, which was originally developed for use as a snow-free switch in yards, is now being offered for use wherever conditions are such as to cause split switches to become clogged and rendered inoperable unless cleaned out. An application on the Lake Terminal Railway on a track at the coke-oven quench track has proved to be resistant to clogging by materials other than snow and ice, and has eliminated a problem with derailed cars at that point.

INVESTIGATION OF 132 LB/YD RAIL MADE FROM VACUUM DEGASSED STEEL
Presently rails are manufactured in 39 ft. lengths. The desire to obtain longer lengths of rail has been expressed by many railroads because of savings anticipated from a reduction in the number of welded joints required in continuous welded rail strings. One factor inhibiting the production of rails longer than 39 ft. is the practice of control cooling in covered containers. Control cooling is employed to prevent the development of internal flakes or shatter cracks that have been causally related to the level of hydrogen absorbed in the steel. With the use of vacuum degassing hydrogen content is controlled by a different technique; therefore, it is believed that rails made of vacuum degassed steel can be air cooled without shatter cracks developing. The purpose of this investigation is to determine whether rails made from vacuum degassed steel and air cooled are comparable in properties with rail steel produced by currently common practices. This laboratory evaluation of 132 lb. RE rail made from vacuum degassed steel was made for the Norfolk and Western Railway. As measured in the laboratory, the properties of these vacuum degassed heats, without controlled cooling, were comparable to those measured previously for steels made by more conventional techniques and subjected to controlled cooling.

RAIL RESEARCH-PROBLEM DEFINITION
A program was initiated to determine and define the problems associated with rail. The purpose was to collect and analyze facts regarding national and international experience on rail behavior, in order to focus attention on the major unresolved problems in rail. These are (1) Joint area problems, both bolted and welded, (2) Plastic deformation of rail head causing shelling, (3) Rail defects and premature removal of rail from track, and (4) Appropriate selection of rail based upon service requirements-use criterion. This report presents a background study of rail design, chemical composition and heat treatment of rail, manufacturing and rolling of rail-reviewing problem areas of each. A discussion of rail defects and the background and techniques of rail defect (flaw) detection is also presented. Recommendations are made for further research and study on bolt hole drilling, rail straightness, new rail steel process and manufacturing techniques, wheel/rail interaction, fracture properties and defect propagation of present and proposed rail steels, rail flaw detection technology, and economic use criterion of rail.

ANALYSIS OF NAD CRANE MAINTENANCE OF WAY
The report represents an in-depth comprehensive analysis of NAD Crane's railroad maintenance of way (M/W) program. Quantitative tools have been developed to provide a rational framework for decision making for M/W. This analysis was prompted by the occurrence of numerous derailments attributed to poor track conditions. The safety aspects of derailments of hazardous material including high explosives required a thorough analysis of causes related to operations of the Ordnance Department and the Public Works Transportation, Maintenance, and Maintenance Control Division. The report presents several recommendations for the establishment of annual levels of maintenance, recommendations on the equipment required, and recommendations on the priority use of maintenance resources. PAPERS PRESENTED AT THE WAYS AND STRUCTURES AND GENERAL SESSIONS OF THE ATA RAIL TRANSIT CONFERENCE HELD IN SAN FRANCISCO, CALIFORNIA ON APRIL 16 AND 18, 1974
Four of these papers concern problems facing the Bay Area Rapid Transit District and the way they are being resolved. Mr. McCutcheon discusses tunnel ventilation, Mr. Mahon deals with track maintenance as well as building and grounds and fire prevention. Mr. Storey deals with measuring vehicle noise and Mr. Todd discusses means of minimizing electrical leakage from running rails. Mr. Lawrence discusses recently completed tunnel construction in Toronto as well as the current construction of the Spadina subway and the unique geology water and vibration problems encountered. The paper by Mr. Reed and Mr. Harris deals with the National Transportation Safety Board and its work with rail rapid transit systems. Mr Aboudara describes the Transit Development Corporation and three of its on-going projects.

MEANS AND METHODS TO INCREASE TRACK STABILITY
The stability of track is a serious problem for every railroad, especially since the introduction of welded rail. The primary concern of this paper is the behavior of track after trackwork has been carried out with particular regard to its geometry. Such work affects the resistance of track to all types of movement, both under traffic and induced by climatic conditions. The attention is directed at conventional track structures because too little is so far known about other types. It is concluded that a high standard of track geometry can only be maintained by lining machines; modern equipment can efficiently increase the lateral resistance of the ballast bed; and track stiffness can be increased with appropriate fasteners and new types of ties.

METHOD OF ASSESSING THE ENDURANCE OF SLEEPERS ON A TRACK USED FOR FREIGHT TRAFFIC [Metodika ocenki vynoslivosti zelezobetonnyk spal e ucetom gruzonaprjazennosti linu]
The article describes a method and results of comparative assessment of the endurance of reinforced concrete sleepers under various operating conditions. The main parameter defining the work capacity of reinforced concrete sleepers in various operating conditions is the endurance threshold of the sleeper in certain transversal cross-sections. The "typical load", a value which determines the endurance of the sleepers for a specific type of freight traffic, is essentially a function of the type of rail and number of fully-loaded heavy wagons; it is calculated on the basis of: (1) the number of loading cycles borne by the sleeper; (2) the maximum load applied during these cycles; and (3) the frequency of the repetition of these cycles, according to the traffic. This method may be applied, for instance, when assessing the endurance of reinforced concrete sleepers in the case of an increase in the axle load. [Russian]

PARTICULAR CHARACTERISTICS OF TRACK MAINTENANCE ON HIGH SPEED LINES [Osobennosti soderzanija puti na ucastkah vysokoskorostnogo dvizenija poezdov]
Based on experience from the introduction of high-speed traffic on the "October" network (Moscow-Leningrad), the article considers the particular characteristics of routine track maintenance on high-speed lines, and gives recommendations for this maintenance for speeds of up to 200 km/h. According to the article, the specific requirements of routine track maintenance, when traffic speeds rise to 200 km/h confirm that man-power demands do not increase beyond 12-15%. This increase is determined in advance by the higher standard of inspection and protection of the track. The increase in speeds up to 200 km/h in passenger transport will not therefore lead to any appreciable increase in expenditure for routine track maintenance, but will require a reduction in the intervals between the periodical engineering work on the line. COMPUTERIZED SUPERVISION OF TRACK MAINTENANCE
Japanese National Railways has computerized the planning of the maintenance of its 26,000 km of main lines, 13,000 km of sidings, and 70,000 switches. JNR has programmed the replacement of 2,000 km of rail yearly. For each individual turnout, data is stored on the parts involved, on the results of annual inspections, and on the speed and volume of movements. Initially tie condition has involved the almost 38 million wood ties on JNR but the growing number of prestressed concrete ties are to be included in the future. Seven high-speed track inspection cars are being fitted to provide input for a maintenance planning system. While problems remain, computerization of maintenance equipment control, track improvement planning and track work estimates are being made.

TRACK TRAIN DYNAMICS, ACCIDENT INVESTIGATION
This manual, a report marking the completion of one assignment of the International Government-Industry Research Program on Track-Train Dynamics, is a guide to systematic investigation of any derailment in order to establish a cause, or combination of causes. It presents information stressing the close relationships between track, train and vehicle characteristics, train handling, and track-train dynamics. Stressed is the need to recognize that a derailment may be combination-caused, rather than mandating the investigators to report a single cause. This is necessary if information from the accident investigation is to accurately reflect the true situation. The manual concludes with six recommendations for individual railroad users.

This project was sponsored by the Association of American Railroads, the Federal Railroad Administration, the Railway Progress Institute and the Transportation Development Agency of Canada.

JOINING AND HARDFACING OF RAILS, POINTS AND CROSSINGS USING MANUAL METAL-ARC WELDING ON THE SWEDISH RAILWAYS
A detailed account is given of work done in developing a suitable technique and filler materials to meet two main objectives. The first main task was to reduce maintenance costs for rail material by the hard surfacing and joining of rail ends and crossings and later also points (switches). The second main task was to further develop a technique and backing material for the joining of rails by means of manual mold welding. The aim was to obtain such a high quality in the form welds that the technique would be approved without any limitations for the joining of rails with a nominal minimum U.T.S. (ultimate tensile strength) of 800 and 900 N/mm2. The following requirements were to be fulfilled: Specifications of the various electrode materials are given, listing weld-metal composition, welding data, and applications.

THE TRIBOLOGY OF WHEEL ON RAIL
The functioning of wheels and rails as a supporting and guiding system depends on a Hertzian contact of 1.2 x 10 to minus 4th power sq m (0.2 in sq) area. In addition to its supporting function, this area must withstand tangential forces to enable the functions of traction, braking and guidance to be fulfilled. Such traction forces are accompanied by a deflection known as 'creep' and classical estimates of this quantity are compared with measurements made on the track. Modes of wear of wheel and rail are described and alternative systems which avoid contact are discussed.

UNSTABLE TRACK: CAUSES AND CURES
The effectiveness of ballast is of prime importance to the stability of track. Burlington Northern has found there are four main factors affecting the durability of ballast. Continuous welded rail is the most significant development. In addition, the quality of the ballast, the condition of the sub-grade and the compactions of the ballast all affect the condition of the track.

STRESS ANALYSIS OF CONCRETE TRACK SLABS ON AN ELASTIC FOUNDATION BY THE FINITE ELEMENT METHOD
In analyzing the track slab stress, it has been revealed that the beam theory has led to certain discrepancies and left unexplicable parts of the actual phenomena. But it is found that these drawbacks can be eliminated by assuming that the rail supporting elasticity is concentrated at fastening devices and considering the track slab as a plate, with the aid of a mechanical model analysis. For the analysis of the plate the finite element method is employed for its flexibility in applying the boundary conditions. The slab track is divided into many triangular elements and analyzed by using the hybrid type potential energy principle. The theoretical results thus obtained are in good agreement with those observed and they are practically employed in the slab track designing.

URBAN RAIL SUPPORTING TECHNOLOGY PROGRAM FISCAL YEAR 1974, YEAR END SUMMARY
Major areas include program management, technical support and application engineering, facilities development, test and evaluation, and technology development. Specific technical discussion includes track measurement systems; UMTA facilities development at the DOT High Speed Ground Test Center, Pueblo, Colorado; rail car test and evaluation; instrumentation for data acquisition and processing; noise abatement technology; tunneling; and car crashworthiness studies.

NORTHEAST CORRIDOR HIGH SPEED RAIL PASSENGER SERVICE IMPROVEMENT PROJECT. TASK 9: TECHNICAL AND ECONOMIC ANALYSIS OF VEHICLE/RIGHT OF WAY SYSTEMS. VOLUME I
This report presents the results of a study performed to define the combination of vehicle and right-of-way characteristics which best meets objectives for upgrading passenger service on the Northeast Corridor. The specific goals of this rail system are 2-1/2 hours travel time between Washington, D.C. and New York City with five stops, and 3 hours travel time between New York City and Boston with five stops. Consideration of technical, economic and intangible factors leads to the conclusions that certain right-of-way improvements should be implemented and that multiple unit electric (MU) cars should be used. Volume One discusses high speed technology, power concepts, vehicle design, kinematics, safety, comfort, train performance, and some mathematical formulations.

NORTHEAST CORRIDOR HIGH-SPEED RAIL PASSENGER SERVICE IMPROVEMENT PROJECT. TASK 3. TRACK AND STRUCTURES STANDARDS DEVELOPMENT
Track and structure characteristics and problem areas to be encountered in upgrading the Corridor are discussed. Standards considerations and applicability are outlined along with the maintenance history of the Corridor. Track system options for application to 150 MPH High Speed Rail (HSR) service are discussed and performance records examined. Concrete ties, fastener systems and ballastless track (concrete slab) are considered with wood tie track in a structural and cost effective investigation. Factors of type and frequency level of HSR train service and potential joint usage with freight movements are projected for these analyses. With this information, design parameters such as lateral and vertical track stability are investigated and established. On basis of structural integrity, selected track system candidates are costed over a 50 year life cycle of construction and maintenance. All projected maintenance items are described in detail with cycle rationale delineated.

DEVELOPMENT OF STANDARD SPECIFICATIONS FOR CONCRETE TIES FOR RAPID TRANSIT. PHASE I. TASKS 1 TO 5
This report presents the results of the first part of a project to develop specifications for standard concrete ties for rapid transit use. The report is presented in five sections: Section 1 estimates the market potential of concrete ties for the transit industry. Section 2 presents a technical and economic evaluation of concrete ties based on international experience. Section 3 presents parameters necessary for the design of standard concrete ties for rapid transit use. Section 4 covers the preliminary specifications for the materials, fabrication and handling of the standard concrete ties.

MEANS AND METHODS TO INCREASE TRACK STABILITY
The author deals with the means and methods of preventing the decreases in track stability following maintenance operations. Above all, he refers to the so-called Plasser-all-side-system RS-System and gives an account of some tests to determine the best conditions for its use. He goes on to provide graphs showing: the results of a large number of measurements of track resistance to lateral deformation; the conditions of buckling stability deduced from theoretical and relative formulae either in the case of simple buckling of a perfectly straight track or that of deformation of a track with a slight flaw at the outset. He comes to the familiar conclusions as far as conditions for good stability are concerned: high standard of track geometry; increased lateral resistance of the ballast bed by use of modern equipment; increased track stiffness with wing-ties, used so successfully by the Austrian Federal Railways.

STEADY-STATE VIBRATIONS OF RAIL ON AN ELASTIC DAMPED FOUNDATION SUBJECTED TO AN AXIAL FORCE AND A MOVING LOAD
The recent practice of continuously welded railroad rails suggests that considerable axial forces may be induced in the rails due to a change in temperature. This paper presents an analytical solution for the effect of an axial force on the steady-state vibrations of a rail continuously supported on an elastic damped (viscoelastic of the Kelvin type) foundation and subjected to a moving load. The presence of damping is shown to result in an unsymmetric dynamic deflection of the rail. Due to phase shift the largest deflection occurs slightly behind the point of application of the moving load, and the deflection ahead is always larger than the deflection behind the point of maximum deflection. The results are relevant to present studies of the temperature buckling of continuously welded railway rails. If the rail is near to the point of buckling due to thermal strains, additional longitudinal strain in the rail due to a moving load may result in buckling of the rail ahead of the moving load.

TRACK SUPERSTRUCTURE-CONDITION SINE QUA NON [Der Oberbau-conditio sine qua nonÖ]
Superstructure is subjected to static and dynamic stresses. In the interests of safety and productivity, wear in equipment must be foreseen in time. To avoid disturbing traffic as far as possible because of work on superstructures, the use of S 60 type rails has been introduced. First class track on main and secondary lines with traffic volumes of more than 25,000 tonnes/day should be composed of S 60 type rails. By 1985, the DB plans to lay 16,000 km of track and fit 15,000 points with heavy rails (S 60 and S 54). Lastly, the author deals with the problem of collaboration with rail manufacturing works and the organization of the superstructure section. [German]

A2 095414
ANALYSIS OF TRACK PARAMETER HETEROGENEITY AS A COMPLEMENT TO GEOMETRICAL METHODS OF TRACK CONDITION RATING
The condition of a track may be defined by track rating indices (W indices at the PKP) taken from recordings by a track inspection car, or obtained by geometrical measurements (longitudinal dip and cross-sectional irregularities, without load or with a moving load, lateral displacement, etc.). By track heterogeneity, the writer means the differences that such indices reveal on lengths of line with identical make-up, similar age, and used by the same traffic. These heterogeneities, which may be caused by the laying or maintenance of the track, or by constructional features with different characteristics, are also likely to result in great differences in the rapidity with which these lengths of line deteriorate, necessitating earlier continuous track renewal. The article proposes methods of assessing these heterogeneities by tests based on classic statistics laws. Numerical examples thus deal with: heterogeneities in the W index, by the X to the 2nd power test; heterogeneities in the track gauge by a method called the "ZM test" taken from an American book referred to in the bibliography; correlations between rail dip and lateral displacement under a moving load, by an analysis of sequential correlation. These complex analyses are not used as a basis of routine maintenance decisions, but in investigations for the purpose of explaining abnormal phenomena.

M/W COSTS: HOW THEY ARE AFFECTED BY CAR WEIGHTS AND THE TRACK STRUCTURE
Using a combination of theory and actual field measurements, the author develops the relative maintenance costs associated with axle loads and the type and condition of the track. The article attaches definite values to variables such as total tonnage carried, track condition and car size. The Illinois Central Gulf considers that 53% of total track expense and capital investment is incremental--varying with the tonnage moving over the railroad. This incremental cost is then broken into its own increments based on rail deflection, rail bending stress, rail life and miscellaneous costs.

PANELIZED STEEL-TIE TRACK FILLS A NEED ON THIS PROJECT
The construction of a six-mile in-plant railroad serving the Tilden iron-ore mine and pelletizing plant near Ishpeming, Mich., was accomplished with all-steel panelized track. A total of 845 pre-assembled steel-tie track panels and 16 all-steel turnouts were used. The panelized track concept was credited with not only maintaining the original construction schedule, but also staying within budget estimates. While the original cost was in excess of that for the same amount of trackage on wood ties, savings in construction labor and time were achieved. It is expected that maintainance will also be lower.

FLAME HARDENING OF RAIL BY THE HAMMON CONTINUOUS PROCESS AND PHYSICAL AND ROLLING LOAD TEST RESULTS
Since the standard carbon rail is removed from track due to abrasion, head flow on the low rail of the curves and shelling on the high rail, it is of interest to the industry to investigate any process that alleviates this problem. Failures due to shelling alone amount to 40 percent of all types of failures. Alloy rail steel chemistries and heat treatment have been found helpful in extending rail life where the above conditions existed. In the area of heat treatment, various types of flame hardening of the rail head have been found applicable economically and available in all parts of the United States. Summarizing, features of this process that may be of interest to railroads are: 1. Evaluation of rail flame hardened by this process at the Research Center and the University of Illinois indicates that it should give good service performance. 2. It is claimed that it will be economical because of its ability to use propane or natural gas for heating the rail. 3. Rail of any length can be continuously flame hardened, before or after welding. 4. The equipment can be mounted on railroad cars to be used either at the welding or cropping site.

RAIL STUDY BESSEMER AND LAKE ERIE RAILROAD
Because of the ever increasing concern with shelling of rail and its possible connection with wheel loads and the present day trend to still heavier wheel loads, a study was conducted on the Bessemer and Lake Erie Railroad to analyze their rail conditions in conjunction with their use of 90-ton cars for transporting of ore. This railroad has been using these 90-ton capacity hopper cars since 1931, with practice being to load ore for southbound movement to capacity, thus creating loads averaging 32,300 lbs. per wheel. It has been noted over the years that even with these wheel loads and rather high annual tonnages, the Bessemer has had little or not shelling of their rail. This study was prompted to see if an answer could be derived as to why no shelling problem exists here. In particular, two locations on the railroad were checked where the present rail in track is 131 lb., laid in 1938, and has had over 400,000,000 gross tons of traffic, most of which consisted of are carried in these 90-ton hopper cars. The northmost location is at Springboro, Pennsylvania, where there is a length of one mile of the 131 lb. rail in track (north and south of Mile Post 116). The other location is through and to the south of Grove City, Pennsylvania, Mile Post 60-63, where there is a 3-mile section of 131 lb. rail in track. Both of these sections of 131 lb. rail now carry both northbound and southbound tonnage, but prior to single tracking and installation of C.T.C. in 1957, this trackage was the southbound main track in both instances and carried the predominant southbound ore traffic. At both locations of 131 lb. rail, rail profiles were taken, degree and superelevation of curves were noted, predominant speeds of tonnage trains in both directions were noted, condition of the entire track structure and, in particular, condition of the rail both on tangent and curves were noted. Photographs were taken to show the rail condition. Because of curvature in the locations not exceeding 3 degrees, other locations on the railroad were chosen to make like studies, these locations having the same or less annual tonnages, and having different weights of rail of shorter service life, but having greater degree of curvature. Rail profiles and photographs were taken at these locations also. Along with the study of the rail and track conditions, a study of the 90-ton B & LE hopper cars was conducted, obtaining all pertinent data, prints, and photographs having to do with their construction and maintenance. The Bessemer's rail replacement policy is guided by the formula--T = .703xWxD.565 where T = Life of rail in million gross tons. W = Weight of rail in lbs. per yard. D = Traffic density in million gross tons per year.
Conducted under sponsorship of AAR Joint Committee on Relation Between Track and Equipment.

INVESTIGATION FOR REPAIRS BY WELDING OF HEAT TREATED AND FLAME HARDENED RAIL IN BOLTED RAIL CROSSINGS
In 1952 a program was developed to provide for investigation of heat treated rail and flame hardened rail in crossing frogs by means of service installations followed by laboratory studies of welding techniques to be used in field repairs to worn and battered units. A contract was made with the Chicago, Milwaukee, St. Paul and Pacific Railroad for installation of three test panels of crossing intersections at Manheim, Illinois, each of the three test panels to consist of eight simulated crossing intersections three of carbon-steel rail, heat treated by various methods; three of flame hardened carbon-steel rail; one carbon-steel panel of control cooled rail (as rolled) and one panel of chrome-vanadium rail. The studies of welding techniques were carried out at the AAR Research Center and the University of Illinois. 1. The flame hardened units held up generally well following welding with electric procedures used as indicated in Table 5. 2. The gas welds on the flame hardened units were less effective than the electric techniques and must be considered to be inferior. 3. The three types of electric welds and two types of gas welds used on the heat treated units gave comparable results and may be considered as satisfactory. 4. The best performing weld on chrome-vanadium rail was the electric weld in the west panel probably due to the hardness obtained by the process used. 5. On the open hearth units the best performance was obtained with gas weld 1G on unit E8. It is difficult to appraise the poor performance of weld 2G on unit C8 as this weld procedure gave good results on the flame hardened and heat treated units.
Conducted under sponsorship of AREA Committee 5-Track.

SERVICE INVESTIGATION OF VARIOUS TYPES OF JOINT BARS ON SANTA FE AND NORTHWESTERN RAILWAYS
This report covers the service investigation of various types of joint bars and variations of bolt spacing on the Atchison, Topeka and Santa Fe Railway near Streator, Illinois and on the Chicago and Northwestern Railway at Sterling, Illinois. 1. All design of joint bars have been adequate throughout the service period of 16 years. 2. Four bolts in 36 in joints with 9-9 1/8-9 in spacing are adequate to hold the rail, but do not provide sufficient rail end support, hence, create additional batter and droop of the rail ends compared with 6-bolt bars. 3. There appears to be little difference in the performance of the current AREA bolt hole spacing of 6-6-7 1/8-6-6 in compared with the 6 1/2-6 1/2-5 1/8-6 1/2-6 1/2 in spacing where such a

comparison can be made in the Santa Fe test. Inasmuch as the current AREA spacing has been shown to produce less stress concentration at the bolt holes and this service test has shown no disadvantage in other respects, it has confirmed the desirability of continuing the current AREA bolt hole spacing.

Conducted under sponsorship of AREA Committee 4-Rail.

METALLURIGICAL, PHYSICAL AND ROLLING LOAD TEST RESULTS OF RAIL ROLLED FROM CONTINUOUSLY CAST BLOOMS

The development of information relative to any new process applicable to producing rail more economically is of interest to the industry. The opportunity of investigating the application of continuous casting in rolling rail presented itself when the M.W. Kellog Company became interested in investigating this process on behalf of a Mexican client. The AAR Research Center cooperated in developing the metallurgical, physical and rolling load test results of rail rolled to the S49 section from continuously cast blooms. The results on the same type of of tests as described above tested in the 12 in stroke rolling load machine are shown on Table 4. The S49 rails and the oxyacetylene pressure butt welded rail joints did not fail. The flash butt welded rail joints failed prematurely due to grinding cracks away from the weld caused by heavy cold grinding as shown in Figs. 8 and 9. The drop test results of the rail as shown on Table 5 indicate that the rail met the AREA specification. Fig. 10 illustrates the effect of the drop test. As mentioned before, very few butt welded rail joints have withstood the standard drop test for rail. The structure of these fractures were noted to be fiberous. The results of the investigation of the S49 rail rolled from continuously cast blooms at the AAR Research Center and comparable results of the investigation by Dr. Janiche indicate that rail produced by this process is of equal quality to rail produced by the standard process. The results are surprising in this first attempt of producing rail in this manner. As the art of of continuous casting in reference to rail is advanced, all of the defects such as segregations will undoubtedly be eliminated. The economy of the process is predicated on the elimination of mold and teeming practices as well as soaking pits and primary mill installations. It is of interest to call attention to the last paragraph of the attached report which states that the UIC specification for rolling rail calling for a bloom cross section of at least 20 times larger than the rail cross section was not met in this case. In the above rolling, the ratio amounted to 15 to 1 in the case of the 30 d rail and 9 to 1 in the case of the S49 rail.

DEVELOPMENT OF UNCONVENTIONAL TRACK BY JNR

JNR has been developing an unconventional, maintenance-free track which may be applicable not only from technical aspects, but also from economical aspects, in comparison with the conventional track structure consisting of sleepers and ballast. This new track will be used on the New San-yo Line (NSL) between Okayama and Hakata which uses standard gauge track, taking into account a maximum speed of 250 km/h, and also on the Kosei Line, the Musashino Line, etc., which use narrow gauge track with a maximum speed of 120 km/h. This paper discusses the technical, economical and social backgrounds, and the history of technical development in changing from the conventional structure, together with relevant problems.

REPORT TO CONGRESS. THE RAIL PASSENGER SERVICE ACT OF 1970.

This report was submitted to Congress pursuant to the Rail Passenger Service Act of 1970 that requires the Secretary of Transportation report on and evaluate the effectiveness of the Act in achieving and promoting intercity rail passenger service and on the effectiveness of Amtrak. Part I summarizes the material in the Report. Part II discusses scheduling, on-time performance, equipment acquisition, and reservations and fares in the light of Amtrak's precedents. Part III considers the orderly assumption by Amtrak of all its operations and the control exercized by its management along with potential benefits from mail transport and problems of track improvements. Part IV evaluates routes and services, present and future. Part V has legislative recommendations.

MINERAL WASTES AS RAILROAD BALLAST

Approximately half of the $100 million allocated annually by Canadian railways for track maintenance is for the purchase, haulage, installation and maintenance of ballast. With the growth of Canadian rail traffic, it has been estimated that the nation will have to undertake major new rail construction in the next few years. Good quality ballast is not available all across Canada, particularly in the prairies. There are sources for the material in several locations, some of which would be the wastes from mining and metallurgical operations. The report discusses the function, characteristics, appraisal and sources of ballast. It is noted that Canadian railways are placing increased emphasis on the materials to be utilized as subballast and ballast in their track.

AN INVESTIGATION OF VARIOUS WELDING TECHNIQUES FOR BUILDING UP BATTERED RAIL ENDS

The building up of battered rail ends by means of different welding procedures and the evaluation of welding rods and electrodes used in these procedures is of considerable importance to the railroads. An investigation on this subject using 12 in. stroke rolling load machines at the Technical Center of the Association of American Railroads has been carried on under the general direction of G.M. Magee, director of engineering research, by Kurt Kannowski, metallurgical engineer. A definite program was outlined and followed in this investigation. The data in this investigation indicate

that, in spite of variations in rods and welding procedures, the oxyacetylene welding method performs well in building up battered rail ends. The occurrence of the porosity near the interface of the weld and rail metal as well as the sharp demarcation line between the rail and weld metal have caused the failures of the electric arc welds rather than the practice of not pre or post heating. The failures of electric arc welds are often caused by a variable that was not given consideration in this investigation. These welds are subject to the human element variations that may be expected due to the welder depositing the metal. This effect on the quality of the weld is gradually being eliminated by improvements in the automatic feed and wire electrode welding process. Welds produced by this method are now under the rolling load test as well as in an extensive service test on the New York Central System. Results from both show considerable promise.

INVESTIGATION OF SPECIAL JOINT BARS AND RAIL PLUGS FOR USE IN JOINING LENGTHS OF CONTINUOUS WELDED RAIL

This report covers laboratory tests of two completely assembled special rail joints with rail plugs (Dutchmen) to determine if such joints will stand up under traffic. A member road developed the special joint for use in connection with laying continuous welded rail at low temperatures and requested that tests be made in the rolling load machines at the Technical Center. It was felt that this subject matter would be of interest to other member roads and arrangements were made for tests of two joints. The purpose of the rail plug with a special length joint is to provide means of adjusting expansion of continuous lengths of rail laid at low temperatures withoug creating an additional joint for a short length of rail used by some railroads when joining continuous lengths. The special joints are made of regular cross section design, metallurgy and heat treatment, but the bars are lengthened to provide for the length of the plug and the spacing between the center bolt holes increased a corresponding amount. In laying continuous welded rail at below mean temperatures, the special joints with plugs would be used, the length of joint and plug being selected according to the amount the rail temperature when laying was below the mean temperature. At some later and convenient date, when the rail temperature was near the mean temperature the special joints and plugs would be removed, rail anchors removed to allow the rail ends to close the gap, and regular joint bars applied. The special joints and plugs would then be held for use on the next rail laying job as needed.

PHYSICAL TEST RESULTS OF OXY-ACETYLENE PRESSURE BUTT WELDS OF HEAT TREATED RAILS

In order to develop all pertinent data in regards to continuous welded rail rolling load, flexure, drop and slow bend tests were performed on oxy-acetylene pressure butt welded fully heat treated rails at the request of the Norfolk and Western Railway Company. The fully heat treated rails, 132 lb. RE section, were supplied by the Bethlehem Steel Corporation and the welds were made by the Norfolk and Western Railway Company at their Roadway Material Yard in Roanoke. Eight of these welds were made by the oxy-acetylene pressure butt welding process. They were also normalized. Each of the tests were 6 ft. long with the weld in the center. The rolling load, flexure and drop tests were made at the AAR Technical Center and the slow bend tests were made at the University of Illinois by Professor R.E. Cramer. Two of the weld specimens were subjected to the rolling load test in a 12 in. stroke rolling load machine using a wheel load of 60,000 lb. with the weld placed 2 in. from the support on the cantilever end of rail. Since the wheel path is 10 in. beyond the weld, the weld was subjected to a bending moment of 600,000 in. lb. Under this test procedure, 2,000,000 load applications or cycles without failure is considered a run out. Both of the test specimens ran out at 2,000,000 cycles without failure. The flexure test was performed on a multi-press using a 60,000 lb. repeated load applied on the center of the weld on the rail head with a wheel shaped contact. The rail was supported on its base to have a 48 in. span. Thus, for each cycle of loading the bending moment at the weld varied from 0 to 720,000 in. lb. with the base in tension, giving a calculated maximum stress at the extreme fiber of 26,000 psi tension. Two of the test specimens were subjected to 2,000,000 flexures each without a failure. The two flexure test specimens, as well as two other test specimens, were then subjected to the drop test on a standard rail drop test machine. A 2,000 lb. tup was dropped 22 ft. on the center of weld with the rail head up. The rail was supported on a 48 in. span. As shown on Table 2, the two flexure test specimens failed at the first blow. One test specimen broke through the weld and a welding defect from a pop out on the outer edge of the base was noted. The other flexure test specimen failed 6 in. away from the weld and a transverse progressive defect in the head originating from a grinding crack was noted. One of the two regular test specimens failed outside the weld area after two blows. The other test specimen failed at the first blow through the weld. It was noted that the lower part of the web and the base were partially fused. The slow bend test results were obtained at the University of Illinois by Professor Cramer. The tests were made with the head up on supports 48 in. apart. The load was applied at two points 6 in. on each side of the weld. Thus, the applied bending moment between these load points was nine times the applied load in in. lb. One of the tests failed prematurely through weld. It was noted that the lower web and the base were partially fused. The other test performed excellently and broke 5 in. from the weld at the edge of the beat affected zone. The data obtained under the testing procedure indicates that even though the benefit from the heat treatment has been eliminated in that part of the rail heated above the critical temperature during the welding process, that fully heat treated rail welded by this process will perform as well as standard control cooled rail in the weld zone. Oxy-acetylene pressure butt welds with control cooled rail are in use extensively without failures if properly welded. The failures noted in these tests are not different from those that have been experienced in laboratory tests and field service in welds made by this process with standard control cooled rail.

REPORT ON ASPHALT TREATMENT OF BALLAST AND BRIDGE DECKS

This report deals with the asphalt ballast treatments made during 1960 on five roads and the bridge deck treatments on two roads. In addition, a progress report is presented on the nine track sections and one bridge project treated in 1959. The general features of these latter projects were described last year and appear in the Proceedings, Vol. 61, 1960, page 715. These treatments are the result of the research project jointly sponsored by the Roadway and Ballast Committee of the American Railway Engineering Association, of the Asphalt Institute and the Research Department of the AAR. Special equipment for the process has been developed and used, the description of which appears in the Proceedings, Vol. 60, 1959, page 712. The applications were made possible by the complete and excellent cooperation of the participating railroads who bore the cost of the materials and application with such technical assistance as required from the staff of the Asphalt Institute and the AAR. The special equipment has been made available upon request to any railroad without charge. It is expected that after revisions and repairs indicated during service in 1960 they will also be available to Member Roads in 1961 upon request to the Research Department, AAR. Some difficulty was experienced with the equipment on this project and full coverage was not obtained under the rail, through the restricted station area. Also, the application of the cover coat was not fully uniform. The project appeared fairly satisfactory upon completion. The 1960 ballast treatments covered a wide range of conditions. They will be valuable in determining the effects of climate and track characteristics on such treatments. Work this year has further demonstrated that good coverage can

be obtained which should serve very effectively toward tie preservation and protection of track fittings against corrosion. With the use of extended spray nozzles directed under the rail, full coverage and a good seal of the full ballast section was obtained in most cases, particularly where there was an opening under the rail in the cribs. The equipment in transfer movements from project to project indicated several deficiencies in security fastenings and appreciable damage occurred. This damage at times interfered with full production on the treatments reducing efficiency and raising costs to some extent. Careful note has been made of all sub-standard conditions and plans have been made for their correction including a number of betterments. If programs during 1961 indicate the need for the cars these changes will be made prior to the season and the cars will be available without charge to the roads on request to the Research Department, AAR.

TEST OF SUSTAMID JOINT BARS FOR 129 LB. TR RAIL

The joints were made of sustamid special type 0.4K 88/04K90. The joint was applied to 129 lb. TR rail ends furnished by the Burlington Railroad. The large deflection this joint takes under load will result in putting larger loads on the ties supporting the joint and increase the track maintenance required. It will also have poor strength to resist high loads that may be imposed under unusual conditions, such as excessive play in track and large lateral forces from poor alignment or equipment nosing action. Further tests were not deemed worthwhile.

THE EFFECT OF UNIT TRAINS ON STRESS OCCURRENCES IN A CHICAGO AND NORTH WESTERN RAILWAY BRIDGE

This report contains a description and analysis of data obtained on the stringers and floor beams of a Chicago and North Western railway bridge to determine the frequency of occurrence of maximum stresses in these short span bridge elements which carry unit trains as well as regular service freight trains. The results may be summarized as follows: Track without rail Joint: 1. The frequency of occurrence of maximum stress was in the range of 3.0 to 4.0 ksi in the stringers and the floor beam under the combined loading of unit trains and regular service freights and was on the order of 2 to 9 percent of the total occurrence respectively. 2. The loaded unit trains comprised 5 percent of the total cars recorded and produced 46 percent of the maximum stress occurrences greater than 3 ksi in the floor beam and 7 percent in the stringers respectively. Track with Rail Joint: 1. The frequency of occurrence of maximum stress under combined loading of unit trains and regular service freights was on the order of 4 percent for the floor beam and 1 to 3 percent for the stringers of the total occurrence.

DEVELOPMENT OF AN INNER BRACING FOR SWITCH STOCK RAILS ON THE GERMAN FEDERAL RAILWAY [Entwicklung einer inneren Backenschienen-Verspannung fuer Weichen der Deustchen Bundesbahn]

The stock rails of switches have hitherto always had outside bracings of various designs, but with increasing speeds, shorter intervals between trains, higher axle loadings and hence greater stresses on the switches, these outside and indirect-acting supports are no longer adequate. The Author describes the development of an inner bracing which with the aid of a specially-designed tension piece provides a flexible and permanently force-locking connection. Details of its design, basis of calculation, and testing by the German Federal Railway are given. [German]

THE CONTINUOUSLY SUPPORTED RAIL SUBJECTED TO AN AXIAL FORCE AND A MOVING LOAD
The recent practice of welding railroad rails to each other suggests that considerable axial compression forces may be induced in the rails because of a rise in temperature. This in turn may reduce the critical velocity for the track to the range of operational velocities of modern high-speed trains. The purpose of the paper is to demonstrate that this is indeed a possibility.

CORRUGATION AND PITTING OF ROLLING SURFACES-ARE THEY CONTINGENT UPON ULTRASONICS?
This article is an abridged version of essay number 28/1973 held in the Archiv fuer Eisenbahntechnik. Rail corrugations, which were a familiar phenomenon in the 1890's and similar periodic forms of wear occur in other rolling contact combinations. An attempt is made in this paper to explain these manifestations. It is suggested in conclusion that it would appear that troublesome corrugations and perhaps damaging pitting could be avoided if, besides the attenuation of low-frequency oscillations, a means could be found to prevent the agitation and propagation of intensive ultrasonic fields within the area of the running surfaces.

THE FRACTURE TOUGHNESS OF CARBON-STEEL, ALLOY-STEEL AND HEAT-TREATED RAILWAY RAILS
The static and dynamic fracture toughness of standard carbon steel rail was determined using precracked Charpy bars. The static, fracture toughness was found to be higher than the dynamic fracture toughness across the entire range of railway operating conditions. Since rails are subjected to dynamic loading conditions, dynamic fracture toughness tests were conducted on specimens from alloy-steel and heat-treated rails in order to compare fracture properties. In addition, the standard British rail steel and two heat-treated grades of British rail steel were evaluated. It was found that carbon levels above 0.55 w/o did not affect fracture toughness while increasing silicon decreased fracture toughness in both high and low carbon rails. In line with earlier work, it was found that decreasing pearlite spacing increased fracture toughness. In addition, the effects of manganese, chromium and molybdenum are discussed.

A2 098080
THE EFFECTS OF MICROSTRUCTURAL VARIATIONS ON THE STRENGTH AND TOUGHNESS OF RAIL STEELS
An experimental program was carried out on fully-pearlitic rail steel to determine the effects of microstructural variations on tensile and impact properties. A heat treating schedule was developed to isolate the effects of prior austenitic grain size, pearlite interlamellar spacing, and to a minor extent, pearlite colony size. Grain size was varied by a factor of ten, and pearlite spacing by a factor of two. Room temperature yield strength increased monotonically with decreasing interlameller spacing, with the latter controlled by the transformation temerature and prior austenitic grain size. Charpy impact tests were performed to obtain an evaluation of toughness, and showed that toughness increased with decreasing grain size, and was largely independent of an influence of pearlite spacing. Dynamic fracture toughness values, (KID), obtained from instrumented impact testing of precracked Charpy bars, were compared with the standard Charpy results, and yielded Similar findings. Thus, it was found that strength and toughness are controlled by different microstructural parameters, and can be varied independent of each other to optimize service performance.

SUMMARY OF PERFORMANCE OF STANDARD-CARBON AND VARIOUS WEAR-RESISTANT RAILS IN TEST CURVES ON THE CHESSIE SYSTEM-SECOND REPORT
This report contains the summary of the second annual inspection of a service test installation of fully heat-treated, induction head-hardened, intermediate- manganese and standard control-cooled rail on the Chessie System. The field inspection is part of the cooperative effort on rail research of the American Railway Engineering Association, the American Iron and Steel Institute and the Association of American Railroads to observe and analyze those rails in curved track that display some potential for improvement in wear-resistance and retarding the onset of shelling. Measurements were made and recorded of curvature, superelevation and gage of four service test curves located near Oakland, Maryland, General track conditions were observed also. Rail head cross-section contours were taken and recorded of the 80 test rails contained in these curves. Rail wear has been calculated for the second year of service for the various types of rail in test.

ON THE TORSIONAL RIGIDITY OF RAIL FASTENERS IN THE LATERAL PLANE
This paper deals with the resistance of the rail fastener to torsion in the plane of the track, as a factor affecting the stability of the track structure. In addition to a review of the various mathematical models used to simulate the track, this paper also reports on the results of experimental measurements of the torsional rigidity of various types of rail fasteners in use in both the United States and Western Europe, including the type of rail fastener utilized in the construction of the high speed test track at the High Speed Ground Test Center of the Department of Transportation, Federal Railroad Administration, located at Pueblo, Colorado. The results of these tests indicate a scheme for increasing the torsional rigidity of track panels. In conclusion, important considerations for the design and selection of rail fasteners for use on continuously welded rail are described.

SUBGRADE OR BASE OF RAIL ELEVATIONS
File name is ENGR. GRADE: This program is designed to calculate subgrade or base of rail elevations. Given the elevation and engineering station of the point of beginning; stations of the PI's and lengths of vertical curves; and the slopes of the courses, the program will calculate subgrade or base or rail elevations for full stations or full stations plus 50 feet if specified. In addition, output will include calculated stations to all control points along with all pertinent grade data.

TRACK ALIGNMENT
File names are ENAL and ENBL. Program provides complete detail for simple or complex alignments including spiralized or simple curves. Input requirements are: Azimuth and distance between PI's or control points; degree or curve and spiral length when applicable. Output will include Engineering stations for all curves and control points; ordinates and coordinates of all PI's and control points, all curve data i.e., length, delta, semi-tangents, etc., and deflections for spirals and curves. In the event of long curves which must be traversed, the program will calculate direction and distance along the radial line between traverse points and the curve, as well as stationing and deflection angles and POC's as determined. This program was designed as a supplement to ENAL to convert random traverse data, which has control points along a predescribed alignment, into distances and azimuths along the alignment course. It will also provide ordinates and coordinates of all points. Calculating the relationship of triangulation control points to the "preliminary" line in new location work is an example of the function of this program.

TRACK CHARTS
This computer program plots the track charts. The track charts contain relevant information about track condition such as type and weight of rail, surfacing information, tie installation, ballast cleaning, etc. The various types of information are plotted on the plotter in a form of a bar chart which reflects the location of the bars within the railroad system. The data base is entered through card. It is hoped to file all this information on disk file for other useful purposes.

A2 098698
TRACK PROFILES
This program permits computer generation of track profiles using a Calcomp plotter. Accurate milepost location of each track element is required. Unless existing manual records are both accurate and current, new data from the field is necessary. This can be accomplished with a track geometry car or any test car where accurate distance measurement is an output. The program utilizes data in a three-step process. The first is to input the type and milepost location of each track element in the symbol master. The output from this step consists of two reports--a symbol listing in milepost order and the distance between each milepost. Elements include yard track locations, spring switches, railroad crossings, private crossings, three types of public crossings, railroad bridges, rivers, underpasses, overhead bridges, tunnels, hot box detectors, 13 types of train signals. The second step merges the symbol master data from step 1, grade and curve data from the track characteristics master, and milepost locations from the milepost master. Output from this step is a printed listing of each track element in milepost order and a plot tape. The third step uses the plot tape as input to drive a Calcomp plotter and produce the track profile (generally on a paper original). Plot scale is two inches to the mile (5280 feet). Height of the profile is 4 1/2 inches and can be of any length. Plot consists of a milepost line dividing distance between adjacent mileposts into ten equal parts regardless of actual distance, a grade line, a track line showing single track, double track, sidings, spurs, and all track elements and a curve line.

RAIL FAILURE SYSTEM
File name is ENRF. Computer program. The "Rail Failure" application is designed to compile statistics of all types of rail failures. The system employes two highly regimented input forms entitled "Rail Removal Order" and "Rail Insertion Report" which also serve to cause the appropriate physical action to take place. The system is modular and as such contains over twenty (20) separate programs re: data validity edits, maintenance and print routines which can provide monthly, year-to-date and yearly statistics, e.g.: (a) "Audigage and Reflectoscope; Detector Car; and Service Rail Failure Statement": a three part statement, i.e., a separate report for each potential input source, giving a complete description by Division and District of type of track, location of rail, position, grade, weight, mill, etc. of all failures reported. (b) "Rail Insertion Report Statement Covering Service and Detected Rail Removal Orders"; this statement lists all rail that has had a defect and that has been replaced by a new rail, angle bar repaired or taken out of service. (c) "Annual Report of Rail Failures, Service and Detected, in Rail of All Ages and Sections". (d) "Rail Removal Orders not Covered by Insertion Reports on the Eastern, Western and Coast Lines". Report will flag any removal order over 30 days old for which as insertion report has not been issued. (e) The "Transverse Fissure Rail Heat Statement": This statement provides listing of all transverse fissure heat failures over the system. The statement is written out in mill order and year rolled plus pertinent detail data. (f) The "Thermite and Butt Welded Joint Failure Statement"; This statement lists all thermite and butt welded rail failures by division, district, mile post, type track, weight or rail, mill and year rolled. Each report is year to date.

A2 098704
ALLOWABLE GROSS LOADS ON VARIOUS RAIL SECTIONS
File name is RAILSTR. Computer Program. Application: Used as a one-time guide for determining the maximum allowable loading on various rail sections. Contains many assumptions and some "retrofit" based on actual loadings previously known to have been carried. This program computes the maximum allowable total gross weight for any type rail

equipment with identical axle loads on 15 different rail sections. The theory and formulas are based on the rail acting as a continuous beam on a continuous elastic base (AREA proceedings of 1918, Vol. 19, pages 875-1058). Two moduli of elasticity of rail support are assumed for each rail section, one for "good roadbed and one for "poor" roadbed. Input consists of all information required about the axle configuration of the equipment being considered. Output includes documentation of the input, a listing of each rail weight and the assumed impact for each, and the allowable gross weight for good and poor roadbed for each rail section. This program makes many assumptions having to do with roadbed, impact, and unit stresses which may or may not be justified.

RAIL AND TRACK CHARACTERISTICS PICKER PROGRAM
File name is Track Characteristics Master, Rail Defect Master, Derailment Master. Computer Program. The purpose of the rail and track characteristics picker program is to provide the information with which to develop the relationships between various rail and track characteristics and their correlation with rail failures, rail defects, and derailment frequency. The Track Characteristics Master contains rail type (jointed versus welded, kind of steel) weight, rail rolled and laid dates, history of surfacing dates, rail and track inspection and test data, grades, curves, load limits, and traffic density (tons per year) for all system track. Locations of rail failures, rail defects, and exceptions to track geometry standards found by testing and inspection are contained in the rail defect master. The derailment master contains pertinent data on all derailments. The rail and track characteristics picker program selects and prints out track locations from the track characteristics master with user-defined selection criteria; these can be minimums and/or maximum for any combination of the characteristics listed above. Up to 50 different combinations, i.e., cells in a matrix can be requested at one time. For each cell or specific request, the number of miles of track and the number of ton-miles is printed out. In addition for each cell, the progrm gives the types and numbers of rail defects and derailments reported over a time period selected by the user. Once relationships have been established, the program can be used for developing rail laying and timbering and surfacing programs, anchor and double spiking programs, problem area identification, budgeting, and other applications.

RAIL CONSIST AND HISTORY
File name is EN980930. Computer reporting program of all pertinent information on main line and branch track of Union Pacific Railroad. This track information can be reported to one one-hundredth of a mile accuracy for main line and branch track. The output shows milepost from, milepost to, track miles involved, degrees of curve, weight of rail, what company rolled the steel and type of treatment of the steel, the length of the rail in either 39 feet, 78 feet, or CWR, the year laid, work order number, if the steel was transposed, cropped, welded, or ground the size of the plates and year installed, million gross tons, of traffic over given segments of rail, passenger and freight speed allowable, and failures reported for the last two years broken done into three classes fo failure, then combined to show defects per mile per month. This Consist and History program evolves from four other basic programs plus a failed rail master. The four programs used to generate Consist and History are a tonnage master (EN9601), the description table (EN9602), an initial track master file (EN9603), and a revolving track master file (EN9805). EN9601 is a program which generates a tonnage table and a tonnage code. The railroad is broken down into segments depending on the million gross ton miles per year run over those segments. This program is fed into the initial track master file, EN9805, for a basis to calculate the million gross ton miles in the Consist and History report. The tonnage table for a given section of track has been calculated from our Way Bills to insure accuracy. EN9602 is a program which generates heading information for given sections of track (e.g. direction, and milepost limits). Also, it generates a cost center description so that the final report can be produced either by cost center or divisions. This program also genrates an order number, which we have assigned to help us segregate different parts of track. EN9601 and EN9602 are combined into EN9603 which begins to set up the initial master file. EN9603 at this time inputs all of the curve information of the railroad. EN9805 then adds the actual track relay information into the program.

EXTENSIVE RESEARCH INTO THE NEW TRACK STRUCTURE WITH LS FASTENINGS [Der Grossversuch mit dem neuen Oberbau Ls]
On the DB network, extensive research with the new Ls fastening (set sole plates, sleeper screws and SKL1 tightening spike) has been carried out regularly as shown in Tables 1 and 2 during track laying in the second half of 1974. Experience has shown that it would be better to use nut-headed sleeper screws instead of normal screws. Despite the somewhat high cost involved, the overall result (assembly, laying, maintenance, annual costs) for the new rail fastening with nut headed sleeper screws could work out to be more economical. To reach a final conclusion on the use of the new sleeper screw, further extensive research should be carried out next year (1975). [German]

A RAIL INVENTORY OF THE NORTHEAST AND MIDWEST UNITED STATES
Bechtel Incorporated's primary role in the survey of rail facilities under the Regional Rail Reorganization Act of 1973 was that of technical direction contractor. Using input from the United States Railroad Association and five other associate contractors, Bechtel established administrative and procedural guidelines to assure consistency in work performed and to rationalize the data gathered. The result was a quantitative and qualitative inventory and assessment of the rail facilities to determine condition, identify required rehabilitation work and materials and estimate the cost of rehabilitation. In the inventory was trackwork, yards, shops, bridges, tunnels, buildings, terminals, signals, communications, servicing facilities and motive power.

TIE DEMAND NOSEDIVES FOLLOWING LAST YEAR'S SURGE
This report on a meeting sponsored jointly by the Transportation Materials Management Forum and Railway Progress Institute described the upturn of the wooden cross tie market in 1974, then its collapse in 1975 as producers had succeeded in raising production. To assure that needed ties will be produced in coming years, it was agreed that it is necessary to have a stability in tie production. Railroad managements were said to overreact to fluctuations in business at both ends of the business cycle--first ordering more than can be produced or used, and then eliminating virtually all such purchases with a downturn of almost any magnitude.

P&LE UPGRADES CROSSING PROTECTION
In the course of installing welded rail, the Pittsburg & Lake Erie was confronted with eight grade crossings in a 1 1/2-mile stretch. The goal was to produce a safe system that would not unduely delay vehicular traffic. Audiofrequency overlays of the conventional type would have been extremely complicated. The solution was installation of electronic movement detection through measurement of rail impedance changes. Several frequencies are overlapped for some distance beyond the crossings.

A RAILROADER'S BAD DAY AT BLACK MESA
The coal-hauling Black Mesa and Lake Powell Railroad has encountered numerous technical problems as it has attempted to move to the level of operations for which it was designed. Problems with the automatic control system, the concrete ties, the crushed river rock ballast, and with wheel and rail wear are all combining to force a complete redirection of the operation. It is estimated that up to $10 million could be required for the locomotives, cars and track changes to permit the level of train operations that will properly fuel the generating station for which the new electric railroad was built. The 78-mile railroad opened in 1974 is due for a major redesign.

ECONOMIC IMPACT OF TRIBOLOGY
Friction and wear-caused mechanical failures and maintenance normally have their roots in phenomena based on tribology, the science and technology of interacting surfaces in relative motion. Developments in tribology since the publication of the "Jost Report" have utilized existing and new knowledge from physics, chemistry, mathematics, statistics, engineering, etc. As a result, advances in diverse fields, from metalworking to medicine or space technology, have been produced. The economic benefits that may accrue to industry can be substantial; in the case of the U.S. the savings obtainable through tribology could amount to as much as $16 billion per annum. Some of the means used in the United Kingdom in order to reap the benefits attainable by application of the principles of the multi-disciplinary subject of tribology, and some of the results obtained, are described.

DESIGN OF A HIGH QUALITY INFRASTRUCTURE SYSTEM REQUIRING MINIMUM MAINTENANCE, EVEN UNDER CONDITIONS OF HIGH SPEEDS AND HEAVY LOADS
The paper is intended to demonstrate the limits of certain basic criteria generally accepted for the design and construction of a railway network, and to indicate some of the aspects from which it is possible to envisage the development of research relating to the following factors: infrastructure, alignment, engineering structures, together with the economic aspects of these elements.

STRUCTURAL DESIGN CRITERIA FOR THE NEW LINES OF THE GERMAN FEDERAL RAILWAY CONFORMING TO THE OBJECTIVES OF THE EUROPEAN INFRASTRUCTURE MASTER PLAN
In 1971, the European railway administrations cooperating under the auspices of the UIC decided to initiate investigations into the possiblities of improving the European railway network on the basis of uniform standards on an international scale. The Planning Committee was asked to prepare a corresponding plan. The first result of this effort has been the draft of a "European Infrastructure Master Plan--First Preparatory Stage" which was submitted to the UIC Management Committee in the summer of 1973 and unanimously adopted by it. Meanwhile, in the autumn of 1973, this plan was published and submitted to the Governments in the East and West so that the political objectives may also be included. The Master Plan is based on the recognition on the part of the European railway administrations that they are confronted with broadly the same problems. The railway network must be adapted to the economic and technical development which has occurred during the 20th century. Although the present financial situation of the German Federal Railway cannot be regarded as rosy, the construction of the new lines is essential to its improvement and therefore also to the future of the German Federal Railway. This assessment is also reflected in the thirteen objectives indicated by the Federal Minister of Transport to the Board of Management of the German Federal Railway at the end of 1974.

POLYETHYLENE TIE PLATES GAINING ACCEPTANCE
After six years of field testing, high density polyethylene tie plates are gaining acceptance from an increasing number of railroads for use on industrial and branchline track. Further evaluations are now being made of the plates possible use on heavy-load, high-speed mainlines. The tie plates were developed by Koppers Company, leading suppliers of creosoted ties, as part of a continuing program to extend tie life. The injection molded plate weighs up to 1 1/2 pounds.

THE USE OF SIMULATION TO DETERMINE THE CAPACITY OF SINGLE-TRACK RAILWAY LINES
The assessment of various upgrading alternatives is presented here in terms of the capacity of the line. Several definitions of single-track line capacity are given; the capacity definition based on weighted delay computations and differentiated by train class is shown to be a promising approach. However, more research is needed into the ways of determining the weighting factors and delay costs of various classes of trains.

PREVENTION AND CURE OF RAIL CORRUGATION
The author has discovered that corrugation is a function of track modulus and wheel loading. There is a critical range of shear and compressive stress within which rail corrugation takes places but below or above this range the phenomenon is absent, possibly because wear particles are either not generated or they are removed altogether. Not only will correct matching of track modulus, to axleloads carried avoid generation, but elimination of a mismatch will also cause existing corrugation to disappear without the need for grinding.

BLUEPRINT FOR TRACK REHABILITATION?
The Iowa Department of Transportation has been authorized by the legislature, concerned about track conditions in the state, to take several steps. A program of rehabilitation of branch lines has seen work started on ten segments involving expenditure of $8.7 million. Condition of all trackage in the state is to be monitored annually by a new track-measuring car. Development of a numerical "sufficiency rating" for all trackage in the state will rate ability of the lines to perform in accordance with accepted standards. Steps will be taken to assure sufficient supplies of materials and machines and enough manpower to meet any crash program of railroad rehabilitation which might be initiated at the federal level. So far state, local and railroad funding is involved.

THE DB'S OPTICAL WARNING SYSTEM FOR PERMANENT WAY MAINTENANCE GANGS [Die optische Rottenwarnanlage der DB]
The use of audible warning signals to gangs working on the line causes much disturbance for people living near the railway, especially at night. The DB has tried to replace audible warnings by optical signals for work on the permanent way at night. The principle is that at the arrival of the train, the lighting intensity at the worksite is varied according to the two frequencies used by the DB to show the track on which the train is arriving. On engines

with autonomous lighting, electronic flash-devices are used to warn the gangs. Finally, the author stresses that the present warning system depending on a look-out man, as used by the DB, is unsatisfactory from the safety point of view. Only automatically operated equipment could meet safety requirements. Moreover, this optical warning device saves manpower, as the look-out man is not required. [German]

COMPUTER APPLICATIONS IN CIVIL ENGINEERING DESIGN AND MAINTENANCE--WESTERN AUSTRALIAN GOVERNMENT RAILWAYS
The use of computers in the Western Australian Government Railways dates back to 1966 when an IBM 360/30 computer was installed. In the next five years the computer was used for nonscientific work including data processing. The Civil Engineering Branch made use of these techniques for financial control of large projects. Since early 1973 both scientific and nonscientific programs have been processed and some progress has been made toward the use of minicomputers for data capture and toward the use of terminals for on-line calculations. Programs to solve the following problems have now reached the production stage: realignment of compound curves; structural analysis; waterway design; earthworks & surveying; estimating; rail wear monitoring; and metrication records.

WIDE GAGE INVESTIGATION, VOLUME 1
One of the immediate problems in track maintenance and improvement is Gage Widening. Track lateral stability has been of great concern in recent years, both from the thermal load aspects involved in the use of continuous welded rail, and the train dynamics aspects of heavier equipment and rail, and the train dynamics aspects of heavier equipment and longer trains. Two particular problems attributed to track-train dynamics interactions are wide gage and rail rollover. For this investigation of wide gage in tangent track, an experiment was conducted on a stretch of track on the Union Pacific Railroad near Pocatello, Idaho. Eight sections of track with different combinations of tie plates and fasteners were installed by the Union Pacific at a site noted for recent wide gage problems. The purpose of the experiment was two-fold: first, as a track train dynamics study, to identify specific factors contributing to development of wide gage; second, as a fatigue test, to evaluate the ability of various test sections to maintain gage under heavy, high speed traffic conditions. Measurements of gage and observations of track conditions at the test site were periodically collected by Union Pacific personnel, so that long term trends could be established. In addition, field experiments measured the dynamic response of the track to traffic during both summer and winter ambient conditions. Volume 1 presents a description of the wide gage experiments and results from the summer field experiment, during which 315 trains were recorded over a 3-week period about 1.5 million gross tons of traffic.

WIDE GAGE INVESTIGATION, VOLUME 2
The wide gage investigation involved test measurements in the summer and winter months. The reasons for performing measurements by season was because experienced railroad engineers felt the phenomena of gage widening was accelerated during winter months. As reported in Volume I, permanent widening of gage occurs in the summer. Significantly, no appreciable permanent track deformation was found in periodic gage measurements at the test site between May (the installation of the test sections) and November of 1974. After a sufficient period of snow and subzero weather had passed,

to assure that the ballast section had deep frost, the track dynamics instrumentation as described in Volume I was again set up for measurements. This report presents the results of this winter series of experiments.

RAILWAY DYNAMIC TESTS

The verification of running safety and the quantitative assessment of the comfort of railway vehicles involves the taking of many dynamic measurements. The author first lists the range of the main recordings required and explains how they are taken: fitting of gauges, isolation of the phenomenon to be studied and transformation of the results into readings that can be interpreted more easily (usually an electric process), amplification, filtering, remote transmission of this data, reception and recording. The complex behaviour of a moving vehicle means that numerous phenomena must be recorded simultaneously and continuously by a whole series of measuring instruments. The author describes and explains in three sections the techniques used for measuring stresses and wheel-rail interaction, the series of measuring instruments, and the interpretation of the many and varied experimental results obtained, particularly with the TGV 001 trainset and the Z 7001 railcar. These results are very close to those obtained by calculation; they show the high value of the method using an analogue computer. [French]

The Velim Railway Testing Circuit, located 50 km east of Prague is the test facility for the Institute which is engaged in technology relating to transport economics, track construction and maintenance, rolling stock and electric and diesel traction, communications and other areas. The 200-kph test loops are energized at 25 kV 50 Hz and they may be used for controlled service tests for ORE, OSShD and for European and Russian railways and suppliers. Slab and conventional track are being evaluated. Laboratories have computers which can be coordinated with dynamometer car activities.

LARGE SCALE CONSTRUCTION WORK OF CONCRETE SLAB TRACKS FOR THE SAN-YO SHINKANSEN
The concrete slab track utilized by JNR (16 km on the Shin Kansen and 84 km on the narrow gauge line) has proved satisfactory and has shown the need for little maintenance. Therefore concrete slab track is used for 70% of the line between Okayama and Hakata. This article describes design requirements, construction methods and track details. JNR has two types--one with minimum provision for adjustment used only on straight track in tunnels and the other with larger adjustment margin used on all elevated sections (straight or curved) and on curves in tunnels. For the 393 km line 12 concrete slab production facilities were set up, 60 slab distribution points, 58 mortar plants and 25 depots for rail and fastenings. JNR is researching additional problems associated with the slab track.

MECHANICS OF TRANSPORTATION SYSTEMS
This is a continuation of the work of the Applied Mechanics Division of the American Society of Mechanical Engineers on dissemination of information on application of mechanics in transportation. In no aspect of transportation technology does applied mechanics play a more decisive role than in suspension system design. The papers in this volume are: (1) Classifying Track by Power Spectral Density by Corbin and Kaufman, (2) Active Suspensions for Ground Transport Vehicles, A State of the Art Review by Hedrick and Wormley, (3) The Tire as a Vehicle Component by Segel, (4) Development of Advanced Suspension Systems for High Speed Railcars-The Metroliner, A Case Study. Part I-Dynamic Performance Requirements by Strong and Herring, Part II- Prototype Development and Testing by Dean.

The papers in this book were presented at the winter Annual Meeting of ASME, Houston, Texas, Nov 30-Dec 5, 1975. Individual papers are RRIS 03 128606, 03 128607, 01 128608 and 02 128609.

CLASSIFYING TRACK BY POWER SPECTRAL DENSITY
Historically, the Power Spectral Density (PSD) has been used as a diagnostic tool and as a classifier in many disciplines. This paper illustrates how this valuable tool can be applied to railway track geometry data to assist in the understanding and management of the permanent way. The PSD can be used to diagnose random and periodic behavior in the track surface (profile). Three parameters are developed that are capable of describing this behavior. Furthermore, the PSD can be used to classify the track. Two of these parameters have a strong impact on the deviations of a 19-m (62-ft) midchord offset. Within prescribed confidence limits, these can be tied to the Federal Railroad Administration's track safety standards. This permits the assignment of the speed class at which the track may be economically maintained without major overhauling.

This paper was presented at the Winter Annual Meeting of ASME, Houston, Texas, Nov 30-Dec 5, 1975 and is from ASME Mechanics of Transportation Systems, RRIS 02 128605.

AN INVESTIGATION OF FACTORS CONTRIBUTING TO WIDE GAGE ON TANGENT RAILROAD TRACK
Wide gage--a fatigue failure of the track to maintain the nominal lateral distance between rail heads--is one of several modes of track failure on which the AAR-FRA-RPI-TDA Track Train Dynamics Program has focused attention. To investigate the generation of wide gage on tangent track, experiments were conducted to measure track dynamic response and long-term fatigue life of track sections on the Union Pacific Railroad in Idaho. Results of these experiments have defined the important factors in this mode of track fatigue.

This paper was contributed by the Rail Transportation Division of the ASME for presentation at the Winter Annual Meeting, Houston, Texas, November 30-December 5, 1975.

ICG RESTORES ELASTICITY TO ITS TRACK
Illinois Central Gulf is restoring elasticity and strength to sections of track damaged by the action of heavy high-speed traffic. Upward action of subgrade material reduces ability of ballast to distribute loads, causing deterioration of track quality. Problem is particularly severe on sections with poor drainage and abundance of mud. Three such sections are currently being rehabilitated. ICG is using new machines-Plasser combination undercutter and battast cleaner, and Tamper vibratory crib and shoulder compactor. Results have been good and an added feature is the relatively low cost.

THE TIES THAT BIND
After years of deferred maintenance, Norfolk and Western Railway has embarked on "rebuilding" policy, emphasizing plant as opposed to equipment improvement. The policy is evidenced by the increase in capital expenditures and maintenance programs, including track ballasting and surfacing, ballast cleaning, vegetation control, replacement of ties and switches. Other aspects of the program include yard rehabilitation, installation of microwave network, and modernization of communications system.

CLOSE-UP OF SOUTHERN POLICIES AND PRACTICES
In a four-part feature, the Southern Railway policies in track maintenance are examined. Southern started early in mechanizing m/w operations and has achieved a high degree of efficiency in manpower use. It has always emphasized rail and tie renewals. In Part 1, The Strategy Behind the Progress, the development of a five-year plan, the acceptance of a high m/w ratio, and use of a track geometry car and rigid quality control are discussed. Part 2, Dual Method of Laying Highlights Rail Practices, tells how a 54-man gang lays eight welded rail strings in a day and discusses welding, heat-treated rail and hardening of frogs. Part 3, Top Efficiency Is Goal in T&S Operations, tells how highly mechanized system gangs are organized around machines, including those which remove ties for possible reuse. Part 4, Innovations Feature Prefabrication of Turnouts, Track Panels, tells how turnouts are produced for rail relay programs and new industrial tracks. Track panels are used in building sidings and industry tracks and for reconstructing tracks damaged during derailments.

AXIALLY STRESSED RAILROAD TRACK ON AN ELASTIC CONTINUUM SUBJECTED TO A MOVING LOAD
The recent introduction of the welded railroad track raises the possibility that high axial compressive forces may occur in the rails due to constrained thermal expansions. This in turn may reduce the critical velocity of the track to within the operational velocities of present day trains. Recently the effect of axial forces upon the critical velocities of the track was analyzed by A.D. Kerr using the Winkler model for the base response. In this study, the effect of the axial compressive force on the critical velocity of the track is studied assuming for the base an elastic half space with inertia.

EFFECT OF A MOVING SYSTEM OF FORCES ON A BEAM LYING ON AN ELASTIC BASE [Deistvie dvizhushcheisya sistemy sil na balku, lezhashchuyu nauprugom osnovanii]
Steady-state vibrations of an infinite beam supported by a Winkler base are investigated for the case when an infinite system of identical forces moves along the beam at a constant velocity. In addition, a uniformly distributed load pressing the beam to the base acts on the beam. A computation algorithm is worked out taking into account the possibility of the appearance of a zone of separation of the beam from the base. The relationship between problem parameters accompanying the onset of such a zone is made clear. Results of numerical calculations for a wide range of parameters are presented. The possiblity of the loss of stability by the beam from the plane in which the moving load acts is investigated. An example close to railroad track parameters is given. [Russian]

LIMITED ANALYSIS OF THE SAFETY IMPLICATIONS OF THE PRELIMINARY SYSTEM PLAN FOR RAILROAD CONSOLIDATION
This Study looks at the safety impact of the system changes resulting from the reorganization of the railroads of the Northeast and Midwest due to the reduction of ton-miles of freight transported by rail, the increase by truck, the elimination of rail-highway crossings, and the upgrading and improved maintenance of the system. The subjects considered are the rail system itself, interaction with its surroundings, and interaction with other types of transportation. Only the change in transport mode of freight originating or terminating on the lines scheduled for abandonment is considered. Tables comparing safety performance for different transport modes are included.

A REVIEW OF MEASUREMENT TECHNIQUES, REQUIREMENTS, AND AVAILABLE DATA ON THE DYNAMIC COMPLIANCE OF RAILROAD TRACK
The need for increasing train speeds and operating safety while, reducing track maintenance is responsible for much of the current research on track structues, vehicle dynamics, and vehicle/track interaction. This report covers Phase I of a 3-phase program to design and fabricate equipment for measuring track dynamic characteristics. It is generally recognized that the available data and measurement techniques for obtaining this type of data for U.S. track and inadequate. This Phase I report includes a review of previous measurement techniques, a compilation of available data on track dynamic characteristics, an evaluation of data requirements, and the development of concepts for measuring track dynamic compolance.

"CUSHIONED" TRACK
The shock absorbing characteristics of track tie pads is gaining increasing acceptance as railroads witness the growing wear on tracks caused by higher speeds and heavier tonnages, the damage to ballast and ties caused by the pumping action of track. Improved materials are now available for tie pads and economically it is becoming advantageous to invest in this additional material when skyrocketing track maintenance costs are considered. Three cushioning systems are described: (1) a pair of pads between the tie plate and the rail and between the tie plate and the tie; (2) rail-base encasement in place of the tie plate; (3) concrete slab track. Initial installations over a sixteen year period has shown a 50% maintenance cost reduction.

THE ROAD TO DISASTER
Most crucial problem faced by North American railroads today is the deplorable condition of the roadbeds, the result of years of deferred maintenance. Money cannot now be found within the industry to stop the deferrals, much less to eliminate previously accumulated deferrals. A conservative estimate of this M/W deficiency is $4,727 billion. Possible solutions to the problem are the nationalization of the railroads, so far rejected in the U.S.; a Congressional aid program that will not destroy the private enterprise rail system; government-guaranteed low-interest loans; or a self-liquidating rail trust fund, financed by highway excise and diesel fuel taxes and a special surtax on all surface freight transportation.

MODERN SYSTEMS FOR TRACK BUILDING
According to the authors, modern systems of track building and renewal can be classified into two large groups: systems using prefabricated track panels; systems with direct laying of sleepers on the ballast and fastening of the rails on the sleepers. For application of the first group of systems, two sites are necessary: one for assembly and the other for dismantling, which should be organized taking several factors into account: expenses, manpower, mechanization of the sites and frequency of train circulation. In this particular group, the authors mention the system used by SNCF which achieves the complete laying of track at a speed of 350 m/h. The integrated systems in the second group do not need the above indicated sites. However, special mention should be made of the system used by the "SECMAFER" gangs, presently adopted by the Mexican National Railways, the replace the track fastened with sleeper-screws by the track with an elastic pad. A2 129414
STUDY OF THE VARIOUS PROTECTIVE LAYERS OF THE TRACK FORMATION FOR BALLAST TRACK [Untersuchung verschiedener Planumschutzschichten fuer den Schotteroberbau]
The authors apply several sub-soil deformation modules to calculate stress for the following types of ballast track: without protective layer; with a 30 cm gravel layer; with a 20 cm or 25 cm cemented protective layer. Proposals are made for applications of the various types of protective layer. A cemented protective layer (with an elasticity module of 60,000 kp/sq cm) on ground of average hardness can account for a characteristic ballast coefficient of up to 30 kp/cu cm and a ballast pressure of 3.2 kp/sq cm which can be considered a maximum limit. Therefore, it is advisable to use cemented layers only when the elasticity module of the track formation is less than 500 kp/sq cm under 20 t axle loads. However, above 150 kp/sq cm, the ground must be stabilized and deep draining is necessary. [German]

TROUBLED TRACK
This article puts the industry in perspective, noting deferred maintenance is not confined to the publicized difficulties of the Northeast railroads. Over

the past two decades railroads have worked themselves into an overwhelming imbalance with equipment money being available and investments having been primarily above the rail. Money-starved track has then been punished by higher speeds and heavier axle loading. Government could decide it is time to equalize the "public cost" for transportation right-of-way betterment. Technology is of little use unless the railroad right-of-way is fit to serve contemporary needs and railroad personnel learn to use technology to best advantage.

DYNAMICS OF INTERNAL STRESSES IN RAILS AND BUCKLING DURING CORE HARDENING [Dinamika obrazovanija vnutrennih naprjazenij i iskrivlennost rel'sov pri obemnoj zakalke in v masle]
This article explains a method for studying stresses in a rail when it is core hardened. It is possible to: -monitor the dynamics of stresses in the rail section and -obtain a diagram of these residual and temporary stresses. By the analytic and experimental method, the rail section is divided into zones having equal cooling times, and the increase in stresses is noted at fixed moments after cooling has begun. The values in the diagram obtained by this method tally with those provided by extensometric methods as regards residual stresses in the surface layers of the rail. The article also gives an analysis of the buckling mechanism which may occur in rails during hardening. [Russian]

RESIDUAL STRESSES IN SERIES P65 HARDENED RAILS [Ostotocnye naprjazenija v Zakalennyh relsah P65]
This article gives the results of a study on residual stresses in core hardened rail produced by the Nijni Taghil (Central Urals) steel combine. The authors discuss new rail, as well as rail over which trains of various tonnages have been hauled. A comparison of diagrams showing residual stresses in new rail and those in rail over which 152 and 235 million gross tonnes have been hauled show that, for the most part, there is no difference between the location of these stresses in the web and the rail flange of new rails, and those in rails which show wear. However, the study showed that the type and extent of residual stress on the contact area of the rail head is modified when trains run on these rails. Traction stresses of 8.1 kgf/mm2 were recorded on the rail head of new rails, whilst stresses of 4.5 and 3.1 kgf/mm2 were recorded on rail heads over which 152 and 235 million gross tonnes had been hauled. WHAT REALLY HAPPENED ON THE BLACK MESA AND LAKE POWELL?
In the face of conflicting reports concerning the track problems of the Black Mesa & Lake Powell, this article reports the results of an on-site investigation. Management view is that the track bed is sound, rail was properly laid and has perfact alignment, but there have been problems with rail fastenings. This has led to problems with the concrete cross ties, which developed spalling under the rails. BM&LP is replacing about 75,000 of its original 196,000 concrete ties with 100,000 wood ties, leaving 121,000 concrete ties in service. All concrete ties on curves greater than 30 minutes are being replaced. The spalled areas of all remaining ties are being repaired with a sand/epoxy mix. Clip bolts on all remaining concrete ties are being replaced with high-tensile steel and the rubber pads under the rails are being replaced with hard polyethylene pads, retaining original clips.

RAILROAD REHABILITATION PROGRAM, A PROGRAM TO UPGRADE SELECTED BRANCH LINES IN IOWA
This report describes how Iowa participates with railroads and shippers in upgrading track and roadbeds, through direct financial assistance. Major topics include a discussion of the selection, negotiation, implementation, follow-up and payback procedures; the factors related to transferring the program from Iowa to another state; the authorizing legislation with back-ground information; and comments about future directions for the program. The Iowa Railway Assistance Act establishes a fund to be expanded by the Iowa Department of Transportation for upgrading the branch lines, serving not as a substitute for abandonment but as a realistic approach for saving viable branch lines.

METHOD FOR CALCULATING THE TRANSITORY HEAT FIELD DURING RAIL SURFACE AND CORE HARDENING [Metodika rasceta nestacionarnogo temperaturnogo polja pri obemnoj i poverhnostnoj zakalke relsov]
The authors explain the main requirements for establishing a method for calculating the heat field during rail surface and core hardening. The results of these calculations are compared against experimental rail cooling graphs of core hardening at three characteristics points in the rail section. The comparison shows that the calculations and experimental results tally. This

calculation method can be used to determine the structure and hardness of rail sections which have been cooled by different methods and hardening mediums for which the heat transfer coefficient is known. [Russian]

RESIDUAL STRESSES IN RAILS [Ostatocyne naprjazenija v zeleznodoroznyh relsah]
The article examines the effect of residual stresses on rail breaks along the length of the web and on stability during rupture tests on core hardened rail: the aim of decreasing residual stresses in core hardened rails and the formation of residual stresses in the rail head can be achieved by making further improvements to the cold hardening process; residual stresses do not have any substantial effect on stability during rupture tests on rails when the break begins because of a drop hammer failure and, before the break occurs, the rail changes considerably; this is precisely what happens in tests on core hardened rails when the temperature changes from-60 degrees to 20 degrees C. [Russian]

FATIGUE STRENGTH OF STEEL WIRE FOR PRESTRESSED CONCRETE SLEEPER
This paper describes calculation of the fatigue strength of steel wire used for prestressing concrete cross ties. From the results of rotating bending fatigue tests of deformed prestressing wires and plain wires pretreated in various ways, the following conclusions were obtained: (1) Suitable deformed prestressing wires are available for concrete cross ties; (2) Some surface damage may decrease the fatigue strength of the prestressing wire (corrosion, notching and sparks, for instance); (3) JNR's present prestressing loads are sufficient. The effects of spark damage to wires are particularly critical.

LI TRIES FOR MORE TIE LIFE BY REDUCING TIE-PLATE WEAR
To reduce the cutting of wooden cross ties by tie plates, the Long Island Rail Road has initiated tests of Pandrol rail fastenings with special plates having shoulders that accommodate the legs of the spring clips. The goal was to increase the 28-year tie life experienced on heavy-density routes. A 13-mile stretch of new continuous welded rail has been secured with the Pandrol fastenings; tie plates are secured with three Lock Spikes. Tie life is enhanced by eliminating movement of the plates on the ties and a stiffer track structure is thought to have been produced. In addition to the longer service from ties, the Pandrol assembly simplifies the changing of defective rails and avoids problems of spike killing of ties and the loss of plate gauge every time a rail is changed.

BAM: A TRACK FORMATION OF HIGH DURABILITY [BAM-dologovecnoe zemljanoe polotno]
The article examines the geological and civil engineering conditions in the Eastern Siberian and Eastmost region to be crossed by the Baikal-Amour (BAM) main railway line, the special features of the project and the construction of the line's track formation. This line, which is now being built, goes through a whole series of mountain ranges and across large rivers, regions with different geological structures, and various Eastern Siberian and Eastmost climatic zones. The line's route is characterized by complex

geological and civil-engineering conditions due to: the presence of terrain hard frozen for many years, a sinuous profile, high seismicity as well as deep tactonic and exogeneous cracks in the mountain masses, and also to the active frost process affecting the ground surface. Added difficulties include: rock falls, ground subsidence and dejecta cones, ice layers and thermokarsts, underground ice layers. The ground surface is constantly strained by distension and subsidence phenomena brough about by the eroding effects of rivers and lakes during the seasonal freezing and thawing processes. [Russian]

A2 130827
THE DEVELOPMENT OF ANALYTICAL MODELS FOR RAILROAD TRACK DYNAMICS
A renewed interest during the past decade in high-speed rail transportation has underlined a need for better understanding of the dynamic interaction between vehicle and track. Speeds in excess of 160 km/h tax the presently used rail-tie-ballast track structure in terms of long-term stability and required track accuracy. Hence, the investigation of improved structures with better dynamic response characteristics and greater stability has followed in the wake of improved high-speed railcar design. This paper presented some recent developments in analytical modeling of railroad track structures for the study of vehicle-track dynamic interaction by computer simulation. Field measurements taken on main-line track of several North American railroads were used to evaluate the accuracy and define the necessary modifications of the computer model. Predictions of better overall system response and long-term stability from this computer model have aided in the preliminary design of several new track structures which are currently undergoing field evaluation.

THE MECHANICS OF RAIL FASTENERS FOR CONCRETE-SLAB TRACKS
In the growing use and potential development of the concrete rail base in place of ballast, rail fasteners serve a vital function. To a large extent they substitute for the elasticity that is traditionally provided by ballast. In addition, they may aid in the possible suppression of noise. Since the first use of concrete slabs for railroad use, fastener problems have been persistent. In this paper, Bramall summarized basic design principles and practical applications that are being developed for rail fasteners for such installations. An analysis and comparison of experiments with various fasteners and analysis of their characteristics may serve as a design guide and a basis for further investigation.

A2 130830
RAILROAD TRACK STRUCTURE FOR HIGH SPEED LINES

Speeds in the 250-300 km/h range demand a track with precise alignment with elastically mounted rails, and low maintenance cost. Along with an improved ballasted track, a track structure mounted on a rigid pavement, distinguished by a precise mounting of the rails and the promise of low maintenance cost, was discussed. Prof. Eisenmann described a track structure using a concrete paving slab. The results presented were based on research carried out at the Institute for Construction of Land Transport Routes of the Technical University of Munich. On the basis of research work of the last two decades and current practical experience, it has been determined that a reinforced ballasted track may be used for speeds up to 250 km/h. For higher speeds an elastic rail mounting on a rigid pavement has been investigated. Experiments performed on the high-speed section of the Deutsche Bundesbahn between Bielefeld and Hamm using concrete ties demonstrated a noticable improvement with the insertion of a soft rubber pad in the area of the rail fastening. Experience in highway construction indicates the pavement should have a multi-layered structure, and the supporting system must be frostproof. With a correct calculation of dimensions and structural design, ideal conditions are created for trouble-free wheel motion with an almost complete elimination of maintenance work.

THE LATERAL BUCKLING OF RAILROAD TRACKS DUE TO CONSTRAINED THERMAL EXPANSIONS

Thermal buckling of jointed tracks has been a problem for quite some time. Its occurrence has greatly increased since the introduction of CWR. In spite of intensive research conducted in several countries over the past several decades, to date there are no reliable analyses to predict the buckling temperature of a railroad track. The purpose of this paper was to review the relevant test results and various analytical attempts to solve this problem. The discussion sought to review their deficiencies and thus pave the way towards a solution of the track- buckling problem.

A CONTRIBUTION TO BALLAST MECHANICS

Most railroaders are apparently convinced that conventional track, will not meet the performance requirements of future traffic. It is clear that immediate progress will stem from current research experiments. In this paper the author described tests he conducted in conjunction with the Austrian Federal Railways to improve conventional railroad track. First, the effect of grain size, grain shape, and quality of ballast upon stability of the road bed were considered. This was followed by a discussion of the plastic and elastic settlement of the ties and a comparison between the behavior of the ballast bed and that of a spring model. Prof. Klugar introduced a new type tie called the "wing tie" devised to increase lateral stability. The author then discussed the lateral displacement of the track in connection with buckling tests in sharp curves.

A2 130833
A REVIEW OF RAIL-WHEEL CONTACT STRESS PROBLEMS

Nearly 200,000 defective rails were located on U.S. railroads in 1972 Rail failures are one of the largest single causes of derailments, ranking somewhat ahead of the next most substantial contributor: wheels and axles (bearings). Furthermore, a high degree of correlation was observed between the rail-related accidents and the ton-miles carried, suggesting that a higher utilization of the rail system may lead to yet higher accident rates. The defective rails and rail-failure-related accidents occur in spite of a massive inspection effort and the installation of over 700,000 tons of new rail annually. Not all defects are equally likely to cause derailments. Rail-end failures (bolt-hole cracks and head/web separations) occur most frequently, but are not proportionately the largest cause of accidents. Transverse defects, which are less frequent, can account for a disproportionately high number of accidents.

A2 130834
STRESSES AND BEHAVIOR OF RAIL TRACKS DURING THE PASSAGE OF TRAINS TRAVELLING AT VERY HIGH SPEEDS; STANDARDS ADOPTED BY THE SNCF FOR ITS FUTURE VERY HIGH SPEEDS LINES (250/300 KM/H)

On the Paris-Madrid line in Southwest France, between Bordeaux and Dax, there is a section on which there are two straight stretches of 20 to 45 km, separated by a curve with a radius of 2850 meters. This SNCF line allows tests to be carried out at speeds of over 250 km/h. Since August 1972, two prototype trains, the TGV 001 turbotrain, and the Z 7001 electric motor train, have been traveling four times a day at speeds between 250 and 320 km/h. This paper summarized the knowledge acquired in France as the result of systematic tests carried out at those speeds in anticipation of the

new Paris-Sud-Est line on which trains will travel at speeds of over 250 km/h. Although the problems are not yet completely solved, they are at least now defined very clearly, and none of them is of a fundamental type. The doubts raised a few years ago now appear to be baseless, at least for speeds of up to 300 km/h.

A2 130835
SELECTION AND PERFORMANCE OF RAILROAD BALLAST

This paper reported an investigation of ballast selection, using standard and modified standard classification tests. The results enable ballasts to be selected with better reliability. A large number of standard laboratory tests were performed on ten ballasts to determine correlation with field performance. The field performance in terms of stability and in terms of breakdown of the ten ballasts was obtained from a CNR field test. In addition, the behavior of a layer of ballast was investigated under ideal loading conditions. Vibration tests investigated how ballast compacts under vibration. Repeated loading tests investigated the fundamental stress-strain characteristics of the ballast. These were supplemented by a model full-scale test. The results of this additional work will improve the specifications for the initial compaction of a layer of ballast and tie configuration to give the best subsequent performance under load. In the future it should lead to the development of a theoretically valid design method for the complete roadbed.

A2 130836
DEFORMATION OF RAILWAY BALLAST UNDER REPEATED LOADING CONDITIONS

The work described in this paper was concerned with the action of repetitively applied stresses on the deformation of track ballast and was confined to the tri-axial testing of dry ballast where the stresses can be accurately controlled. A major departure between this work and the more normal testing in the field of soil mechanics is that it is more usual to concentrate on the determination of the ultimate strength of the material, while here the main purpose is to determine deformations in the material at stresses often well below those which cause failure. At the present moment the work is in mid-program and both interpretation of the existing test results and also the complete test series have not yet been concluded. Therefore, this paper is by way of an interim report suggesting some ideas which may immediately have direct relevance to today's railways and also to act as a spur for work to be done to bring the knowledge of the material properties of ballast up to that of other engineering materials.

DEVELOPMENT OF THE PRESTRESSED CONCRETE TIE IN THE U.S.

Weber traced the history of concrete crossties in the United States, starting in 1893 when 200 were installed by the Reading in Germantown, Pa., through 1972, when several major railroads had installed concrete ties in main-line service for, in the most part, short test sections of one mile or less. Such installations were located on the Western Pacific, the Southern and the Santa Fe. Despite persistent problems (except for the period 1930-1957 when there was virtually no concrete-tie activity in this country because of adequate timber supply and preservation methods) development has continued with emphasis on the requirement for further research. By 1957 several European countries had already developed satisfactory concrete ties designed specifically for the loads and conditions prevailing in those coutries. Until new information becomes available, the new American Railway Engineering Association "Specifications for Concrete Ties (and Fastenings)" will set the standards for concrete-tie performance.

ESTIMATING THE DEGREE OF DEHYDROGENATION OF RAIL STEEL BY THE BATCH METHOD [Ocena stopnia odwodorowania stali na szyny metoda porcjowa]

A study was made of the effectiveness of dehydrogenation of open-hearth steel in a vacuum installation by the batch method. It is found that the optimal degree of dehydrogenation of molten rail steel by the batch method of degassing is attained when the steel circulation coefficient is greater than 3.0 and the pressure in the vacuum collector ranges from 0.5 to 1.0 torr. The hydrogen content in rail steel after degassing by the batch method ranges from 2.0 to 3.7 cu cm per 100 g. An electrode addition of about 1.5 kg per ton of steel increases the hydrogen content after degassing by about 0.5 cu cm per 100 g. [Polish]

WORK ON THE TRACK BY THE ENGINEERING DEPARTMENTS. 1.2

The first paper outlines the activities associated with work on the track which brings the Signal Department and Civil Engineer's Department into close contact and sometimes, conflict. It discusses the Signal Engineer's track problems and raises a number of particular ones which need a mutual approach for solution. It shows how machines have been developed to save time and manpower and ends with a pleas for greater co-operation between the two departments so that each may acquire a greater understanding of the other's disciplines. In the second paper the author describes briefly the history of track arrangements for both plain track and point and crossings before outlining the process of present day track renewals and drawing attention to problems relating to the installation of continuous welded rails. It shows how, in an endeavour to save time and reduce manpower, machines have been developed to assist both renewal and maintenance of track. The problems of maintenance are discussed and reference is made to the need for additional safety requirements for both men and machines.

Papers presented to the Institution of Railway Signal Engineers, December 1, 1975.

STATE-OF-THE-ART OF BALLASTLESS TRACK AT-GRADE
Ballastless track support structures are regarded as possible solutions to the problems of track maintenance and the research and development of these structures is reviewed. The new types of structures include ties embedded in concrete slabs and also beams. These structures are cast-in-place, precast, and slip formed. Several design problems are examined with consideration to the advantages of ballastless track over conventional track. Maintenance and cost advantages are considered. Current research and development is considered for seven countries; United States, United Kingdom, Germany, France, Soviet Union, Switzerland, Japan. This paper reviews the types of structures actually built and put in experimental or revenue service. The development of new types of rail fasteners is also considered with each type of new track structure.

STUDY INTO DYNAMIC FORCES IN RAILWAY TRACK AND LAYOUT OF A TESTING DEVICE [Estudio sobre esfueros dinamicos en las vias ferreas y diseno de un aparato de pruebas, basaco en mediciones directas]
The Secretariat for Civil Engineering in Conjunction with Mexico University's Institute of Engineering, has proposed a series of studies into the stresses caused by dynamic forces acting on the track superstructure, and the determination of pressure distribution under the sleeper and ballast, aimed at designing and developing equipment adapted for laboratory tests. This paper, which won first prize in Section A of the Caracas Congress, contains a description of the initial steps of this plan, and comprises three parts: 1) Theoretical bases, hypotheses, and calculation methods for orienting the on-site experiments. 2) Actual on-site recordings. 3) layout of testing equipment, particularly for concrete sleepers and rail fastenings, aimed at reproducing the necessary load and speed characteristics. [Spanish]

POSSIBILITIES FOR THE DEVELOPMENT OF RAILS FOR HIGH- CAPACITY, HIGH-SPEED TRANSPORT [Moeglichkeiten der Schienentwicklung fuer einen Hochleistungsschnellverkehr]
High-capacity, high-speed transport makes additional demands on the rails. The article discusses the possibility of developing materials for self-hardening rail steels. He presents the results of tests carried out on experimental rails produced industrially. These are mainly made of perlitic steels, steels with a bainitic structure, and low-carbon steels. [German]

THEORETICAL STUDY ON THE DETERMINATION OF SECONDARY DEFLECTION IN RAILS [Theoretische Studie ueber die Ermittlung der Sekundaerdurchbiegung der Schiene]
The calculation of the deflection of a rail is based on the assumption of a continuous elastic support. It is in fact a support at separate spaced points, which causes an additional (secondary) deflection. The author calculates this secondary deflection, and concludes that it does not not have any significant effect on superstructure stress. [German]

WEAR ON EXTERNAL SURFACES OF WHEELS AND RAIL DUE TO FRICTION [Verschleissvorgang im Grenzschichtbereich der Reibpaarung Rad/Schiene]
The stresses borne by rail and wheel elements are analysed on the basis of several fundamental definitions of wear by Fleischer. A number of studies were carried out on plastic deformation, running surfaces and wear characteristics. Partial oxidation can occur when the external surfaces of wheels or rails are deformed because the materials come into contact with the surrounding atmosphere. Oxidised metallic particles are then worn away. Wear is often affected by the characteristics of the process itself or by layers of martensite which are produced by shoe brakes. [German]

A2 131272
EFFECT ON TRACK OF HEAVY AXLE LOADS
The author recalls and makes reference to numerous studies on the problems of damage to rails caused by heavy axle loads. He quotes recommendations developed by AREA with regard to permissible axle loads in relation to wheel diameter and vehicle speed, and the ultimate tensile strength of rail steels. He mentions the experience of Australian Railways operating meneral lines with block- trains made up of very heavy wagons. He then gives formulae and tables in which the track maintenace cost, as per traffic unit, is expressed in relation to various variables and parameters: speed, axle weight on rail, age of ballast, linear weight of rail, curve radius, etc.

A2 131280
THE EFFECT OF LATERAL RESISTANCE ON TRACK BUCKLING ANALYSIS
A model which exhibits the essential features of track buckling mechanisms is used. It is represented by four bars constrained at the interconnecting joints by spiral springs. The bars deform axially according to Hooke's law and the law of linear thermal expansion, but are "rigid" in bending. The author analyses the mathematical model according to three different assumptions. He compares the results obtained and draws conclusions as to the critical temperature at which buckling can occur and the assumption which is most representative of track buckling.

A2 131282
THE TRACK SUPERSTRUCTURE ON SOVIET UNION RAILWAYS [Der Oberbau bei den Eisenbahnen der USSR]
The SZD carry over half of the world's total volume of freight traffic. The average density of traffic on electrified lines is 76 million gross tonnes per year; locomotive axle loads reach 27 tonnes, and the length of freight trains may be up to 2000 m. The lines are classified as "very heavy traffic" (50 million tonnes of freight a year)", "heavy traffic" (over 25 million tonnes), and "normal" (up to 25 million tonnes). For these categories, standard rails (R.50, 65, 75) are shown in tables and figures, together with wear allowances, shaping, temperature, compensation, length and transport. 70% of the tracks are laid on wooden sleepers, but laying on concrete sleepers is on the increase. The measurements of concrete sleepers are given, also those for superstructure on concrete slabs, test results, construction and maintenance costs. The organisation and direction of superstructure work are described, and an organisation chart for an automated district is shown. [German]

OVERALL EVALUATION OF TRACK CONDITIONS FOR THE PURPOSE OF PLANNING SYSTEMATIC MAINTENANCE [Syntetyczna ocena nawierzchni dla planowania napraw biezacych ciagtych]
It is necessary to know what the actual condition of track is to draw up overall track maintenance plans. The author describes a "synthesis" method for evaluating track conditions using an Amsler dynamometer car with Matisa measuring equipment. An index which is a synthesis of track characteristics and condition (Ws) is established on the basis of a statistical analysis of 5 parameters (levelling, gauge, track distortion, superelevation, and alignment). The analysis contains variations of Ws in relation to acceptable train speeds and lineload. The author concludes with a recommendation concerning the use of the Ws index for planning track maintenance operations. [Polish]

ELASTICITY OF RAIL STRETCHES IN RELATION TO THE PARAMETERS OF THE FASTENINGS [Uprugost' rel'sovyh nitej v zavisimosti ot parametrov promezutocnyh skreplenij]
The article examines the theoretical correlation between, on the one hand, the rigidity parameters of rail fastenings during the intermittent actions of loads on the bearings and, on the other, the elasticity of the track during wheel stresses on the rail stretch. Results are given concerning the experimental research into these problems. On the basis of tests with the security devices both in laboratory and under operating conditions, the theoretical research explained in the article provides an overall insight of wheel action, which is vital when defining the optimum parameters of fastenings. DEVELOPMENT OF CORRUGATIONS ON SURFACES IN ROLLING CONTACT
The self-generation of corrugation on metal surfaces in rolling contact has been studied experimentally in a rolling contact disc machine and theoretically using a computer simulation. The system vibrates in the "contact resonance" mode excited by surface irregularities, and these vibrations may be severe enough to cause plastic indentation of the surface in one revolution which then amplifies the vibration in the next revolution.

A2 131315
INVESTIGATION INTO CAUSES OF RAIL CORRUGATIONS
Heavy traffic density and high-capacity cars increased wear and abrasion or curves which CP Rail countered with lubricators that cut flange abrasion but produced rail corrugation with a wavelength of 8 to 28 inches on the low rail. Plastic flow or rail head metal combined with surface fatigue are predominately responsible for rail corrugation. Recommendations for overcoming the problem includes improved wheel rail contact geometry through elimination of wide gauge, elimination of false flanges on wheels, reduction of railhead curvature and modification of the AAR wheel profile; cutting of lateral frictional force by use of self-steering trucks; changes in rail metallurgy to increase resistance to surface fatigue and plastic flow, reduction of dynamic loadings and improved flange lubrication techniques.

ANALYTICAL AND EXPERIMENTAL DETERMINATION OF NONLINEAR WHEEL/RAIL GEOMETRIC CONSTRAINTS
The wheel/rail geometric constraint relationship for actual wheel and rail profiles are generally nonlinear functions of wheelset lateral displacement. Two of these relationships which strongly influence the lateral dynamics of railway vehicles are the effective conicity and gravitational stiffness. An algorithm for the digital computer is presented that calculates these nonlinear relationships for arbitrary wheel and rail head profiles. An experimental apparatus was developed to determine the location of the wheel/rail contact points as a function of wheelset lateral displacement for arbitrary profiles. Experimental data obtained with this apparatus are presented for various cases which validate the results of the analytical procedure.

KANSAS TEST TRACK: WHAT WENT WRONG?
The FRA-sponsored Kansas Test Track, an 8000-ft field laboratory composed of eight segments utilizing concrete ties and continuous longitudinal concrete beams and slabs and ballast stabilized by an elastomeric polymer, has been retired. Early in 1977 FRA will present a final report telling how the stretch adjacent to Santa Fe's mainline at Eldorado, Ks., performed and failed to perform. The goal had been to understand the improvement in track stability, performance and maintenance requirements resulting from incremental increases in stiffness. When AT&SF revenue freight trains first traversed the track at low speed, track fasteners on the beams failed. After months of repairs, trouble developed again after the line was reopened. Beams again developed problems but mud pumping around them and under the stabilized ballast indicated that the entire subgrade was failing. Some of the track components will be reused at Pueblo, Colo.

WIDE-GAUGE RESEARCH LEADS TO A NEW STANDARD ON UP
Following research on the causes of wide gauge, Union Pacific has adopted as standard a 16-inch tie plate with a 1:30 cant. Gauge widening is a problem common on high-speed,heavy-duty mainline track and this phenomenon was investigated on UP as part of the industry's Track Train Dynamics Research Program. Tie-plate cant varied from standard 1:40 down to 1:14. The 1:30 design finally chosen is to reduce the incidence of rail rollover and to reduce overloading on the gauge side so that the wear pattern was down the center of the rail.

DETERMINATION OF LOADS ON TRACK
In the past decade, advances in the technology of instrumentation and of computers have made possible the determination of wheel/rail loads so that proper design and maintenance procedures may be developed for vehicles and track so that the industry can live with today's axle loadings. Methods of determining such loads by measurements on the vehicle and the track are discussed. Mathematical modeling procedures may also be utilized to calculate such loads. Computer simulation which includes both vehicle and track in a dynamic interacting system permits specification of outputs in the form of vertical and lateral forces between wheel and rail. Some of the research programs in load determination are then described.

A2 132961
TRACK STRUCTURES FOR HEAVY WHEEL LOADS
The load bearing capability of track depends on the combined characteristics of foundation, superstructure and loads to be carried. Evidence is that loads imposed by 100-ton cars exceed the load-bearing capacity of much of the track over which they operate. Track deterioration under heavy loads appears in the form of loss of surface and line; in conversion of subgrade and ballast sections into plastic masses that pump mud and water, in wide gauge, plate cutting, tie splitting and spike-killed ties; in rapid wear, battered rail ends and in formation of corrugated and shelly rail. After discussing facets of track design and track deflection, the problems of ballast and subgrade are examined and the effects of wheel loads are detailed. Ten recommendations for combatting effects of high wheel loads and two other lines of action for limiting or accounting in advance for track deterioration are suggested.

OBSERVATIONS ON THE EFFECT OF HEAVY WHEEL LOADS ON RAIL LIFE
The Bessemer and Lake Erie Railroad has operated 90-59 open-top cars since 1931 and has some statistics on rail wear and rail life under the stresses imposed by such equipment. Rail life on tangent track has been around 440 million gross tons for jointed rail and beyond 650 million gross tons for continuous welded rail. Statistics are also available for Curvemaster and controlled cooled rail on curves. On newer ore carrying railways, rail life appears to be appreciably shorter. Among possible reasons are the bidirectional operation of loaded trains on B&LE, the mixing of various capacities of cars, and the predominance of traffic on solid, rather than roller-type, journal bearings.

A2 132963
EFFECT OF HEAVY AXLE LOADS ON RAIL AND TIES
The Quebec North Shore and Labrador Railway was built in 1953 to handle iron ore from mines 350 miles north of the St. Lawrence River. Trains of up to 280 cars with five locomotive units are operated. This presentation reports the maintenance experience on track which carries up to 50 million net tons annually, and has handled almost 700 million gross tons since opening. Among the findings: line, surface and gauge must be maintained even on tangent track; corrugated rail develops quickly on grades and curves and must be countered promptly; joint bars must be kept tight and rail ends restored; oilers are all-important on curves.

WELDING CONTINUOUS RAIL IN-TRACK
Continuous welded rail has usually been fabricated using the electric flash butt welding process to join 39-foot rails into 1440-foot lengths. These are then transported for installation in the field. This entails a major materials handling problem which could be reduced by making field welds. Such welds have not met the criteria of quality or cost. A solution developed in the USSR is a highly portable electric flash butt welder. It adds a new option for rail welding and is suitable not only for field work but also for in-plant welding.

A2 132974
EFFECT OF HEAVY AXLE LOADS ON BRIDGES
It is estimated there are 3500 miles of bridges on American railroads; replacement cost is estimated at $10 billion. The problem is not the spectacular, long-span steel bridges, but the many structures built many years ago for much lighter loading. As reconstruction is deferred, more speed and weight restrictions will have to be imposed; modern equipment may have to be prohibited from many lines. With scarce capital it will be many years before the frail steel spans of 1880-1900 are replaced. The Cooper E-60 rating permitted by the AAR Mechanical Division does not produce cars capable of unrestricted operation over the rail network. Timber trestles are particularly vulnerable to closely spaced axles.

HEAVY AXLE LOADS IN NATIONAL RAILWAYS OF MEXICO AND NEED FOR STRENGTHENING OF BRIDGES
National Railways of Mexico has been confronted with many low-capacity bridges on lines where heavy cars are being, or will be handled. While the

new bridge standard is Cooper E72 rating, those built prior to 1970 range downward from E60 to E35 on some former narrow-gauge routes. NdeM has raised the ratings on some bridges since diesel locomotives have replaced steam with resultant reduced impact loadings. Slow orders are imposed on certain structures to handle concentrated program of strengthening bridges where it is reduce impact on bridges and use of neoprene pads under the rail base for the same reason have been widely applied. A concentrated program of strenthening bridges where it is economical has been undertaken. Bridges of low capacity or in bad condition are replaced.

PRACTICAL PERFORMANCE OF THE TRACK SYSTEM WITH ASPHALT TREATING METHOD
Maintenance required on conventional track/ballast structures has caused Japanese National Railways to investigate ways to preserve track geometry and minimize ballast degradation. The Track System with Asphalt Treating Method was developed to be applied with a minimum of out-of-service time for the track and to prevent track subsidence while also stabilizing ballast. Asphalt is forced into the ballast beneath the ties and the ballast shoulders are paved. A slab tie must be used--these-called Large Prestressed Concrete (LPC) Slab Ties. Tests indicate stability does not decrease in the long term.

NEW SNCF CONCRETE SLEEPERS [Les nouvelles traverses en beton de la SNCF]
After outlining the history of the use of concrete sleepers and describing their technical characteristics, the study on stresses in the track, caused by dynamic overloading, is based on the work of an ORE Specialists Committee (Question D 71) and the experience acquired by the SNCF in the calculation of the maximum stresses to be taken into consideration. So as to be able to compare the performance of the different sleepers and check the results obtained by experiment against behaviour in service, the SNCF decided to have the following types manufactured: composite reinforced concrete sleepers (VAX V30 and SL V 30); monobloc prestressed concrete sleepers; composite "PRETUBE" sleepers in which an extrusion tube serves as a tie-bar and a means of obtaining prestressing. THEORETICAL STUDY OF NATURAL FREQUENCIES AND OSCILLATION AMPLITUDES IN BALLASTLESS AND BALLASTED PERMANENT WAY [Theoretische Untersuchung der Eigenfrequenzen und Schwingungsamplituden bei schotterlosen Oberbau Konstruktionen und klassischem Schotteroberbau]
The study provides the basis for calculating the dimensions of the ballast layer and the intermediate elastic slabs. These elastic slabs replace the ballast bed for load distribution and absorbing shocks, while costing less for maintenance. The slabs can reduce the forces imposed on the track by oscillation, and thus have a favorable effect on noise, track bed stability, rail wear, and smooth running. [German]

RAIL VEHICLE SAFETY RESEARCH

Rail vehicle safety research is aimed at improving railroad safety by delineating problem areas and developing countermeasures to reduce accidents in four major areas: rolling stock, accident avoidance, human factors, and control systems.

The goal of the rolling stock program is to improve railroad safety by research and development efforts to determine achievable performance specifications for (a) vehicles and vehicle components that are less prone to failure; (b) techniques and mechanisms for predicting, detecting and reacting to failures that do occur, and (c) increasing the accident survivability of vehicle occupants. The prevention of catastrophic consequences in the transport of hazardous materials has been a major undertaking in this program, and the full-scale fire test depicted above is one of the important past activities.

The human factors research program strives to improve the interaction between human and machine in order to reduce the number and severity of accidents resulting from so-called human "errors." FRA has sponsored research aimed at acquiring an understanding of the requirements of safety-critical activities and environments.

The objective of the accident avoidance program is reduction in derailments and collisions. This includes grade-crossing research and the development of practical on-board warning technology.

The control systems program is aimed at reducing the number and the severity of railroad accidents by improving control systems. Evaluations are made of both control systems equipment and control systems procedures.

SAFETY AND RIDE-COMFORT OF HIGH-SPEED RAILWAY CARS
Running safety is the essential requirement for the high-speed operation of rolling-stock. However, riding comfort is another important factor which should never be overlooked. Discussion is limited to the car-dynamical problems such as the over-turn or derailment of cars. The riding problem is concentrated to the vibrational riding quality.

STUDIES OF THE PRESSURE AS AFFECTED BY THE AREA OF CONTACT BETWEEN WHEEL AND RAIL. EFFECT OF WHEEL SIZE
The following is a progress report on one phase of this investigation, namely, rolling-load tests in which wheels of various diameters are rolled to and fro on a short length of rail for the purpose of determining the number of cycles of load application required to produce failure. The results of the rolling-load tests to fracture show considerable "scatter" and no very marked difference between the results of tests under a 50-in. wheel and those from tests under a 33-inch wheel. The vertical wear on rail 757C (33-in. wheel) was 0.046 in. at failure, whereas the wear on rail 757C1 (50-in. wheel) at 580,900 cycles was 0.041 in. At failure, 750,100 cycles, the wear on rail 757C1 was 0.0425 in. A second type of test being tried to ascertain the effect of wheel size on the rail is to measure the depth of work hardening in the rail head. The rail head appeared to have been work hardened down to a depth of about 0.45 in. by the 33-in. wheel with a maximum hardness of 296 at a depth of 0.15 in. A test on a section from the same rail rolled with the 50-in. wheel appears to have been work hardened down to a depth of 0.20 in. with a maximum hardness of 269 at a depth of 0.10 in.

DERAILMENT OF ELECTRIC PASSENGER TRAIN
The derailment of the last coach of an electric multiple-unit down passenger train on December 13, 1963, which subsequently came into glancing contact with the side of another passenger train, was caused by axle fatigue. This fatigue would have been detected if the prescribed frequency for ultrasonic inspection had been observed. It was suggested that no axle be tested less frequently than every 18 months. One passenger was killed and 31 injured.

INQUIRY INTO DERAILMENTS ON THE VICTORIAN RAILWAYS
This summary of a committee of Public Accounts inquiring into derailments during the years 1954-1964 examines the incidence of hot boxes, fracture of axle-box guides, track defects, mileage and ballast with total derailments. The conclusions were that the recent increase in freight trains derailments was due to the use of four-wheel wagons and poor track conditions on low traffic country lines. Also, cross ties were in poor condition on some lines, and ballast was inadequate.

NEW BRAKE SHOE CUTS STOPPING TIME, REDUCES WEAR AND SPARKING
A new brake shoe completely interchangeable with the standard metal shoe promises better train control, increased life and almost total spark suppression. Key to the breakthrough is an alloy of iron which exhibits a vastly different metallurgical structure from that of a standard shoe. The Samson shoe reduced stopping distance 32 percent and confirmed the improvement in train handling. The Samson retained the favorable friction characteristics of the standard metal shoe at static breakaway and low speed. Comparative sparking under drag braking conditions tested with cheese cloth placed in the trajectory of sparks leaving the wheel. At 45 mph, sparks from the standard metal shoe ignited the cheesecloth in seven minutes; Samson caused no fire.

TRAILS WITH GLUED WHEELSETS
One of the most recent developments in the metal adhesives field is their use in the assembly of wheelsets. One reason for this is the increasing demand for lighness of unsprung parts. The normal method of assembly of wheelsets by interference press fit has reached the limits which the materials can withstand. A careful choice of the adhesive to be used is most important in all cases, but especially so for such highly stressed parts as wheels, axles and tyres. With these factors in mind, the German Federal Railway decided on an experimental application of the process. Four axles were assembled using adhesive methods in the repair works at Stuttgart-Bad Cannstatt. For the joints between the wheel hubs and axles a very strong adhesive of low viscosity was chosen, but it was decided to press on the axle in the usual manner. A first test on a wheelset testing machine at the Minden Research Institute took the form of running 10,000 km with a constant axleload of 17 tons. This produced no displacement of the glued components, and it was noted that the wheelset ran remarkably quietly.

WHEELSET DEVELOPMENT REVIEWED BY ENGINEERS
Design and wearing qualities to accommodate increased speeds and axleloads predominate in the papers delivered at the Third Wheelset Conference. Spalling of wheels experienced on North American rapid transit systems had been brought about by wheel slip and it was recommended that a total adhesion system should be considered at the design stage of coaches.

In introducing synthetic brake blocks where wheel tyre cracking existed and it was considered that tyre steels which should be used were those which did not have a hardening tendency and soft steels of low carbon content which were immune from heat cracking. Resilient wheels for use under rail vehicles for suburban and main line railways, cast steel wheels, hollow-tread profiles, wrought-steel wheels, and non-alloy wheels are also briefly discussed as well as cast steel wheels.

DERAILMENT AT TYSELEY

An express passenger train comprising 12 coaches hauled by a Type 4 diesel-electric locomotive was approaching Tyesley North signalbox on the down main line at 60 to 65 mile/h when the bracket on the locomotive supporting part of the a.w.s. equipment became loose. The wheels of the rear bogie of the locomotive and of all 12 coaches derailed. Examination of the fractured bracket bolts confirmed that high stress fatigue failures had occurred in the four bolts. Use of maximum tightening torque of 758 lb-ft is essential to achieve the longest life under fatigue loading conditions. It was also recommended that the bracket design should be re-examined to see if longer bolts could be used.

ADVANTAGES OF HYDRAULIC BUFFERS

The hydraulic buffer automatically produces a steady retarding force of such a value that, whatever the speed of impact, the wagon is brought to rest as the buffer-stroke is completed. These buffers also produce a very low recoil. Hydraulic buffers make it possible for the safe speed of impact, to be raised from something over 4 mph to nearly 10 mph. Present-day marshalling yards already work with impact speeds of 10-12 mph and a survey carried out at one hump yard showed that 4 percent of impacts were at speeds of more than 10 mph. Hydraulic buffers also have a part to play in the reduction of shock in trains fitted with continuous brakes.

LIGHTWEIGHT PASSENGER STOCK DEVELOPMENT IN U.S.A.

A prototype stainless-steel passenger car, the Pioneer III, which meets all the strength and safety requirements of the Association of American Railroads, with a net weight of 595 lb. per passenger, has been designed by the Budd Company, Philadelphia. A feature is the lightweight four-wheel bogie with single air spring on each side, with tubular axles, and outside-mounted disc brakes. The basic design is suitable for both suburban and main line stock. The principal parts of the bogie are the side frames, bolster, and two air springs; there are no equalizer beams, springs, swing hangers, spring plank, or transom. Interior partitions are of micarta-faced plywood which is resistant to wear. Use is also made of laminated plastics for doors, vestibule ceiling panels, exterior door inner panels, air ducts, enclosure aroung the air conditioning, and seating.

DEVELOPMENTS IN SPHERICAL ROLLER BEARING AXLEBOXES--2

The carrying capacity of a roller bearing is increased to a greater extent by using larger diameter rollers rather than by increasing the number of rollers. Except for the difference in the end faces of the rollers, the rollers in the new SKF Type C spherical roller bearings are symmetrical. The close conformity and the uniform distribution of the load over the roller length--give an increased carrying capacity of approximately 15 percent. This means approximately three times longer fatigue life, a factor of no little importance. The bearings are pictured in several railway applications.

JOURNAL STOPS FOR WAGON-TYPE PLAIN BEARINGS

In a new A.A.R. journal bearing assembly, with all dimensions nominal and journals central laterally, the maximum displacement from impact is 7/16 in. Bronze stops, cap screwed to the side wall of the journal box to prevent displacement of the journal out of its bearing were considered the most practicable means to achieve the desired stabilization. The increased bearing life obtained with the journal stops is principally because of reduced end wear and the elimination of spread linings.

DISC BRAKES IN THE U.S.A.

In 1948 the Union Pacific Railraod decided to use disc brakes in new stock. When the first disc-braked cars were put in service, they were mixed with cars equipped with clasp brakes. Trains composed exclusively of cars with disc brakes were assembled. The results have been a reduction in noise and in jolting when trains are being stopped. Thermal cracking of wheel tires has been virtually eliminated. Certain interesting cost figures have been got out comparing the use of clasp and disc brakes on one of the trains over a

12-month period. The cast-iron tread shoes of the clasp brakes required renewal after every round trip of 4,598 miles, 73 changes of shoes thus being made during the year; the disc brake shoes ran an average of 90,000 miles each, and so required an average of 3.73 changes only. Over a full year, the renewals of short clasp brakes cost a total of $48,865.60 and of the long type $65,045.26, whereas the corresponding expenditure for Budd disc brake renewals was $7,221.48.

FRICTION MATERIALS FOR RAILWAY BRAKING
The Ferodo composition brake block is compared to cast iron brake blocks. The braking characteristics are shown for the average of 20 stops using emergency brake applications of a train travelling 50 mph. The deceleration time for the Ferodo brake was greater than the cast iron brake, but the stopping distance was less. A composition brake block is less abrasive to the wheel than a cast iron block, and the product of wear less harmful. Although the Ferodo block still wears more rapidly than the wheel, its life has been found to be equal to as many as five cast iron blocks in some instances. Flange profiles are shown comparing the two types of brake blocks as to flange wear.

MAINTENANCE CHECKS FOR ROLLER-BEARINGS
SKF has introduced an instrument for shock-pulse measurement of roller-bearings. The technique is based on spalling or flaking damage in roller-bearings producing mechanical shocks. Short-duration high-frequency oscillations produced by the shocks are transmitted to the bearing housing and by fitting measuring nipples to the housing at selected points, the shocks can be registered by an accelerometer. The magnitude of these is a measure of the degree of damage.

ELIMINATING THE HOT BOX
Elimination of freight car hot boxes is discussed as a result of experience on the New York Central during 1948-1949. The cars used has steel wheels, 5.5 times 10 in. journals, axleboxes fitted with tight lids, deflector strips, packing retainer springs, and drawgear protected by rubber pads. Maximum load on a bearing area in any axlebox could not exceed 199.2 lb. per sq. in. Based on the experience, the following was recommended: a packing retainer should be installed in every axlebox which would be capable of holding the packing in place under impact; journal box lids and dust guards should be kept as tight as possible, and suitable methods used to ensure that water and dirt are kept out of axleboxes; and defective wagon wheels should be replaced at the earliest possible moment. As longer-range measures, redesign of journals and bearings to reduce unit bearing pressures, of axles and axleboxes to eliminate collars on journals, and of frames and drought years of cars to minimize the effects on journal boxes of impacts between cars is suggested.

A GENERALIZED SPECIFICATION FOR COMPOSITION BRAKE BLOCKS FOR RAILWAY VEHICLES
The braking of railway vehicles may be improved technically and economically by a direct replacement of cast iron brake blocks by blocks of a composite material of the correct design and functional characteristic. Numerous available composite materials can introduce large savings due to their good wearing properties when compared to cast iron. As a result of excessive heat dissipation rates and thermal shock, rolling stock wheel treads can be seriously overstressed at the higher operating speeds by blocks of incorrect friction characteristic and physical design. This paper deals with the definition of the physical requirements related to the design of composition brake blocks for railway vehicles, and motivates a generalized specification for the performance characteristic.

PULLMAN'S APPROACH TO CENTER PLATE PROBLEMS
Tests were conducted on fabricated cushioned underframe center plates using a Hy-Cube car, using a car rocking device designed to excite a fully-loaded car at its natural roll frequency. Results were correlated with field service reports. Tests were in progress on the rocking device using a 100-ton covered hopper car. The conclusion of the two-year test program on cushioned underframe cars has indicated these results: rock and roll is instrumental in center plate wear and breakdown; breakdown originates in the transition radius and propagates into the transverse and longitudinal reinforcement; the 3/8" radius is not satisfactory for today's fatigue environment; longitudinal reinforcement on the center plate should be located over the outer circumference of the bowl; a flat center plate application significantly reduces the attachment pre-stress in the transition radius; both fabricated and cast center plates can develop cracking unless fatigue design is considered; the center plate application is related to car configuration; and supplemental snubbing devices that reduce car body roll would increase the fatigue life of center plates.

BALL AND ROLLER BEARINGS IN MODERN ROLLING STOCK
An increasing number of specifications calls for ball or roller bearings to be fitted at all vital points for locomotives and coaches. Advantages which have been realized include: (1) up to 85% lower starting and about 10% lower running resistance. (2) Reduced charges for inspection and maintenance. (3) Fewer hot boxes, resulting in an increased availability factor. (4) More economical use of lubricants. (5) Maintenance of axle and valve gear centres as designed, by virtue of the absence of wear. In the construction of locomotives and rolling stock generally, the following gives a fair idea of the extent to which this type of bearing has been used: locomotives: axleboxes, bogie driving, truck, and bogie pivots; spring compensation beams. Rolling stock: axleboxes bogie pivots. Diesel-engine vehicles; axleboxes; gearboxes; engine bearings; generator, armature bearings; motor armature bearings.

APPARATUS FOR DETECTING WHEEL-SEAT FLAWS IN RAILWAY AXLES
The Research Department of the London Midland and Scottish Railway Company undertook the task of devising and developing a method of detecting wheel-seat flaws in railway axles without removing wheels from axles or even wheel and axle assemblies from the coach. The essential item consists of a rigid steel ring of square cross section, split diametrically to allow it to be clamped to the axle under test. Contact with the axle occurs at three spherical seatings, of which two are fixed to the inside of the ring and the third is adjustable and is screwed to grip the axle firmly after the two halves of the ring have been bolted together. The system described comprises essentially, two nominally rigid reference planes, fixed normal to the axle and set one on each side of a possible flaw situated near the inner end of the wheel seat. If such a flaw does exist the strength of the axle will be less in the direction passing through the center of the axle and the centroid of the flaw than in the direction at right angles to it. Details and case histories are given.

HEAVY-DUTY CAST-STEEL WHEELS FOR FREIGHT CARS
American Brake Shoe Company has developed a wheel now in volume production for hard service on freight vehicles for heavy commodity loads. During service testing on 23 U.S.A. railways in 1947-55 the wheels have run more than 5,600,000 miles on van, hopper, tank, flat, refrigerator, and other types of wagon of 40, 50, and 70 tons capacity. Five of the vehicles averaged 275,000 miles of operation and one totalled more than 350,000 miles. Measurements of rolling and braking wear on 1,000 of the new wheels showed only equal results to that of other steel wheels and was less in some service conditions. The Casting process is described and a cross section of the wheel, known as the Southern wheel, is shown.

TUBULAR CONSTRUCTION OF LIGHTWEIGHT STOCK
Experiments with tubular structure under impact conditions revealed that buckling in both circular-and square-section thin-wall tubes under dynamic

loading always started at an end, and at high speeds it was largely confined to that part of the specimen. As related to conventional railway-coach structure (where the longitudinal strength resides mainly in the heavy underframe) the tubular structure can absorb more collision energy for a given shortening. Some projections to coach construction are also given.

ACCIDENTS ON BRITISH RAILWAYS IN 1959
There were a total of 1154 accidents in 1959. Of these, 609 were attributed to the human element, 113 were caused by technical defects, and 432 resulted from other causes. Within the causes of the human element category there were 276 collision, 119 derailments, 174 running into obstructions, 7 fires, and 2 miscellaneous accidents. In the technical defects category there were 12 collisions, 69 derailments, 14 running into obstructions, 13 fires and 5 miscellaneous accidents. The other causes category accounted for 130 collisions, 27 derailments, 205 running into obstructions, 42 fires, and 28 miscellaneous accidents.

ALUMINUM IN ROLLING STOCK: THE VALUE OF RESEARCH AND DEVELOPMENT
In Canada, aluminum is considered standard for box cars roofs, the inside lining of refrigerator cars, brine tanks, hopper cars for bauxite and alumina, hopper car hatch covers, piggy-back trailers and passenger car furnishings. The properties of aluminum which make it ideal for use in rolling stock are good strength and impact resistance, light weight, excellent corrosion resistance and good fabricating characteristics. Service experience and impact tests, which were more rigorous than conditions encountered normally, have shown that all-welded aluminum hopper cars are strong and rugged enough to withstand such severe treatment. Impact and fatigue test results are reported for several types of aluminum cars. The lightness of aluminum cars mean that fewer of these cars are required to transport a given cargo. The excellent resistance of aluminum to the weather and corrosive cargoes means that annual maintenance costs can be lowered appreciably. The life of the aluminum cars will be governed by failure due to mechanical causes rather than corrosion and even after their normal service life they will have a high scrap value.

THE BEHAVIOUR OF THE MOTIVE POWER AXLES (WHEELS) ON THE S.N.C.F.
Wheel-set stresses are modified by the action of the strains inherent in service which may be categorized as follows: those affecting the shrinking-on; those which correspond either to vertical effort exerted by the wheel on the rail, essentially cylical, or to the lateral reactions of the rail on the wheel both cyclical and erratic (abnormal shocks); and those set up by a temperature rise, due to braking. The SNCF has tested, both in the laboratory and in service, the diverse stresses as they are linked up with strains. Common damages to wheelsets are described and are shown. Wheel manufacturers are using the test results to enhance wheel design criteria.

RESEARCHES ON INCREASING THE FATIGUE STRENGTH OF PRESS-FITTED AXLES
Fatigue tests with 50 mm dia. press-fitted specimens, heat-treated by Tufftride process or other processes, were made to determine the influence of those treatments upon fatigue strengths, sigma(sub omega 2) and sigma(sub omega 1). These are fatigue strengths based upon complete fracture of the shaft and initiation of minute fatigue cracks in fretted region. Main results obtained as are as follows: tufftriding is strongly effective to increase sigma(sub omega 1) as well as sigma(sub omega 2); if the superficial compound layer of iron and nitrogen is removed, sigma(sub omega 1) is lowered but sigma(sub omega 2) does not change; specimens, heated in Argon gas at the same temperature as Tufftride process followed by quenching in water, have the same sigma(sub omega 2) as that of Tufftrided ones. It is concluded that the increases of sigma(sub omega 1) and sigma(sub omega 2) by Tufftriding are due to the hard compound layer and the compressive residual stresses.

DERAILMENT DETECTION SYSTEM
The application of a Servo Rail Detector to cars which carry hazardous materials will cause the brakes to be applied immediately if any of the wheels of the car become derailed. This will bring the train to a stop and greatly reduce the possibility of a catastrophic accident. Each truck of a car has a sensor mounted near each wheel. The sensors are narrower than the width of the wheel. A nickel cadmium battery and wheel-driven alternator provide power for the system. The system will not interfere with or be interfered by signal or communications systems. It will operate over a temperature range of-40 degrees to 160 degrees F., and will operate for 7 days on battery power without car moving.

WHEEL, AXLE, AND RAIL STRESS PROBLEMS RELATED TO HIGHER CAPACITY CARS PART 1 AXLE PROBLEMS
This paper submits some fundamental considerations in the design of axles and propose two new axle designs of 72,000 and 80,000 pounds capacity. Larger axle design standardization must satisfy a wide range of car geometry factors such as (a) center of gravity height from 72 to 94 in and (b) wheel diameter ranging up through 40 in. The effect of these factors on axle capacity is shown by curves derived from the Reuleaux formula; serious deficiencies in this formula are also discussed. Other primary axle design factors presented are (c) wheel seat design (f) effect of switches, frogs, and crossings (e) effect of curved track (h) effect of flat spots and shellouts of wheel treads.

BRITISH RAILWAYS INVESTIGATIONS INTO THE PROBLEM OF AXLE FATIGUE FAILURES UNDER THE WHEEL HUB
This paper discusses the problem of the fatigue failure of railway axles and points out the main factors contributing to failures of this type. The reasons behind the investigation currently in progress are described and the results obtained to date are given. Future work is detailed and it is shown how the results of these experiments should enable a more satisfactory axle service performance to be obtained. A certain amount of increase in axle fatigue strength has been obtained by the straightforward application of metallurgically better materials--as happened when wrought iron was replaced by steel. However, because of the overriding importance of shape in a component subjected to fatigue loading, as an axle is, it can be predicted that the use of even higher strength steels will not produce proportionate increases in axle fatigue strength unless allied to a shape of axle which excludes, as far as possible, all notch and stress concentration effects.

RESEARCH ON THE OPERATING STRESSES IN PATH RAILCAR AXLES, DRIVE SYSTEMS, WHEELS, AND RAIL JOINTS
This paper identifies the cause of premature cracking of axles with inboard bearings as being the bending-mode oscillation of the axle. It points out the importance of gear-tooth separation produced by torsional oscillations in the drive motor system in both right angle and parallel drive gear failures. A unique technique of simultaneous measurement of impulse and thermal loads on the wheel tread is explained and the test data are presented. The relation between the wheel impact loads and the dynamic behavior of rail joints is shown.

WHEEL, AXLE, AND RAIL STRESS PROBLEMS RELATED TO HIGHER CAPACITY CARS--WHEEL PROBLEMS
Factors to consider in selecting a wheel for high capacity cars--aside from dimensional compatibility with the rail and truck, are wheel class, wheel diameter, and rim thickness. Rim thickness determines replacement period and is primarily a function of car utilization. Wheel diameter determines stress in the contact area of the wheel tread and rail. Wheel class determines relative resistance of wheels to wear and service damage, principally shelling and thermal cracking. Safety and economy of the operation depends largely on freedom from excessive shelling, thermal cracking, and rapid wear, all commensurate with the cost of new wheels, reconditioning, and maintenance.

A THREE-DIMENSIONAL FINITE DIFFERENCE SOLUTION FOR THE THERMAL STRESSES IN RAILCAR WHEELS
A numerical solution is presented for both the transient temperature and three-dimensional stress distribution in a railcar wheel resulting from a simulated emergency brake application. A computer program has been written for generating thermoelastic solutions applicable to wheels of arbitrary contour with temperature variations in both axial and radial directions. The results include the effect of shear stresses caused by the axial-radial temperature gradients and the high degree of boundary irregularity associated with this type of problem. The program has been validated by computing thermoelastic solutions for thin disks and long cylinders; the computed values being in good agreement with the closed form solutions. Currently, the computer program is being extended to general stress solutions corresponding to the transient temperature distributions obtained by simulated drag brake applications. When this work is completed, it will be possible to synthesize the thermal history of a railcar wheel and investigate the effects of wheel geometry in relation to thermal fatigue.

ANALYSIS OF RESIDUAL, THERMAL, AND LOADING STRESSES IN A B33 WHEEL AND THEIR RELATIONSHIP TO FATIGUE DAMAGE
This investigation involves the problem of service loading conditions that produce the highest stresses and the possibility of fatigue damage. Static loading, rim heating, residual stress measurements, and fatigue tests were made in the laboratory on representative b33 wheels. A series of simulated loading conditions was studied and the resulting stresses combined by simple superposition principles. The resultant stress patterns were compared with fatigue test results using the modified Goodman relationship. In this way the service loading conditions that produce fatigue damage may be predicted.

EFFECT OF DESIGN VARIATION ON SERVICE STRESSES IN RAILROAD WHEELS
The continuing trend of present railroad operating practices toward higher wheel loads and speeds has created the need for better design criteria to insure that wheel configurations are the best attainable. Computer programs to simulate service braking and loading conditions have been applied to various wheel designs and the braking and loading stresses computed. The results indicate that cyclic stresses of significant magnitude may occur under different operating conditions, so fatigue concepts are important in wheel design considerations. There was no one optimum wheel design for all possible service conditions, although several configurations showed promise. A method was proposed for optimizing design for specific service conditions to safeguard against fatigue damage.

ANALYSIS OF TAPERED ROLLER BEARING DAMAGE
Tapered roller bearings, damaged in field applications or laboratory tests have been subjected to a systematic analysis of such damage to prevent its recurrence in the field or to gain knowledge of its control in the laboratory. A method of analysis is described which has been developed for examining such bearing damage. The essential steps of the analysis are described with emphasis on the visual classification and metallographic examination of the damage. Bearing damage is classified in two major categories, that resulting from contact fatigue, and that due to other mechanisms. Damage which is related to material, surface finish, geometry, local asperities (grooves and bruises), the lubricant viscosity is usually due to contact fatigue. Damage due to other mechanisms is that which results from obvious mechanical, chemical, or electrical factors in the application which either change bearing geometry or eventually cause contact fatigue.

FATIGUE TESTS OF FREIGHT CAR AXLES 5 1/2 TIMES 10 INCH JOURNALS
The series of fatigue tests was concluded on a proposed design of raised wheel seat freight car axle with "as forged" (unmachined) body between wheel seats. The proposed design has a considerably greater fatigue strength in the wheel fit than the Standard Freight Car Axle (Black Collar Design). One group of Standard Freight Car Axles had an abnormally low fatigue resistance of 13,000 psi in the body portion between the wheel seats. This value was raised to the normal value of 17,500 psi by stress relieving at 1150 degrees F for six hours. One group of axles of the proposed freight car design had a similarly low body fatigue resistance of 13,000 psi. Machining the axle body was found to be beneficial in improving the fatigue resistance. This finding may mean that unfavorable residual stresses due to straightening were removed by machining.

STRESSES IMPOSED BY PROCESSING
Types of residual stress, measurement and formation are discussed. Residual stresses were measured on two different sizes of truck axle shafts of 1 11/16-in. and 2 1/8-in. diameter. Two specimens were taken for residual stress investigation from each shaft, one toward the flange end and the other from the splined end. Metallurgical examination was made. Results of completely reversed torsional fatigue tests made on 1 11/16-in. diameter shafts are presented. Fatigue tests were made in rotating bending on full-size large-diameter shafts of two different designs. Fatigue results are summarized. Residual stresses were measured in these large shafts. Favorable surface compressive stresses were determined for these shafts water-quenched from the tempering temperature as compared with nil stresses in those aircooled. It was concluded that favorable thermal stresses were a very important consideration in improving fatigue strength.

FATIGUE OF LARGE SHAFTS BY FRETTING CORROSION
Rotating bending fatigue tests were made for the AAR on sixty-six shafts of 9 1/2 inches diameter. A press-fitted member was mounted on each shaft. Fatigue failure initiated in the shaft under the fitted member. Six different engineering steels were used for the shaft forgings. Some steels were normalized and tempered while others were quenched and tempered. Two groups of specimens were quenched below the critical temperature to develop residual compressive stresses in the surface zone. All shafts were run 85 million stress reversals unless breakage developed earlier. The maximum allowable bending stress of endurance limit to prevent the shaft breaking off under the fitted member for all normalized and tempered or quenched and tempered shafts ranged from 9,500 to 12,500 lb. per sq. in. The two groups of shafts given a subcritical quench gave endurance values of 18,000 and 19,000 lb. per sq. in.

FATIGUE TESTS OF FREIGHT CAR AXLES 5 1/2 TIMES 10 INCH JOURNALS
This report concludes the series of fatigue tests made at the Canton Laboratory on a proposed design of raised wheel seat freight car axle with "as forged" (unmachined) body between wheel seats. These tests constitute a part of the program undertaken to develop an improved freight car axle. The conclusions drawn from this investigation are as follows: 1. The proposed design "as forged" raised wheel seat freight car axle has a considerably greater fatigue strength in the wheel fit than the Standard Freight Car Axle (Black Collar Design) due to two factors: (a) The removal of the black collar and use of the raised wheel seat design gives an improved shape, resulting in at least 13% greater fatigue resistance to breaking off in the wheel fit. (b) The increased diameter at the wheel seat decreases the stress at that location by 21%.

IMPACT TESTS OF BALTIMORE AND OHIO RAILROAD TWO-POCKET FIFTY-TON HOPPER CAR LOADED WITH FERROMANGANESE
This report covers the results of a series of impact tests with a two-pocket fifty-ton hopper car loaded with ferromanganese. The purpose of this series of impact tests was to determine the safety of shipping this dense commodity in a standard hopper car that has auxiliary bracing between the hopper doors and also to determine the extent of the damage that can normally be expected on the hopper pockets and door equipment when the car is

subjected to over-solid impacts. The following conclusions were made. The Baltimore and Ohio two-pocket hopper car, Class N-44, is representative of equipment that can be safely used to transport ferromanganese if the hopper doors are properly braced in the same manner used in this series of tests. The results of this test show that it is reasonable to expect a certain amount of bulging and distortion to the hopper doors, frames, and the hopper sheets adjacent to the door when ferromanganese is transported in this type car when the car is subjected to impacts at speeds of 6 mph or greater. The impacts in this series of tests were as high as 10.9 mph, which is higher than would be expected in normal service.

COMPOSITION BRAKE BLOCKS--INTERACTION BETWEEN COMPOSITION BRAKE BLOCKS AND WHEELS

The service tests with various makes of K-block on the Berliner S-Bahn are described. The object of the tests was to study the interaction of the two friction elements, block/wheel. Although a strong tendency for the formation of cracks in wheel tires had occasionally been observed with K-blocks, in the service tests such a tendency could not be detected. All the stages of grooving and follow-wear were present on the tires. Similar phenomena had been observed by the SNCF on suburban services. Experience gained by the DB showed that some difficulty arose due to metallic particles sometimes becoming embedded in the braking surface of the block. K-blocks were used extensively on the London Transport Underground lines. Thermal cracking, tire spalling and wear constituted a special problem on the frequently-stopping motor coaches with heavily-loaded small diameter wheels, running in tube tunnels. The performance of a K-block depended on various parameters: characteristics of the block and of the wheel steel, application conditions, service conditions, weather, and shape of block. The development of a universal K-block would be difficult.

COMPOSITION BRAKE-BLOCKS-EFFECTS OF HUMIDITY ON BRAKING

Tests carried out by the SNCF, to determine the effects of humidity on braking; were made with 20 different types of existing composition brake-block. On the test rig at Vitry, braking tests were made from speeds of up to 160 km/h to a stop, and continuous braking tests were made with single cars at about 60 km/h. In service, fly-shunting tests at speeds of up to 140 km/h were made. The brake-block wear was not measured during the tests on wet rails. The similarity of the curves obtained with the different makes of block on dry wheels was not repeated on wet wheels. It would seem that not all the blocks have been designed and manufactured with the same object of obtaining satisfactory performances under wet conditions.

Restrictions on the use of this document are contained in the explanatory material.

COMPOSITION BRAKE BLOCKS-METALLIC INCLUSIONS IN THE COMPOSITION BRAKE BLOCKS

Metallic inclusions is given types of composition brake blocks lead to excessively severe wear of the tires and of the blocks. Recent experience has shown that not all composition brake blocks are affected by metallic inclusions. A list indicates those composition brake blocks which, according to data collected up to mid-1969, are unaffected or are affected only in certain isolated instances by metallic inclusions, and which therefore behave favourably with respect to undue wear of the wheel-tire. The list also shows which organizations obtained these favorable results, with which type of vehicles and in which kind of service.

COMPOSITION BRAKE-BLOCKS-TESTS WITH COMPOSITION BRAKE-BLOCKS OF VARIOUS DIMENSIONS AND SHAPE

The German State Railway conducted the necessary tests on the bench and on the Berlin S-Bahn. The tests were based on the assumption that the wheel wear might be diminished if the shape of the composition brake blocks was altered from the usual rectangular shape taken over from cast-iron blocks. A number of different geometrical shapes of the friction surface of composition brake blocks were considered. The coefficient of friction under various conditions was similar with all block shapes tested. None of the block shapes tested produced any bad side effects. It was not possible to find any significant differences between the different block shapes when braking with one block per wheel or with two blocks per wheel; though tire wear for braking with one block per wheel was slightly lower than that for braking with two blocks per wheel. The tests have not revealed any compelling reason for diverging from the customary simple rectangular shape brake blocks.

Restrictions on the use of this document are contained in the explanatory material.

GENERAL PROBLEMS CONNECTED WITH WHEELS AND THEIR ASSEMBLY: SOLID CAST-STEEL WHEELS, WHEELS OF DIFFERENT DIAMETER AND SHAPE--THIRD CONTRIBUTION TO THE STUDY OF SOLID CAST-STEEL WHEELS

In this report an account is given of the running tests, the braking tests on the wheel testing machine and the test runs on steep falling gradients. The running tests employed wheels of 730 mm diameter with treated wheel-rim of non-alloyed steel with a carbon content of either 0.61% or lower than 0.5% with an ultimate tensile strength of 115 to 130 hbar and 84 to 101 hbar respectively. Other tests were made with solid wheels of 920 mm diameter made of Wt steel (carbon and manganese content lower than or equal to 0.52% and 0.80% respectively. These tests consisted of falling-gradient runs on the St. Gothard line and of runs on flat sections under loaded wagons. Some wheels were also submitted to tests on the test rigs at MINDEN, VITRE-sur-SEINE and DERBY, in order to determine their behavior under the effect of heat generated by braking (liability to thermal cracks and deformations of the wheel-rim). Finally, one wheel of 730 mm diameter and wheels of 920 mm diameter of Wt steel were submitted to investigations in the laboratory and the latter wheels were in addition, studied with a view to the stresses developed. The braking tests carried on the rig with 730 mm diameter ABEX wheels have given unfavorable results. The running tests in commercial service have also given unfavorable results (spalling of running-tread). Concerning the GRIFFIN wheels of the same diameter, the running tests have also supplied disappointing results, there wheels displaying spalling or even perhaps flaking. The ABEX and GRIFFIN wheels of 970 mm diameter with treated wheel-rim and somewhat high carbon content showed a good behavior in SWEDEN during tests under high load (25 t/axle) but very mild braking conditions, the climatic conditions however being very severe. The 920 mm ABEX wheels, ordered in Wt steel have shown a good behavior during the running tests and du-

the braking-tests on the MINDEN, VITRY and DERBY rigs (resistance to thermal cracks). However, during the falling-gradient runs on the St. Gothard line, they had given rise to deformations reducing the play of the axle.

BEHAVIOUR OF THE METAL OF THE RAILS AND WHEELS IN THE CONTACT ZONE--ENQUIRY INTO THE PROBLEM OF SMALL DIAMETER WHEELS

This report summarizes the responses to an enquiry into the effect that a reduction in the diameter of wheels would have on the behavior in service of the rails and wheels. Information was collected on the subject of P/D ratios (P = load per wheel in tons, D = diameter in meters) and includes an analysis of tests carried out by the U.S., Russia, Germany, the British and the French. Very different values of P/D were found, depending on the railway and especially on the type of steel in the rails.

THE DUAL ROLES OF DESIGN AND SURFACE TREATMENT IN COMBATING FATIGUE FAILURES

The problem of producing components which will have satisfactory lives under repeated stress conditions requires a twofold approach. In the first instance the design must take account of any stress concentration effects in the component by geometrically distributing the material in the most efficient way so as to reduce such stress concentration effects to a minimum. The second approach is based on the fact that fatigue failures in the vast majority of cases are initiated on the surfaces of components. The designer must consider what deleterious surface effects occur on the component being designed, and counter these with the use of a surface treatment applicable to the particular case being studied. The present-day incidence of fatigue failures in all branches of engineering 90 percent of all service failures, is intolerably high. The importance of the twofold approach in designing for fatigue loading conditions is extremely important.

COMPOSITION BRAKE BLOCKS AND TYRES

This paper describes some of the problem which have arisen from the use of composition brake blocks in the past. For at least two of these, wet stopping performance and thermal cracking, there is now an understanding of the problem and possible solutions. Present-day production has also resulted in blocks free from the other difficulties. Other methods of avoiding the dangers associated with thermal cracking have been indicated: these involve moving away from the classic wheel and tire arrangement and the materials which have persisted for many years.

MEASURES TO COUNTER FATIGUE FAILURE IN RAILWAY AXLES

This paper reviews the experience in London Transport of fatigue cracking in railway axles, and presents the results of laboratory fatigue tests on full-scale axle specimens under simulated rotating bending. The investigation was undertaken with the aim of entirely eliminating fatigue cracking and fretting under the press fits of wheel-axle sets. Cold rolling of wheel seats strongly inhibits the propagation of such fatigue cracks but it does not prevent their initiation. The introduction of a stress-relieving groove, such that the edge of the press fit overhangs the groove, leads to a marked reduction in fretting and increase in life of test specimens, and the results of a limited service test suggest that the presence of such a groove reduces the stresses under the wheel hubs to a level at which cracking is eliminated.

DESIGN CONSIDERATIONS FOR NEW ROLLING STOCK FOR THE VICTORIA LINE, LONDON TRANSPORT RAILWAYS

The 1967 Tube Stock incorporates many new features, some arising directly from the fact that the trains will only carry a single operator. The background to the development of many of the new items is traced and reference made to prototype testing which was carried out on a very extensive scale. The rolling stock, which is suitable for operation in 12 ft. diameter tunnels, is made up into 4-car units each consisting of two driving motor cars and two trailer cars. Two units will normally be coupled together to form an 8-car train. The trains are arranged for automatic operation and are controlled by a single operator, situated in the front cab, who controls the door operation and the starting of the train. The station to station run is normally performed entirely automatically, but manual control can be substituted in the event of failure of the automatic equipment.

SUMMARY OF FATIGUE TESTS OF FREIGHT CAR AXLES AND ESTIMATED EFFECT OF OVERLOADING
This report was prepared to accumulate and consolidate all data now available for consideration on the problem of overloading of cars in order to resolve the question as to whether the strength of axles and other car conditions justify changes in the present rules which would permit or restrict heavier loading. With a 10 percent overload, the estimated number of axles which will fail before running their full life expectancy is 72 percent. With a 20 percent overload, the estimated number of axles which will fail before running their full life expectancy is 100 percent.

FATIGUE COMPARISON OF 7-IN. DIAMETER SOLID AND TUBULAR AXLES
The object of this experimental investigation was to determine the fatigue resistance of solid versus tubular type axles for railroad car service. Solid axles tested represented conditions consistent with existing railroad specifications. The tubular axles investigated were of two types; one of which was tested with permission of A.A.R. and the results reported by the manufacturer, the other was tested as a separate project in order to contribute information on certain questions pertaining to the fatigue strength of axles. Rotating cantilever beam fatigue tests were made on axles about 7 in. in diameter using steel of about S.A.E. 1045 analysis. Comparison of axle fatigue resistance due to a press-fitted wheel was made between "as-forged" solid members and seamless tubes in "hot-rolled" and several conditions of heat treatment. Results showed that tubular axles having high tensile strength values may or may not exhibit greater fatigue strength than those having lower physical properties. Observations on the effect of residual stresses are given. Some tubular axles showed greater fatigue strength than the solid ones.

PANEL DISCUSSION--C&NW WAGES WAR AGAINST TRAIN ACCIDENTS
This paper surveys the creation and current operation of the C&NW, Accident and Loss Prevention Department. Topics include procedures for analysis of derailments, review of hot box and dragging equipment detector systems and implementation and rules education. The first year after creation of this department, the costs of our train accidents were down over 30% from the previous year of 1966. Even more encouraging was the fact that losses resulting from human failures decreased over 90%.

WHAT CAUSES WHEEL TREAD DEFECTS? PART 1: SHELLING
Studies were made of wheels that shelled in service after being subjected to the usual on-tread braking as well as a wheel equipped with disc-type brakes. These studies have indicated that shelling is essentially a fatigue failure that is caused by rolling loads. The formation of structurally weakened metal as the result of the heat of braking friction is believed to accelerate the formation of shelling cracks. Macroscopic examinations of radial-tangential sections from shelled areas have indicated that shelling is caused by cracks that form at angles of 30 to 50 deg to the tread surface. Because shelling cracks are oriented at 30 to 50 deg to the tread surface they are assumed to be caused by high shear stresses developed by rolling loads.

B1 040812
WHAT CAUSES WHEEL TREAD DEFECTS? PART 2: THERMAL CRACKING
United States Steel undertook an investigation of wheel-tread defects. Shelling was shown to be the result of repeated stress application to the rolling wheel, which apparently caused the tread metal to fail in shear. Cracks propagate from below to the tread surface. When two of these cracks of opposed orientation meet beneath the tread, metal between them is loosened and finally expelled. This is the typical shelling type of failure. While shelling apparently is not caused by braking, there are wheel defects which can be caused by stresses that develop in the wheel rim as a result of thermal gradients generated by friction between the tread and brake shoe during braking. Shelling and thermal cracking of railroad wheels shorten wheel life, and checking brought on by severe braking may occasionally result in a complete wheel failure.

STANDARDIZED FORMAT FOR RAILROAD ENVIRONMENT WITH APPLICATION TO FATIGUE DESIGN AND TESTING
This paper outlines a format for recording railroad environmental spectrum data that utilizes the standard arrangement of the modified Goodman diagram. In this form the environmental data is applicable to theoretical finite life fatigue design and to variable-cycle spectrum-type fatigue testing. Maximum loadings for operational guidance, equivalent static design analysis, lading damage studies, and proof testing are also accurately portrayed. The extensive environmental data requirements for modern design dictate the need for standardization of data format and content to provide compatibility of data from various sources and facilitate formation of the national data bank required by the railroad industry.

THE REQUIREMENTS FOR A BALANCED DRAFT SYSTEM COUPLERS, RAILWAY FREIGHT CARS TO PRESERVE INTEGRITY OF OPERATIONS, MAXIMUM AVAILIBILITY AND LOW MAINTENANCE COSTS. PANEL DISCUSSION
Train Partings are a problem, but railroads do not have unlimited funds. So a balanced draft system is required, in which each component is engineered with regard for the other components. Specifications are presented for Grade C and Grade Couplers. The knuckle is designed as the weakest line, but with new knuckles, many old couplers fail first. Standardization of couplers and components of the draft system is discussed. Statistics are given on components in service and on failures. The comments of delegates and the responses of the panel are presented.

CHIEF OPERATING OFFICERS' VIEW OF MODERN FREIGHT CARS AS THEY AFFECT TRAIN OPERATIONS
The success of a company depends on the judgement used in making capital expenditures. The single most important area for capital investment is the freight car fleet. The freight cars are the key to quality service, new business and future profitability. Engineering of freight cars is a must. Component reliability and ride quality are critical. Investment price and maintenance cost are problems. The dynamic characteristics of cars and the reliability of their components have major influences on freight train safety. 'Scaled up' car fleets have had an impact on track. There must be a total systems approach to freight trains and their operation. On the B&LE, two industrial engineers have been appointed to investigate each derailment, to pinpoint responsibility, and to identify a solution. A summary of their investigations is given. Delegate comments and the panels responses are included.

BRAKE SHOE PERFORMANCE ON 100 TON FREIGHT CARS
The braking performance of 100-ton cars should be viewed from the ability to provide a braking level or stopping capability no less favorable than lighter weight cars. Such a performance level can not be matched by 100-ton cars with cast metal shoes at a reasonable braking ratio. However the performance criteria for COBRA shoes on 100-ton cars is to provide a stopping ability, at minimum, on less favorable than a 50-ton car with cast metal shoes. This has obvious benefits in the areas of signal spacing, high speed consideration, etc. With this stopping ability however the most advantageous maintenance and economic relationships available should be realized. With the number of existing 100-ton cars with metal shoes presently in service, together with the majority of new 100-ton cars having COBRA shoes, it has been possible to accurately measure the economic and braking performance relationships between the two brake shoe concepts. The information contained in this presentation provides a summary of data in both of these areas.

YOKE SERVICE PERFORMANCE, AAR MECHANIZED CAR REPAIR BILLING EXCHANGE SYSTEM DATA
Presents the initial 18 months of yoke removal data (for foreign cars only) reported to the newly established AAR Mechanized Car Repair Billing Exchange System in Washington, D. C. This computerized system lists the reason the yoke was removed under eight code numbers which interpreted mean, worn out, broken, missing, bent, bent beyond repair, obsolete, account other repairs, and removed in good condition. There were a total of 19,647 yoke removals reported in the initial 18 months. The number of reporting railroads (11 total) participating in the system at the end of the first 18 months accounted for a little over half of the freight car ownership in 1972 and therefore perhaps about half of the yokes removed from foreign cars by railroads (foreign cars are cars not owned by the reporting railroad). Considering this condition combined with other factors it seems reasonable to multiply the total removals reported to the AAR Billing Exchange by about 6 to obtain the total removals by the industry for the entire current service fleet of freight cars.

HOW SAFE WERE THE MOTOR TRAINS?
This article is a facet of a comprehensive study on the rise and fall of motor trains in the United States. The term "motor train" is used in this article because "motor car" has been used loosely in the railroad literature to designate "motor trains," maintenance-of-way cars, and automobiles and buses. For the purposes of this article, a "motor train" is a passenger train of one, two, or three cars, which is not pulled by a locomotive, but has a self-contained power plant in a vehicle partially devoted to revenue space.

WHEEL LOAD, WHEEL DIAMETER AND RAIL DAMAGE
The dual study of wheel load, wheel diameter and rail damage is presented. It is concluded that formulas derived from earlier studies should be applied to today's situations for worn wheel on worn rail. A report on shelly rail reviews previously gathered information before discussing a recommendation that a limitation be placed on wheel loads for diesel and turbine locomotives. The recommended limit for wheel loads is 800-lb per inch of diameter. The study concludes that shelly rail stress increases in proportion to the cube root of the load; the life of the rail up until the time failure occurs decreases very sharply for any small increase in stress.

STANDARDISATION OF WAGONS. PROGRAMME OF TESTS TO BE CARRIED OUT ON WAGONS WITH STEEL UNDERFRAME AND BODY AND SUITABLE FOR BEING FITTED WITH THE AUTOMATIC BUFFING AND DRAW COUPLER
This report replaces the previous B 12/RP 17 report, 1st edition. It surveys all the tests which are at present considered as representing the complete series of tests to which a new type of wagon can be exposed. The conditions under which these tests should be made and the results to be obtained (maximum or minimum values) are laid down for each test. On account of the detailed information, it contains taking into consideration the developments which have taken place the last few years in the construction of goods wagons, this report constitutes a valuable basis for the design of new types of wagons.

Restrictions on the use of this document are contained in the explanatory material.

STANDARDIZED FORMAT FOR RAILROAD ENVIRONMENT

This paper outlines a format for recording railroad environmental spectrum data that utilizes the standard arrangement of the modified Goodman diagram. In this form the environmental data is applicable to theoretical finite life fatigue design and to variable-cycle spectrum-type fatigue testing. Maximum loadings for operational guidance, equivalent static design analysis, lading damage studies, and proof testing are also accurately portrayed. The extensive environmental data requirements for modern design dictate the need for standardization of data format and content to provide compatibility of data from various sources and facilitate formation of the national data bank required by the railroad industry.

COMPONENTIZATION FOR FATIGUE DESIGN AND TESTING

This paper briefly reviews the most common cause for fatigue initiation in freight cars, the specialized data required for theoretical fatigue design, fatigue design criteria, appropriate modern fatigue testing equipment, and the types of full-scale component tests believed most applicable to the car building and railroad industry. The concept of componentization is introduced as a means for expediting both the fatigue design and testing phases of a freight car development program. An objective has been to present the overall aspects of the subject in terms understandable to the person who is not an expert in the fatigue area by presenting only the fundamentals most directly applicable to freight cars.

ENVIRONMENTAL FINITE LIFE FATIGUE TESTING. UTILIZING MINER'S HYPOTHESIS

This paper outlines one method suitable for cost effective computerized theoretical finite life structural fatigue design and determination of means for conducting laboratory fatigue tests that can predict or confirm finite service life of a component or product. Basic modified Goodman type fatigue test data is utilized with the actual environmental loading spectrum and Miner's hypothesis to determine the damaging cycles experienced in service. The total damaging portion of the environmental loading incurred during the long life of railroad equipment can then be applied in laboratory tests of practical duration. Hence, this is truly an environmental test and not what is often termed an accelerated fatigue test. The technical opinions expressed herein are those of the author and do not necessarily represent the policy of the Association of American Railroads.

DEVELOPMENT OF FATIGUE STANDARDS FOR FREIGHT CAR TRUCK COMPONENTS AND WHEELS

Factors which should be considered in the development of fatigue standards for freight car truck components and wheels are discussed. These standards would be formulated to provide a desired level of operational reliability, and they would be based on the fluctuating loads acting on the components in service. Typical data describing this environmental are presented. Statistical considerations in establishing the margin between the environmental loads and component fatigue strength are also described.

DETERMINATION OF CAR BODY CENTER PLATE FATIGUE DESIGN CRITERIA BY FULL-SCALE CAR TESTING

Fatigue design criteria are established based on full-scale car tests conducted on a 100-ton Southern Railway Hopper car. Stress levels on body center plate and its attachments to the car were determined for static car loading by means of jacking, for standing car dynamic loading under a full roll mode received on AAR rock and roll environmental prepared track testing. Correlation of determined stress loadings leads to three proposed axioms for design criteria.

GESCHICHTLICHER WERDEGANG, ARBEITSGEBIETE UND GLIEDERUNG]
After some general remarks on the problems in connection with the riding qualities and vibration properties of railway vehicles, the present state of research in this field is outlined briefly. The department for riding qualities and vibration engineering of the research institute, which is engaged in research work in this field at Deutsche Bundesbahn, has originated from the research centres for locomotives and wagons of the former RAW in Berlin-Grunewald. As compared to the original tasks of these research centres, the present fields of activities of the department are considerably more diversified and mainly focussed on the solution of the problems arising in connection with the proposed higher train speeds. In conclusion, the setup of the department is described, referring also to the special requirements regarding the technical qualifications and character of the employees. [German]

STRUCTURAL PROBLEMS ASSOCIATED WITH THE PREDICTION OF VEHICLE CRASHWORTHINESS
The magnitude of problems associated with employing destructive testing as a means to determine vehicle structure crashworthiness in the early design stages, coupled with the availability of modern computing systems and a host of promising numerical methods, has resulted in the development of a number of vehicle structure crash simulation computer programs. This paper delineates the problems associated with the theoretical prediction of large deformation dynamics of crash impacted vehicular structures, assesses the prediction capabilities and technical approaches of the recently developed vehicle crash simulation programs, and identifies areas of research needed to improve current crash simulation capabilities.

METALLURGICAL FACTORS CONTROLLING THE FRACTURE TOUGHNESS OF WELD MICROSTRUCTURES, WITH PARTICULAR REFERENCE TO THE MICROMECHANISM OF FRACTURE INITIATION
To link fracture toughness measurements specifically to particular micromechanisms, correlations between toughness, microstructure and composition must be related directly to the mechanism of initiation by inspection of the fracture surface in the region of the specimen notch after testing. Some factors which are beneficial to resistance to cleavage may be deleterious as regards resistance to microvoid coalescence and that, for optimum toughness over a wide range of temperature, applied strain rate and stress state, compromises in composition are required. However where, in a given application, only one micromechanism of fracture is of concern, efforts can be more simply concentrated on optimizing composition and welding procedure to produce HAZ and weld metal microstructures having the maximum resistance to fracture by this particular mechanism, subject, of course, to any other requirements, such as retaining adequate tensile properties and resistance to weld cracking problems.

APPLICATION OF FRACTURE MECHANICS TO RAILWAY FAILURES
The authors have attempted to demonstrate both the potential and the current limitations of fracture mechanics in the context of railroad engineering. The principal limitations are the need for detailed service stress data and the establishment of appropriate K-calibrations. The benefits of applying a fracture mechanics approach to railway failures are discussed. In failure investigations, fracture mechanics enables the failure stress to be estimated.

FIRE EXPERIMENTS OF COACH
As part of the equipment development program of the Japanese National Railways, steps are being taken to step up the fire prevention and protection qualities of passenger cars. Because of the high speeds, long tunnels and subways in which trains operate, and the large amount of new rolling stock which is planned, preventing train fires is given high priority. The resistance of various seat upholstery materials to ignition from a burning newspaper were checked initially. Subsequently the same second class coach was ignited and the fire allowed to burn fiercely with smoke concentrations, gasses and temperatures monitored as the conflagration continued inside the standing car. Further work on fire suppression is planned.

RAILROAD ACCIDENT REPORT: SOUTHERN RAILWAY COMPANY TRAIN 154 DERAILMENT WITH FIRE AND EXPLOSION LAUREL, MISSISSIPPI JANUARY 25, 1969
Southern Railway train 154 was wrecked at Laurel, Mississippi on January 25, 1969 at about 4:15 a.m., when 15 tank cars of liquefied petroleum gas derailed. The train, with four diesel-electric locomotive units, 139 cars and caboose was moving northward at about 30 mph when the west wheel on the lead truck of the 62nd car in the train broke. The wheel which broke as it was passing over the crossing of the Gulf, Mobile, and Ohio Railroad, derailed about 256 feet north of the crossing, and the train continued northward for about 2,146 feet before the 62nd car and 14 loaded tank cars behind it were derailed. Most of the tanks were mechanically damaged by the derailment resulting in an immediate violent eruption of fire and explosion. Two fatalities resulted from injuries caused by the fires and explosions after the wreck, 33 persons were hospitalized. Property damage in the town was extensive and total damage to Southern Railway track, equipment and lading was estimated at about $3,000,000.

THE FRACTURE PROPERTIES OF TWO FAILED CAST STEEL WHEELS FROM THE UNION PACIFIC RAILROAD
During the late autumn of 1972 the Union Pacific Railroad had what appeared to be an unusually high number of wheel failures associated with low ambient temperatures. This behavior suggested to the Union Pacific that the temperature may have dropped below the materials transition temperature. In this connection the AAR was requested to determine the fracture properties of two cast steel wheels which failed during low temperature conditions (less than 35 F). On the basis of both the Charpy and critical stress intensity factor tests both wheels did not significantly change their fracture characteristics over the entire range of operating temperatures.

SUMMARY OF VISUAL INSPECTION RESULTS CRACKED OR BROKEN FREIGHT CAR COUPLERS, KNUCKLES AND YOKES
This report contains the results from a visual inspection of 1097 broken freight car couplers, knuckle and yoke components collected by five railroads during a thirty day period. The sample was collected as part of a joint AAR-Railroad program, just prior to the start of this joint RPI-AAR Railroad Coupler Safety Research and Test Project, to initially determine the approximate extent and character of current failures in couplers, knuckles and yokes. The result of this inspection, when combined with current population data, do not permit the determination of failure rate for the various components because the proportion of the total industry failures represented by the sample is indeterminate and the sample is, for most components, too small to provide the desired reliability. The results from this inspection will, however, supply valuable insight required to determine the necessary procedures, data and sample size to achieve the project objective.

YOKE SERVICE PERFORMANCE
Presents the initial 18 months of yoke removal data (for foreign cars only) reported to the newly established AAR Mechanized Car Repair Billing Exchange System in Washington, D.C. This computerized system lists the reason the yoke was removed under eight code numbers which interpreted mean: worn out, broken, missing, bent, bent beyond repair, obsolete, account other repairs, and removed in good condition. There were a total of 19,647 yoke removals reported in the initial 18 months. The number of reporting railroads (11 total) participating in the system at the end of the first 18 months accounted for a little over half of the freight car ownership in 1972 and therefore perhaps about half of the yokes removed from foreign cars by railroads (foreign cars are cars not owned by the reporting railroad). Considering this condition combined with other factors it seems reasonable to multiply the total removals reported to the AAR Billing Exchange by about 6 to obtain the total removals by the industry for the entire current service fleet of freight cars.

RESIDUAL STRESSES IN THE PLATE FILLETS OF TWENTY-EIGHT-INCH DIAMETER WROUGHT STEEL WHEELS
Past experience with the B-28 wheel has shown that this design is susceptible to plate cracking. This reports the results of a program to determine the state of residual stress in class U untreated and class B heat-treated wheels. Measurements were made according to the procedure outlined in the AISI Steel Products Manual for Wrought Steel Wheels and Forged Railway Axles. Measurements were taken at the front hub-plate fillet and the back rim-plate fillet on each wheel. While the maximum principal residual stresses developed in the class B wheels were two to four times higher than those developed in the class U wheels, analysis by Goodman diagram shows similar fatigue properties in both wheels.

METALLURGICAL ANALYSIS OF FAILED RIMS ON FIVE BURLINGTON NORTHERN UNIT TRAIN TRUCK BOLSTERS
Results of fracture analysis, dimensional study, chemical analysis, Brinell hardness tests, and examination of the microstructures of five failed unit train truck bolster castings are reported. It was concluded that the failures were all triggered at the rim-bowl base fillet by various stress risers created by impacts of the horizontal liner plates against the rims. The failures propagated suddenly or in fatigue under impact of the rims with the body center plates. It was also found that the vertical liner rings had broken away from the rims of two bolsters before they were removed from service.

STABILITY OF RIBBED PLATES IN THE CONSTRUCTION OF RAILWAY VEHICLES [Zur Stabilitat gesickter Bleche im Schienenfahrzeugbau]
In the case of plates with tailed-in ends, compressed along the ribbing, coupled elongations are produced as a result of bending deformation. These additional compression stresses are superposed upon the primary buckling constraints. For this reason, the elastic limit can be exceeded locally in ribbed walls, more especially in the intervention zone of the transversal forces. Other origins of this phenomenon can be: lack of precision in assembling, pre-existent deformations in the ribbed plates, residual welding tensions and the very asymmetrical form of the ribbing. Tests have been carried out in order to determine the bending stress. [German]

STATE-OF-THE-ART CAR DEVELOPMENT PROGRAM FINAL TEST REPORT. VOLUME I. COMPONENT TESTING
The Urban Rapid Rail Vehicle and Systems Program is an integrated development program directed toward improving high speed, frequent-stop urban rail systems. The overall objective is to enhance the attractiveness of rail transportation to the urban traveler by providing service that is as comfortable, reliable, safe and economical as possible. The objective of the State-of-the-Art Car (SOAC) is to demonstrate the best state-of-the-art in rapid rail car design, with two improved cars using existing proven technology. Primary goals for the cars are passenger convenience and operating efficiency. This document, Volume I of the SOAC Final Test Report, presents the test results of the component testing of the State-of-the-Art car. The purpose of these tests was to show compliance with the SOAC Detail Specification (NTIS PB-225 934). All component tests were conducted by the supplier of the applicable subsystems. An introduction, test procedures and results, and conclusions are presented. Appendices are titled: Propulsion, Dynamic Braking and Auxiliary Power Equipment; Truck Frame; Truck Bolster; Windshield; Seat Strength; and Materials-Fire Resistance.

STATE-OF-THE-ART CAR DEVELOPMENT PROGRAM FINAL TEST REPORT. VOLUME 5. POST REPAIR TESTING
The Urban Rapid Rail Vehicle and Systems Program is an integrated development program directed toward improving high speed, frequent-stop urban rail systems. The objective of the State-of-the-Art car (SOAC) is to demonstrate the best state-of-the-art in rapid rail car design, with two improved cars using existing proven technology. Primary goals for the cars are passenger convenience and operating efficiency. This document presents the test results for the Post-Repair Testing of the SOAC. The purpose of these tests was to show: (1) compliance with the SOAC Detail Specification (NTIS no. PB-222 147) following repairs to the Number 2 car damaged in an accident on August 11, 1973 at the DOT High Speed Ground Test Center, Pueblo, Colorado; and (2) to complete the Simulated Demonstration Testing (Volume 4) which had been interrupted by the accident. Chapters present configuration, instrumentation, test procedures, test results and conclusions.
See also Volume 4, PB-244 051. Paper copy also available in set of 5 reports as PB-244 047-SET, PC$26.00.

SOAC: STATE-OF-THE-ART CAR ENGINEERING TESTS AT DEPARTMENT OF TRANSPORTATION HIGH SPEED GROUND TEST CENTER. FINAL TEST REPORT. VOLUME I. PROGRAM DESCRIPTION AND TEST SUMMARY
The six-volume report presents the technical methodology, data samples, and results of tests conducted on the SOAC on the Rail Transit Test Track at the High Speed Ground Test Center in Pueblo, Colorado during the period April to July 1973. The Test program comprises three areas: Vehicle testing, ways and structures testing and track geometry measurement. The objective of the SOAC program is to demonstrate the current state-of-the-art in rail rapid transit vehicle technology, with passenger convenience and operating efficiency as primary goals. In this series, Vol. I contains a description of the SOAC test program and vehicle, and a summary of the test results; Vol. II, Performance Test data; Vol. III, Ride Quality Test data; Vol. IV, Noise Test data; Vol. V, Structural, Voltage, and Radio Frequency Interference Test data; and Vol. VI a description of the Instrumentation system used for performance, ride quality and structural testing.

CRASHWORTHINESS ANALYSIS OF THE UMTA STATE-OF-THE-ART CARS
An engineering assessment of the crashworthiness of the UMTA State-of-the-Art Car (SOAC) has been conducted as part of a program to provide safer transportation to urban rail vehicles. Crash dynamics and crashworthiness methodology based on post-yield energy absorption characteristics and a 'weighted acceleration' severity index has been applied. Sensitivity studies have been conducted to show the effect of car buff strength, passenger relative velocity, passenger spacing, and cushioning on casualties as defined by the severity index. Major gains in injury reduction through improved internal cushioning are indicated. The prevention of car penetration by override is treated. The SOAC collision dynamics model is validated by comparison to the SOAC-gondola accident of August 11, 1973, and by comparison to a nonlinear finite element mathematical simulation of the SOAC in crash conditions.

OVERHEATED JOURNAL BEARING DERAILMENT PREVENTION SYSTEM
An anti-derailment system is disclosed in the patent application to prevent train derailment due to axle failure resulting from journal bearing overheating. The system includes a thermal sensor to continuously monitor the temperature of the bearing and to activate the brake system when the temperature exceeds a predetermined level. A thermally-responsive element located in the journal bearing adapter physically deforms to activate a power source. The resulting signal initiates an electro-explosive brake line venting mechanism, puncturing and venting the brake line to stop the train. Several configurations of the thermal sensor and the power source are possible.

AN ASSESSMENT OF THE CRASHWORTHINESS OF EXISTING URBAN RAIL VEHICLES. VOLUME I: ANALYSES AND ASSESSMENTS OF VEHICLES, CHAPTERS 1 THROUGH 7
The crashworthiness of existing urban rail vehicles (passenger cars) and the feasibility of improvements in this area were investigated. Both rail-car structural configurations and impact absorption devices were studied. Recommendations for engineering standards for urban rail vehicles were developed. The report covers: (1) The development of analytical tools to predict passenger threat -environment during collision; (2) criteria for predicting passenger injury due to train collisions; (3) an application of injury criteria and analytic models to predict passenger injuries resulting from collisions of trains that represent existing construction types; (4) a preliminary investigation of applying impact absorption devices to transit vehicles; (5) a design study of car structural configurations for improved impact energy management; (6) a review of engineering standards for Urban Rail Car Crashworthiness.

A FIRE HAZARD EVALUATION OF THE INTERIOR OF WMATA METRORAIL CARS
A series of fire tests was conducted for the Washington Metropolitan Area Transit Authority to assist them in assessing the potential for fire hazard in the new Metrorail subway cars. Results of small-scale laboratory tests were found inadequate for this assessment. Results of full-scale tests on mock-ups of the interior (and on a real car for a smoke penetration test) show that the potential for hazard arises primarily from the seat padding and covering and from the plastic wall lining. The hazard arises both from smoke development and from spread of flame and heat. The times to reach unacceptable conditions has been determined for several test conditions. It is recommended that the authorities review these times in the context of what they consider to be appropriate times for safe escape. Recommendations are made for increasing the amount of time available for escape. These would require changes in the seating and wall lining materials.

LIFE CYCLE COSTING: A KEY TO FREIGHT CAR COMPONENT EVALUATION
The cost of repairing and replacing freight car components represents a very sizeable expenditure for the railroad industry. Of major concern to the railroad industry are the "costs" associated with various components. These costs include not only the direct costs of procuring and servicing such components but also related costs such as occur in derailments, train delays, and train handling mishaps. Phase II of the International Government-Industry Research Program on Track Train Dynamics is concerned with improving freight train performance and operating safety through the development of performance specifications and design guidelines for car components. If this activity is to be effective, it is essential that present and potential costs of component ownership be thoroughly evaluated. The authors have pursued this end through the development of a life Cycle Cost Model. Once necessary data sources are developed, this model will be used to evaluate research and implementation strategies for the program.

CAUSE FOR THE FORMATION OF GROOVES ON THE WHEELS OF BLOCK-BRAKED RAILROAD ROLLING STOCK AND THEIR PREVENTION [Ursache der Rillenbildung und Deren Vermeidung bei Raedern Klotzgebremster Schienefahrzuege]
Grooves on the friction surface of block-braked car and locomotive wheels are not formed as a result of hard structural consitituents in the cast-iron brake blocks, but rather as a result of partial melting and displacement of the wheel steel softened by heating in excess of the solids temperature during the friction process. The displaced steel collects for the most part on the braking surface of the block in the form of foil laminations. The cause for this phenomenon lies in an excessively high softening temperature of the brake block material. To prevent the occurrence of this defect, it is suggested to use cast iron containing low-melting structural constituents in adequate quantity and distribution. [German]

HUMAN FACTOR AND HARDWARE DESIGN CONSIDERATIONS FOR PASSENGER PROTECTION IN HIGH SPEED CRASHES
Included in the objective of the paper are the identification and summary of significant human factor considerations for restraint and protection of passengers involved in barrier-type collisions at speeds up to 300 miles per hour. These considerations result in computed values of minimum stopping distance as a function of initial velocity. The bases of the calculations are upper limits of tolerable deceleration which are a function of impact duration. Two types of lap and shoulder restraint schemes for achieving optimal restraint conditions are described. The advantages and disadvantages of each are discussed. A totally passive hydraulic/pneumatic shock isolation system for constraining the deceleration levels to acceptable and approximately constant values is described. Typical results of digital computer simulation studies demonstrate the significance of energy dissipation by means of structural deformation of the vehicle. Also, the simulation results demonstrate that the passive shock isolation system can be utilized to achieve an approximately constant and safe deceleration.

SAFETY CONSIDERATIONS IN DESIGN OF NEW TRANSIT BUS SEATS
This paper describes the results of a program to develop advanced cantilevered transit bus seats. The Department of Transportation's Urban Mass Transportation Administration funded the $26 million Transbus Program. The paper is divided into two parts. The first part describes the results of a detailed analysis of passenger accidents on-board current transit buses. The second part describes the results of sled tests that evaluated the safety of three new cantilevered seat-sidewall section designs proposed for Transbus relative to the safety of current transit buses. The testing facilities and procedures are described, along with a summary of the results of 16 sled test runs that employed four different sizes of anthropometric dummies. The results clearly indicate that the new seats have safety characteristics superior to current transit bus seats, especially in severe crash situations.

AN EXAMINATION OF FATIGUE STRENGTH IN THE CONSTRUCTION OF RAILWAY VEHICLES [Berucksichtigung der Betriebsfestigkeit bei der Konstruktion von Schienen]
The author discusses the importance of fatigue strength in the construction of railway vehicles and problems connected with designing construction components which will withstand stress, taking into account their service life. Moreover, construction elements which undergo great stress must often weigh as little as possible and therefore careful attention must be given to the properties of specific materials and to the field of force.

BEHAVIOR OF FREIGHT CAR CONSTRUCTION MATERIALS AT CRYOGENIC TEMPERATURES
The purpose of this study was to explore the action of wood and steel construction materials when impacted at low temperatures. Cooling and heating rates were also determined since these properties affect the quantity of coolant used to produce croygenic temperatures and the time available for demolition after the material has been cooled. Liquid nitrogen (B.P. 77.4 degrees K or-320.4 degrees F) was used in the study since this chemical is readily available in laboratory quantities and is less susceptible to explosion hazards than hydrogen or oxygen. The laboratory tests of thermal properties of wood and steel at cryogenic temperatures showed that both materials cool rapidly when immersed in liquid nitrogen with steel cooling about five times more rapidly than wood. These materials also heat rapidly when removed from the liquid nitrogen environment with steel having about five times the heating rate of wood. In the tests conducted, wood exhibited little change in fracture characteristics when the temperature was lowered to that of liquid nitrogen. Conversely, steel, at this temperature, shows brittle fracture properties as compared to ductile properties of steel at room temperature. Based on the tests conducted, scrapping wood freight cars by lowering the temperature to cryogenic levels would be impractical. Large quantities of relatively expensive coolant would be required to lower the car temperature which would heat rapidly as soon as the collant was removed. In this scheme of scrapping freight cars, it was thought that wood shattering would take place with heavy impact blows. The laboratory tests did not show any shattering effect of the wood at cyrogenic temperatures but it is possible that some steel shattering might occur if the impact blows were struck quickly after the car was cooled.

INNOVATIVE CONCEPTS IN UNIT TRAIN OPERATION
The transition to haulage of taconite pellets on the Duluth, Missabe & Iron Range Railway found unit train services attractive. To achieve optimum train operation, DM&IR coupled its short ore cars in four-car sets with drawbars, introduced the Wabco straight-air retainer system, and eliminated angle-cocks and air-hose connectors where the drawbars are installed. The road uses a planned 1,188 cars assembled in "miniquads" in 124-car unit trains. With this operation so successful, attention has now turned to on-train monitoring of derailed equipment and plans for a more comprehensive real-time measurement of condition throughout any unit train. It is concluded that more can be done to improve the operational control, efficiency and safety of unit trains.

This is a paper from the proceedings of the 11th Annual Railroad Engineering Conference held at Southern Colorado State College, Pueblo, Colorado, October 23-24, 1974. Other individual papers from this conference have been accessioned separately for RRIS. SOME OBSERVATION ON FATIGUE PHENOMENA IN A LARGE PLATE SPECIMEN OF SPRING STEEL AFTER SHOT-PEENING TREATMENT
To obtain the fundamental data for the nondestructive finding of fatigue damage in vehicle parts, the fatigue due to pulsating repeated bending in a large plate of spring steel which had been shot-peened to increase its fatigue strength as a vehicle part, was investigated. It was clarified that there were two ways to find the fatigue damage: to observe the changing state of the surface residual stress and to detect the internal cracks non-destructively.

ACTIVE CAR SAMPLE
Computer program: ACTIVE CAR SAMPLE MASTER FILE. The objective of this program is to provide estimates of car mileage on Southern Railway System for selected groups of cars. The mileage estimates may be any of the following characteristics or combination of characteristics which are obtained from the Umler File and added to the Active Car Master File (age range, AAR car type, truck tonnage capacity, SRS marketing code, cubic foot capacity, nominal capacity, tare weight, lining, outside length, side door width, clearance, bearing type, draft gear travel, truck center length, fittings, compartments, floor type). These mileage estimates are used in calculating failure rates for groups of cars. Examples include studies of (1) derailments by AAR car type and age range, (2) uncouplings by cut-lever type and car cushioning, and (3) broken knuckles and couplers by AAR car type and age range. The input data (consisting of car number and supplemental information obtained by inspection of the car such as air hose arrangements and/or cut-lever type) is collected at selected hump yards for a sample of cars going over the hump. The file is of unlimited length. This method of estimating car population approximates mileage more closely than would ownership figures since cars will be included in the sample in proportion to their movement. The program produces a microfiche listing of all data in the file by car initial and number. Other reports are generated by a general purpose picker program (RSVP) which has the capability to select certain records, to sort them in any order, and to print the selected records with summaries on any field.

ADVANCED DESIGN TECHNOLOGY FOR RAIL TRANSPORTATION VEHICLES
This is an interim report on a cooperative research project between Washington University and AMCAR Division of ACF Industries Inc. The purpose of the project is development of a new finite element stress analysis capability which is more cost effective and better suited for fatigue life evaluation than existing finite element computer programs. The report contains a general outline of the method, description of the algorithm structure and methods by which the computational efficiency can be further increased. A benchmark problem established by experimentation and by computation using an existing finite element computer program (STARDYNE) is presented.

The Association of American Railroads and AMCAR Division of ACF Industries, Inc. provided for partial funding of this project.

SAFETY PRIORITIES IN RAIL RAPID TRANSIT. VOLUME 1-REPORT
Rail Rapid transit presently produces the lowest number of fatalities of any of the major passenger transportation modes. This report develops a program to identify what should be done to aid in assuring that rail rapid transit safety continues. All aspects of rail rapid transit safety are reviewed, hazards are identified, priorities established, and remedial actions recommended. Recommendations include: (1) an evaluation program for materials which utilizes new methods of computing and assessing risk in the areas of flammability, smoke and toxicity; (2) compilation and dissemination of procedures, techniques, and equipment used in the safe evacuation of rail rapid transit patrons; (3) an improvement study of fixed stairs in rail rapid transit facilities to determine whether significant reduction can be achieved in the number of patron falls; (4) a safety education plan to produce films for public education and use in primary schools; (5) work efforts in the development of fire detection and transit vehicle fire extinguishing equipment; (6) establishment of criteria for transparencies used for transit vehicles; (7) determination of hazards of power regeneration and the evolution of procedures to eliminate them; and (8) continuation and support of the Safety Advisory Board techniques for analyzing and assessing safety in rail rapid transit to help assure coordinated technical information input to transit safety development. A bibliography is furnished.

Sponsorship was by the Urban Mass Transportation Administration, DOT. See also Safety Priorities in Rail Rapied Transit. Volume 2-Exhibits. Paper copy also available in set of 2 reports as PB-242 952-SET, PC $11.00.

FRACTURE RESISTANCE OF RAILROAD WHEELS
The effects of manufacturing method, chemical composition, heat treatment, temperature, and loading rate on the plane strain fracture toughness KIC of railroad wheels have been determined. Carbon content of the wheels is shown to be the principal factor which controls their toughness. One hundred wheels which fractured in service are analyzed by means of fracture mechanics procedures. The locations, configurations, and size of thermal and plate cracks which initiated brittle fracture are reviewed, and estimates made of the stress levels which resulted in failure. Estimates have been made of the minimum size of crack which could result in the failure of wheels under adverse service conditions. These are discussed with respect to the minimum size of defect which can be reliably detected by NDT. Included in the report are state-of-the-art reviews on thermal and plate cracking and on the stresses developed in railroad wheels.

TESTING OF BOGIE FRAMES FOR RAILWAY CARS [Pruefung von Drehgestellrahmen fuer Eisenbahnfahrzeuge]
A new method of testing by the German Federal Railways laboratories is described. Only arc-shaped road travel is simulated. The deviations from the mean stress observed in these tests are treated as the basic stress amplitude. The forces are applied by servohydraulic equipment. A nomogram for determination of permissible lateral fatigue stresses is given. [German]

MOORGATE TUBE TRAIN DISASTER
This two-part article describes the medical aspects of the crash of a London Underground transit train in a dead end tunnel which resulted in 43 deaths and 72 injuries requiring hospital treatment. Part 1 describes the experience of the medical staff and reports a substantial advantage in using on-site medical teams that could offer anaesthetic facilities. Adequate communication between the accident site and hospital is important. Part 2 reviews injuries sustained by 113 causalities, showing the need for rapid evacuation. Recognition of the "crush syndrome" is important and a radical surgical approach is suggested. Chest injuries were common and contributed to many of the deaths.

Direct requests to J.O. Robinson.

URBAN RAPID RAIL VEHICLE AND SYSTEMS PROGRAM ANNUAL REPORT, JULY 1974
This report reviews the third year's efforts of the Urban Mass Transportation Administration's Urban Rapid Rail Vehicle and Ssytems Program. The objective of the Program is to enhance the attractiveness of rail rapid transit to the urban traveler by providing him with transit vehicles that are as comfortable, reliable, safe and economical as possible. Accomplishments for the year ending June 1974 included the following: completion of the review of BART data; completion of the SOAC test and simulated demonstration programs at the High Speed Ground Test Center, Pueblo, Colorado after repairing the damage to the SOAC cars resulting from a collision with a standing car on August 11, 1973; completion of SOAC demonstration runs on the NYCTA lines. The ACT-1 program progressed to the award of a contract for the design and construction of ACT-1 train. A list of candidate subsystems has been proposed for test and development under the Advanced Subsystem Development Program (ASDP).

METHODS OF REDUCING WEAR ON THE ROLLER BEARINGS OF WAGON AXLE BOXES AS CAUSED BY TRACTION CURRENT [Sposoby umensenija povrezdenija tjagovym tokom buksovyh rolikovyh podsipnikov vagonov]
The article examines the causes of wear by electric erosion occurring in the roller bearings of axle-boxes, and provides recommendations framed for the protection of bearings against damage caused by traction current. By equipping the electric locomotives with contact devices for evacuating the traction current in the rails, through the axle-boxes, the number of roller-bearings damaged through electric erosion is reduced by some 15%. This damage can be reduced by introducing, in the earthing circuit, an additional resistance between bogie-underframe and axles-boxes, themselves isolated from the underframe. The total resistance of the earthing circuit of a wagon must be roughly 0.0625 ohms. [Russian]

ULTRASONIC INSPECTION OF GRAIN SIZE IN THE MATERIALS FOR RAILWAY WHEEL SETS
This work outlines the present theory of attenuation of the ultrasonic waves, particularly the theory of scattering, and describes the measurement of attenuation in metals. Experiments were carried out to measure the attenuation of samples with different grain size taken from materials for railway wheel sets; in these experiments the pulse echo method, with elimination of the effect of the reflexion factor, was applied. The article presents the relation between the overall attenuation coefficient and its scattering component, the grain size and frequency. On the basis of our measurements and an analysis of the obtained results, two methods of evaluation of the structure of railway materials by ultrasonic inspection were derived.

THE ELASTIC FACTOR OF RAIL VEHICLE WHEELS [Die radiale Radfederkonstante von Eisenbahnraedern]
There have been constant efforts to increase the elasticity of rail vehicle wheels, in other words the elastic factor to be applied. This is determined by calculating the maximum dynamic vertical stress borne by the wheel when passing over a rail joint in relation to the radial elastic factor. The authors, who use a system of ordinary differential equations to solve this problem, with the help of an analog computer, obtain a radial elastic factor for impact reduction. [German]

WEAR ON EXTERNAL SURFACES OF WHEELS AND RAIL DUE TO FRICTION [Verschleissvorgang im Grenzschichtbereich der Reibpaarung Rad/Schiene]
The stresses borne by rail and wheel elements are analysed on the basis of several fundamental definitions of wear by Fleischer. A number of studies were carried out on plastic deformation, running surfaces and wear characteristics. Partial oxidation can occur when the external surfaces of wheels or rails are deformed because the materials come into contact with the surrounding atmosphere. Oxidised metallic particles are then worn away. Wear is often affected by the characteristics of the process itself or by layers of martensite which are produced by shoe brakes. [German]

RESEARCH ON THE STABILITY OF THE GAUGE MEASUREMENT OF WHEELSETS WITH SOLID WHEELS AND BRAKE SHOES
The purpose of this research was to determine the effect of the shape of solid wheel centres on their permanent heat- induced axial deformation, when brake shoes were used for braking. First, mathematical analyses based on the finite element method were used to find wheel centre shapes with a minimum tendency to deformation under the effect of heat. Then braking tests with prototype wheels on a test bench were performed to confirm the mathematical analyses. Certain types of corrugated wheel centre show minimum deformation. [German]

BEARING BRINELLING FROM COUPLING IMPACTS OF UNIT TRAIN CARS
Problems of "excessive" wear and failure have arisen in new cars in unit train service. Some were due to over-the- road running, others to rough handling of empty cars. Early and high incidence of failure of all roller bearings on a fleet of year-old unit train cars was the pessimistic prediction made for a western railroad. This paper describes their determining the cause and their solutions to this problem.

INVESTIGATIONS OF THE TRACK GAGE STABILITY OF WHEEL SETS WITH BLOCK-BRAKED SOLID WHEELS [Untersuchungen zur spurmasstabilitaet bei Radsaetzen mit klotzgebremsten vollraedern]
The investigations described were carried out to determine the influence of the shape of the wheel centers of solid wheels on their thermal distortion and permanent set in axial direction during or after heating of the wheel tire by the brake blocks. Analyses by computation using the method of finite elements served the purpose of finding wheel center shapes featuring a minimum thermal distortion. Subsequent braking tests on prototype wheels on the test stand proved that a small thermal distortion results also in small permanent set. [German]

USE OF IMPACT-ABSORBING DAMPERS IN ELECTRIC TRAINS [Primenenie antiavarijnyh amortizirujuscih ustrojstv v elektropoezdah]
It is known that in about 92% of cases, collisions between electric train coaches occur at running speeds of 15 to 20 km/h. For this reason, when designing the mechanical parts of suburban electric train coaches, it must be borne in mind that, to comply with strength calculation standards, the body bearing sections should not be liable to deformation which would be dangerous for passengers in a collision at 20 km/h. The article contains regulations for the construction of electric train bodies to protect passengers in the event of a collision, examines the problem of using dampers to absorb a considerable part of impact energy, and, finally, gives the results of tests on a prototype of a device of this kind. [Russian]

COATING FOR THE PRESERVATION OF FRACTURE SURFACES

In order to perform a meaningful examination of a fracture surface in the scanning electron microscope it is necessary for the examined surface to be in a condition as close to the fractured condition as possible. Laboratory preservation techniques are not available to the engineer in the field so that fracture surfaces are best preserved by coating them with a material that can be easily removed later without damage to the fractures. In this paper, a preservative is described that is suitable for the protection of fracture surfaces both in the field and in the laboratory. The restrictions and limitations of the preservative are discussed and examples of fracture surfaces before coating and after coating and exposure to a humidity cabinet are shown.

WHEEL-RAIL ADHESION
The subject of adhesion between locomotive wheels and rails has been an area of vital interest to locomotive manufactures and to the railroads. Horsepower of internally powered locomotives has continued to increase significantly, thereby providing more power for traction. The trend of increasing horsepower has been the product of progress in technology and engineering development. Wheel-to-rail adhesion within the lower speed range has been a limiting factor in tonnage ratings for locomotives in drag service on U.S. railroads. Factors Affecting Adhesion are: (1) Vehicle Factors, (2) Track Factors, and (3) Contact-Area Common Factors. Additional discussion of the conclusions follows.

FRICTION CREEP PHENOMENON OF ADHESION BETWEEN STEEL WHEELS AND RAILS
The purpose of this article is to present a summary of the laboratory and field tests which have been conducted by EMD to evaluate the friction and creep phenomenon of adhesion between steel wheels and rails. The available adhesion coefficient between the driven wheels and rail is a primary factor in determining the amount of power that can be converted to tractive force by the locomotive. For this reason, experimental investigations into rolling contact friction-creep phenomenon were conducted on model equipment in 1968 along with full scale field tests on an SD-45 model locomotive.

RUNNING SAFETY OF RUSSEL SNOW PLOW FOR DOUBLE TRACK
Running safety from derailment of the Russel snow plow for double track was studied by test and analysis. Shape is useful to push snow away to one side only, but it increases the amount of side pressure of the front wheel on the rail and may endanger the car for possible derailment. In the course of the test and analysis (a) the snow-plowing resistance, (b) the equilibrium of forces applied to the car during the operation, (c) the amount of the lateral and vertical thrust of the front wheel on the rail, (d) the derailment quotient--the ratio of lateral thrust to vertical load at the wheel tread--and its critical value, and (e) the recommendable speeds for safety under various operational conditions.

ON THE TYRE PROFILE OF FREIGHTCAR WHEELS
Adoption of the N-profile tyre wheels for double-link suspension freight cars has been decided upon. Fundamental considerations in determination of wheel tyre and flange profile are as follows: (1) high stability to hunting, (2) little wear due to running, (3) great safety against derailment. The N-profile tyre proposed to meet this demand has been confirmed to be effective both theoretically and experimentally; it is going to be adopted in all two-axle freight cars of double-link suspension. It is expected to make drastic cutdown of derailment cases of two-axle freight cars.

CALCULATION ON DYNAMIC PERFORMANCE OF HYDRAULIC CUSHION UNDERFRAME (REPORT 1)
The car structure with a movable through-member which connects the draft gears at the car ends-the cushion underframe--is considered for the case when a hydraulic shock absorber acts against the relative motion between the through-member and the car body. The impact motion between a conventional car and the car with a cushion underframe is solved in order to give a practical method to determine suitable dimensions of elements and also to predict the motion under any initial conditions. For the calculation, use of electronic computer is considered. Numerical examples show the favourable performance of the system, giving the coupler forces within the limit of car-end strength even for a very high impact speed, say 20 km/h, of the cars. The method described in this article has been successfully applied for the designing marine-container cars. The test results are quite favourable.

CALCULATION ON DYNAMIC PERFORMANCE OF HYDRAULIC CUSHION UNDERFRAME (REPORT 2)
Car end-to-end impact of the hydraulic cushion underframe car was analyzed numerically, not only for one-to-one but also for one-to-two car impact. The result shows a good agreement with the data of the actual car test. Besides, effects of masses of coupler and sliding sill, coupler rigidity and draft gear damping were clarified.

EVALUATIONS OF TRAIN RIDING COMFORT UNDER VARIOUS DECELERATIONS
When a train runs on the track at high speed, passengers are subjected to various forces which are produced by the change of its speed. In general, the riding comfort felt by them is evaluated in terms of this change. Determine the allowable limits of the train riding comfort for passengers, obtain the data on their feelings and evaluate them quantitatively under various conditions. Also intended to calculate significant differences between individual passengers.

BRAKING SHOCK TEST OF PASSENGER-AND FREIGHT-CARS MIXED TRAIN
According to the existing regulation on train operation of the Japanese National Railways, cut-off of the supplementary auxiliary air reservoirs of passenger cars is required in a mixed composition of train, when six or more freight cars are included in the train, in order to alleviate the difference of brake effects. The present test was planned for examining the effect on train impact of application of emergency brake under the condition of the supplementary reservoir included or excluded in the operation, and for exploring the possibility of modernizing the regulations.

TESTS ON THE TRACK ON THE RIDING STABILITY AND THE GUIDING QUALITY OF VEHICLES BY MEANS OF A SPECIAL VEHICLE. CHARACTERISTICS OF THE EXPERIMENTAL VEHICLE
In order to study experimentally the riding stability and the hunting movements of vehicles, it was decided to consider a vehicle of the simplest possible design i.e. a two-axled isolated bogie. Each of the factors entering into the dynamic phenomena connected with its running can be separately varied. This experimental bogie is placed under the middle section of the body of an ordinary bogie coach. The bogie and the experimental coach are described in detail and also the methods adopted for measuring the interesting magnitudes.

PREVENTION OF DERAILMENT OF GOODS WAGONS ON DISTORTED TRACKS. STATISTICAL ENQUIRY RELATING TO THE PERMISSIBLE TRACK TWIST

The study of the permissible wheel load deviations and of the resultant characteristics for the goods wagons requires an exact knowledge of the existing track "twists". A statistical inquiry was made on the lines of the DB, the SNCF and the PKP. The inquiry has principally dealt with continuous measurements of existing track twists, related to a basis of 5.00 m (wheelbase of the recording coach), and a length of 1,820 km of track on the DB, 1,805 km on the SNCF and 1,955 km on the PKP has been examined. In each case, the measurements were made on tracks of all categories. The present report gives an account of the results of these measurements-each classified in "ranges of twist" of 1 degree/00-for twists exceeding 4 degrees/00. A statistical analysis, which is based on the assumption of a critical value of twist of 7 degrees/00, related to a base of 5.00 m, has been appended to the present report. This statistical analysis indicates, for the actual state of maintenance of the tracks and for a wagon running an average distance of 1,000 km, the probability of encountering at least "a" twists greater than the above mentioned limit. It also shows the possible reduction in risk to be expected through the application of special measures with regard to track maintenance and vehicle design. The following possibilities have been studied: a) stricter control of accident twists of dangerous magnitude; b) extention of the maintenance regulations for track category 2 to the lower categories of track; c) improving the adaption possibilities of the vehicles to track twists.

Restrictions on the use of this document are contained in the explanatory material.

B2 033203
STUDY OF THE OPTIMUM DAMPING REQUIRED BY THE SUSPENSION SYSTEMS OF WAGONS SO AS TO ENABLE THEIR RUNNING, UNDER ANY LOADING CONDITIONS, AT A SPEED OF 80 KM/H ON TRACKS IN AN AVERAGE STATE OF REPAIR

The running of trains in ordinary service at a speed of 80 km/h as of 1970 entails problems especially as regards certain series of existing wagons, which will not have been redeemed in the forthcoming years and which may give rise to difficulties when being run at higher speeds. In the present report of enquiry the measures to be taken in order to improve the riding stability of these latter vehicles are examined. These arrangements concern both the constructional modifications to be made and the adaptation of the damping systems. They should, however, be economic in order that they can rapidly be redeemed. The study shows as regards the two-axled wagons the importance of the ratio between wheelbase and length of the wagon body and, more exactly, between the wheelbase and the radius of gyration in relation to the vertical axis of the centre of gravity. The increase of the wheelbase has shown to be one of the most efficacious measures in order to improve the stability of the wagons having insufficient riding qualities. In the case of bogie wagons, the study gives an account of the damping systems based on friction aiming at an improvement in the behaviour of the vehicles fitted with helical spring suspension systems. Such systems also enable bogies to be visualised capable of being used at speeds up to 120 km/h. The report finally supplies some general indications on the choice of the lines where the tests on vehicles could be undertaken within the frame of studies of a Specialists Committee. These tests should make it possible to guarantee the safety of the running of the modified wagons on all the lines where a speed of 80 km/h is authorized.

MAINTENANCE OF THE WHEELSETS OF TRAILER STOCK. TESTS ON PASSENGER COACHES TO ASCERTAIN THE PERMISSIBLE OUT-OF-ROUNDNESS AND OUT-OF-BALANCE OF THE WHEELS OF THESE FOR SPEEDS OF BETWEEN 0 AND 250 KM/H

Previous reports contain the results of the tests carried out with a view to determining the permissible out-of-roundness and out-of-balance values for the wheel-set of trailer-stock, for running speeds comprised between 0 and 150 km/h. New tests have been carried out for speeds comprised between 0 and 250 km/h. These have consisted of bench-tests, carried out on the SNCF dynamic test-rig for vehicle suspensions at Vitry-sur-Seine, and have concerned 3 coaches (SNCF, DB and FS). In addition, line tests have been carried out with the SNCF coach; in a first series of tests a speed of 250 km/h was reached, while, in a second series of tests the running-speed was only 160 km/h. The results obtained have permitted the following limit values of plus minus 0.15 mm for the out-of-roundness and 0.125 kg.m for the out-of-balance per wheel (static balancing would seem to suffice in most cases) to be fixed, such that the comfort obtained with the three coaches is still acceptable. This is valid up to the speed of 250 km/h in the case of the DB and SNCF coaches and up to 220 km/h for the FS coach. It has also been found: a) that the test-bench used constituted a perfect reference basis and that it seem desirable to devise a better correlation between the excitation obtained on the track and that produced on the rig; b) that, for the purpose of determining the comfort, the whole of the floor of the coach should be covered by the examination, since, for speeds beyond 150 km/h, the body can present a complex vibratory system with several nodes; c) that, if it is whished to use a coach for high running speeds, it must be checked to see that, beyond a certain speed, there is no very sharp increase in all the recorded accelerations.

A NEW TRANSIT PROPULSION UNIT SUSPENSION-PROVED ON NORTHEAST CORRIDOR HIGH SPEED TEST CARS
The old generation propulsion units for lightweight, inboard journal trucks had the motor and gear unit bolted solidly together, driving the axle through, and supported on, rubber around the axle. By correcting deficiencies in this design, yet retaining the principle of floating the motor in rubber to isolate it from rail shocks, this new propulsion unit arrangement for lightweight, inboard journal trucks has successfully permitted the car operating speeds to double, from 75 to 150 mph in one jump. Paper has been written to emphasize the growing importance of dynamic vibration analysis in the design of rail vehicle trucks and truck and axle-mounted propulsion equipment. Detailed analytical studies of the wheel and axle, truck, and propulsion equipment suspension dynamics has generally been deferred in the past. The car body dynamics have been studied closely to ensure that the passengers receive a smooth ride, but the ride of the trucks and their equipment has been of little concern to most. We will point out why the suspension dynamics of the truck must be studied, how they can be analyzed, and the consequences of failure to do so.

NEW PRINCIPLES IN BOGIE-BODY CONNECTIONS. TWO PROTOTYPE BOGIES DESIGNED BY THE S.N.C.F.
Until recently the problem of the comfort of railway coaches was settled empirically. It was not till 1952 that a start was made with experimental research into the conditions determining comfort in a railway vehicle. There was a problem in connection with the link between bogie and body as far as railway vehicle comfort was concerned. It appeared that the choice of the solutions made by trial and error was not the best. The problem of comfort has two aspects: transversal comfort; and vertical comfort. Two bogies have been designed on the same theoretical bases: Suspension rods of the body in relation to the bogie 0.500 m long, inclined 1/10 towards the interior. Transversal play of the body in relation to the bogie plus or minus 65 mm. Complete freedom of rotation of the bogie in relation to the body.

FREIGHT CAR TRUCK PROGRESS
The modern High Speed Freight Car Truck of the present-day 50-ton freight car has a weight complete of about 14,000 lbs. in Grade "B" steel, and is capable of transporting 110,000 lbs. of material safely and without damage at speeds up to 100 mph. The trucks also support the car body, which in some cases weighs 40,000 to 45,000 lbs., making 150,000 to 155,000 lbs. in all. This is 11 lbs of load carried per pound of weight. The cast steel truck bolster supports about 90 lbs. per pound of its own weight, and the cast steel side frame about 65 lbs. per pound of weight. The cast steel bolster is capable of carrying 65 lbs. and the cast steel side frame 46 lbs. of revenue freight per pound of their own weight. Analysis shows that the forged steel axles carry 34 lbs. of revenue freight per pound of weight and the one-wear steel wheels 24-1/2 lbs., indicating the excellent efficiency and weight economy of the cast steel side frame and bolster.

DRAFT GEAR RESEARCH IMPACT TESTS OF AAR APPROVED STANDARD POCKET DRAFT GEARS
This report describes an investigation conducted by the utilization of impacts made on eleven AAR approved (24-5/8 in.) standard pocket draft gears. During the study two gears of the same manufacturer were installed in two identical 50-ton box cars and impacted under test conditions of: (a) empty cars (no load), (b) half or medium load, and (c) full load. The draft gears investigated included six friction, three rubber, and two friction-rubber types. This investigation resulted in the development of a large volume of data related to such variables as force input, gear closure, stress distribution in the car underframe and car body, and load accelerations. Only a part of the data has been reduced and analyzed for this report. No attempt has been made to present any conclusions.

RELATION BETWEEN SUPERELEVATION AND CAR ROLLING
Springs and links between car body and axles can be thought as a mechanical filter to isolate the car body from axle motion (except axle revolution). Then the problem to know the relation between track irregularity and car vibration is the problem to know the characteristics of this filter. there are three methods to study the characteristics. The first method is to calculate the characteristics theoretically from the parts constants. The second method is to know the characteristics by measuring the output of filter for special input. The third method is to determine the characteristics by analyzing the input-output relations for normal operation. No special equipment except measuring instruments is needed. Second, the effect of random noise can be cancelled out by statistical treatment of data. An application of this method is described.

ALUMINUM IN ROLLING STOCK IMPACT TESTS AT COLLISION SPEEDS
The paper records the results of 75 impact tests, 47 of which occurred between the speeds of 5 to 15.4 mph on an all-aluminum 70 ton capacity covered hopper car. Coupler forces ranged between 500,000 and 947,000 lbs. The hopper car was equipped with aluminum centersill and bolsters. Summary values of strain gauge reading are presented. Considerable space is devoted to describing the damage to various parts of the "hammer" and "anvil" cars as a result of the highest speed collision. One of the unique results of the test explained in the paper is a schedule showing coupler force distribution from the centersill to the carbody, along the length of the car from the collision point. The discussion on location of strain gauge is very adequate, but little specific information is given on stress levels recorded. There is a graph showing average longitudinal compressive stresses recorded in the aluminum centersill along with a design specification for the centersill.

STUDY OF THE VERTICAL SUSPENSION OF A RAILWAY VEHICLE
In the following pages, we propose to study the vertical suspension of a railway vehicle considered as a rigid body resting on elastic supports. This study will make it possible to determine the numerical values of the suspension components to obtain the best possible comfort in the body, i.e., (1) the rigidity of the springs making up the 2 stages of the suspension; (2) the positioning and rate of amortization. In addition, a study of the transitory regime will make it possible to describe the behaviour of the suspension when the vehicle passes over an isolated defect in the track (low joint, faulty frog, etc.) and to see whether the stipulated rate of amortization is sufficient to damp out the oscillations rapidly.

PROCEEDINGS OF SEMINAR ON RAIL CAR UTILIZATION
It was the purpose of this seminar to explore the newest techniques in rail car and systems design along with railroad programs which provide the greatest degree of rapid recovery of use of rail cars. The effective adaptation of almost instantaneous data retrieval is one method explored as a means of

more fully utilizing available rail car capacities. Other means included more efficient use of railcars while in the hands of shippers, reduced warehousing use of existing cars and better designed cars and systems. All of these methods were discussed in this seminar with the hope that it would provide all interested in reduced distribution costs with a greater knowledge of the latest tools available to move the goods of commerce faster and more efficiently. Specific presentations included: Planning for Improved Rail Fleet Utilization; Designing for Improved Car Utilization; Inventory Control of Rail Equipment; and use of a Computer Based Information System to Reduce Total Distribution Costs.

IMPACT TESTS OF VIRGINIAN RAILWAY 70-TON HOPPER CAR NO. 5000

The Virginian Railway had impact tests made on a newly built 70-ton hopper car, class H-14, No. 5000, to determine the location of the highest stress points in the car, whether any weakness existed in its design or construction and to compare force and stress levels obtained with friction and rubber draft gears. A similar class car was used as the impacting car. Comparison of the test results revealed that the force and stress levels at 7.7 mph impacts for the rubber draft gear were approximately equivalent to those at 6 mph impacts for the friction draft gear. These tests indicated that satisfactory performance and service life could be expected from the 70-ton hopper cars of the design tested. Cars of this design and construction can be expected to receive impacts up to 6 mph without sustaining permanent damage when equipped with friction draft gears, and up to 7-1/2 mph when equipped with rubber draft gears. Under special impact conditions such that the force of impact is divided between the striking casting and the rear draft stops, the maximum safe impact speed with friction draft gears was found to be approximately 6 mph. When the entire impact force was directed against the striking casting and the draft gear restricted from functioning, the maximum safe impact speed with friction draft gears was approximately 5 mph.

TRACK-TRAIN DYNAMICS STUDY PROJECT TR-14 RAIL-VEHICLE INTERACTION STUDY REPORT NO. 1 (PRELIMINARY ANALYSIS OF SAMPLE DATA)

As a result of various derailments, a task force was formed to investigate the dynamic forces exerted by locomotive and freight car wheels against the rail. Critical study was directed at the 3 and 2 axle trucks of high horsepower locomotives, 85 feet TFC cars, and 50 feet box cars. The objective of this investigation was to determine if dynamic forces of sufficient magnitude to cause derailment were being generated by equipment, track structure and operating practice, and to recommend whatever corrective action might be indicated. Extensive field tests of wheel-rail interaction were conducted in various territories between Los Angeles and Pine Bluff, Arkansas. An analysis of these test results led to the following general conclusions: 1. Dynamic forces of sufficient magnitude to cause derailments are being generated in every day operation of revenue trains. 2. The forces are also sufficient to cause greatly accelerated wheel and rail wear. 3. Forces of sufficient magnitude to exceed the ability of the track structure to resist permanent deformation in alignment are also being generated.

STUDIES OF THE PRESSURE AS AFFECTED BY THE AREA OF CONTACT BETWEEN WHEEL AND RAIL. EFFECT OF WHEEL SIZE

The following is a progress report on one phase of this investigation, namely, rolling-load tests in which wheels of various diameters are rolled to and fro on a short length of rail for the purpose of determining the number of cycles of load application required to produce failure. The results of the rolling-load tests to fracture show considerable "scatter" and no very marked difference between the results of tests under a 50-in. wheel and those from tests under a 33-inch wheel. The vertical wear on rail 757C (33-in. wheel) was 0.046 in. at failure, whereas the wear on rail 757C1 (50-in. wheel) at 580,900 cycles was 0.041 in. At failure, 750,100 cycles, the wear on rail 757C1 was 0.0425 in. A second type of test being tried to ascertain the effect of wheel size on the rail is to measure the depth of work hardening in the rail head. The rail head appeared to have been work hardened down to a depth of about 0.45 in. by the 33-in. wheel with a maximum hardness of 296 at a depth of 0.15 in. A test on a section from the same rail rolled with the 50-in. wheel appears to have been work hardened down to a depth of 0.20 in. with a maximum hardness of 269 at a depth of 0.10 in.

A THEORY OF THE DERAILMENT OF WHEELSET

In this study, in order to find out an allowable limit of derailment, the author made four assumptions and analyzed the simplest case where a wheelset derails. In order to prove the theory, the author made experiments by 1/10 and 1/5 scale model wheelset. The results of either case of 1/10 or 1/5 models coincide with theoretical values, and no difference was observed on the limit value of derailment by stationary side thrust having various kinds of radii of wheels.

ON THE RELATION BETWEEN SUPERELEVATION AND CAR ROLLING

Springs and links between the car body and axles can be thought as a mechanical filter to isolate the car body from axle motion (except axle revolution). To know the relation between track irregularity and car vibration is the problem to know the characteristics of this filter. Method is to know the characteristics by analysing the input-output relations for normal operation. Application of this method is introduced in the following section.

IMPROVING THE RUNNING QUALITIES OF THE COACHES TO BE INCLUDED IN HIGH SPEED LUXURY TRAINS--MODERN BOGIES--POSSIBLE TECHNICAL EVOLUTION
Discusses the needs of bogie design when rolling stock speeds reach 200 km/h. Suggested areas include relationship of connections between axles, bogie frames and coach bodies; tire profile for stability of 250 km/h speeds; vertical suspension systems for light weight coaches, reduction of unsprung weight, use of rubber in suspension systems. Finally, the problems of running coaches on lines with superelevated curves where problems exist in retaining a level coach interior.

BASIC PRINCIPLES FOR THE DESIGN OF BOGIES FOR PASSENGER ROLLING STOCK
Discusses the parameters to be used in the design of the bogie unit. The principles which are established concern good lateral control of car body, critical speed of bogie and tread profile. New devices and materials may be necessary for the design of units for speeds in excess of 200 km/h. Good matching between the characteristics of bogie and attached body. Design of each unit alone is not satisfactory but matching of the components is necessary.

HIGH SPEED RUNNING AND RELATED TRACK PROBLEMS
High-speed running does not set any track-make-up problems. The conventional type is quite suitable. Strengthening the track is not a must, neither from the angle of safety nor that of fatigue. Strengthening, which could be useful on the lines carrying both dense fast traffic and numerous slow heavy trains, could be carried out simply at the time of the scheduled renewals. The layout problem is more difficult. On certain important lines on the S.N.C.F. there are sufficiently long sections where the radii are over the minima indicated above. Consequently, scheduled service traffic at 200 km/h could be envisaged on these sections in a not too far distant future.

RESULTS OF TRIALS WITH A NEW TYPE OF BOGIE DESIGNED BY THE SNCF
These tests dealt with the truck Y 207 and considered particularly the transverse stability of this truck at speeds of from 140 to 245 km/h, with wheel tires in tread worn condition, corresponding to 350,000 km of operation, and with tires worn to profiles to generate "shaking". After the wheels on this truck had actually made 350,000 km (217,000 mi.) without requiring turning for sharp flanges or instability on the track, and having an average depth of tread wear of 2 mm, this vehicle was tested at 140 km/h. These tests were the first ever run at speeds over 200 km/h with wheel treads in such worn conditions, and have significant results.

CAR DYNAMICS STUDY
In the calculation of car vibration, for instance, especially that of hunting motions, the electronic computer is almost indispensable. Manual computation is quite inadequate for a problem such as this, involving a large number of degrees of freedom of motion. Calculations of the hunting characteristics of electric cars for the New Tokaido Line is now under construction by using a digital computer to find out the roots of the characteristic equation of such a high order as stated above. In this way, we have played since last year a leading part in developing measures to reduce hunting motion in the design of the bogie truck.

EFFECT OF WHEEL FLAT ON THE CAR VIBRATION
A series of running tests was performed with the prototype "B" train for the new Tokaido line. The object is to investigate the effect of the wheel flat on the car body and truck vibration. The data were expected to give a reference for design and maintenance of car, and to give a base for determining the allowable limit of the flat length in practical operation. The running speed was 200 km/h for the flat up to 90 mm, and 50 km/h for 110 mm. So far as the truck and car body vibration is concerned, flat caused more vibration at a low speed than at a high speed. So car vibration is not considered the most decisive factor limiting the allowable length of flat.

TESTS ON THE TRACK ON THE RIDING STABILITY AND THE GUIDING QUALITY OF VEHICLES BY MEANS OF A SPECIAL VEHICLE-RESULTS OF THE FIRST TRACK TESTS
The report gives an account of the results of the tests made with the experimental bogie described in a previous report. The first part of the report supplies data relating to four series of tests during which the various parameters of the bogie (lateral play between axle-box and axle, axle load) and also the riding speed were successively varied. These tests have made it possible to establish conclusions relating to the wave-length of the hunting movement, the amplitude of the transverse movements of the bogie and the maximum transverse forces occurring between bogie and axles. The second part of the report supplies data relating to the tests during which the wheelbase of the test bogie was varied. The data obtained have permitted the establishment of some conclusions relating to the wave-length of the hunting movement, the transverse displacement of the bogie frame, the maximum angle of rotation of the bogie and the transverse forces. The third part of the report contains an account of the results obtained during the tests, the object of which was to study the same magntiudes as those prevailing during the previous tests, the wheel tyres of the test bogie having however been machined in accordance with the wear profile "Muller No. 2". All the tests were made on one and the same section, this being in an excellent state of repair and having a relatively constant gauge and chiefly consisting of straight track.

Restrictions on the use of this document are contained in the explanatory material.

FIRST PROGRESS REPORT LATERAL ACTION OF COMMON DESIGNS OF FREIGHT CAR TRUCKS HAVING AXLES WITH AND WITHOUT END COLLARS
The objective of certain instrumentation in the tests was to obtain fundamental information on the lateral action of different common designs of freight car trucks having standard and modified parts in the journal box assemblies, and having axles with and without end collars. It was desired to determine the motions of truck parts, and relation between these motions and lateral car body accelerations, and the origins of lateral disturbances to the car body, relative importance of these origins, and manner of transmission of these disturbances from the rail through the truck to the car body. A mechanical recorder was attached to one truck to obtain records of the relative lateral movements of truck parts (axle, bearing, wedge, frame) at both ends of one axle, and records of the vertical and lateral displacements of both side frames relative to the bolster. The conclusions are as follows: The most important origin of lateral disturbance to the car body is the nosing of the wheel-axle assemblies and truck, due to coning of the wheel treads. The effects of axle end collars on truck action are to increase the activity of truck parts but to limit the forces transmitted through the truck. Increase of lateral clearance, which does not reduce the beneficial effects of axle end collars, should improve the lateral riding quality of conventional trucks with snubbers. Curved track produces a quieting influence on truck action and improves lateral riding quality. Definite improvement in lateral riding quality should result from the use of a device which would cause the car body to seek a centered position between lateral clearances.

DYNAMICS OF HIGH SPEED ROLLING STOCK
Test on passenger ride comfort on curved track and also under braking were carried out in March 1962 to supplement the data obtained by the previous tests. Tests were planned minutely with the theory of sensory inspection and

experimental design, and the analysis of the subjects' evaluation of ride comfort was made with a statistical technique. Main difference of these tests from the previous ones lies in the method of evaluation of ride comfort. The evaluation was marked separately for degree of sensation against acceleration, for degree of mood or comfortableness, and for judging whether the ride is permissible or not in terms of sensation or mood.

TRACK-TRAIN DYNAMICS STUDY PROJECT TR-14 RAIL-VEHICLE INTERACTION STUDY--REPORT NO. 2 (COMPLETE ANALYSIS OF DATA USING COMPUTER TECHNOLOGY)
Following a description of the problem involved in preparing a hybrid computer program for the analysis and reduction of transient data taken in the actual field tests of the TRACK-TRAIN DYNAMICS STUDY PROJECT and an explanation of the computational approach, there is a description of the method of interfacing the digitized data with the digital computers used to obtain an in-depth engineering analysis of the results of the tests. The evaluation of the numerical data indicated that under controlled operating conditions, the L/V ratios were significantly repetitive, which fact can be helpful in future studies. However, the inability to measure the track lateral deflections simultaneously to obtain the combined effect of vertical and lateral displacements in the rail was a severe limitation, and it was not possible to derive any information concerning track stresses and probable damage due to high dynamic loads. Graphs and bar charts were developed from the computational results to show the relationship between speed, drawbar load and L/V ratios for locomotives and cars, and graphs were used to illustrate the accumulative distribution of dynamic rail deflections on various segments of the railroad where the tests were run. Parameters that were not included in the field measurements which could have possibly contributed to the establishment of a more definite pattern include: the relative velocity between instrumented cars, track curvature and truck hunting action and the cross-level of track.

INCREASE OF TRAIN SPEED ON CURVES
For a train to reach the destination in shorter time is to increase speed on curves and gradients. It would involve enormous investment to eliminate curves and gradients through re-routing the track in a mountainous country like Japan. Thus, the alternative would be to achieve an effect of speed by selectively investing in certain high-speed trains. Introduced a bogie truck TR96 which is an experimental one built for the purpose of exploring the

possibilities of increase speed on curves. The data collected using this truck will offer the basis upon which a new high-speed train will be developed for actual service in a few years.

DESIGN AND MAINTENANCE ASPECTS OF FREIGHT ROLLING STOCK RELATIVE TO THE EFFECTS ON THE TRACK
A modern Railway has grown up in this country with new and more powerful forms of traction and improved signaling and track, but the majority of wagons in use still consist of small four-wheelers, the basic design of which has not changed for over 50 years. These wagons incorporate a 'Box-on-Wheels' design which was robust and cheap, suitable for the low axle weight, low speeds, and low utilization of their day. They are, however, incapable of meeting today's conditions of high utilization and speeds without an unacceptable degree of maintenance and inspection. Until recently very little was known of the behaviour and design parameters necessary for high-speed wagons, and because of this, in 1963 when it became obvious that improved wagon suspension was required B.R. adopted the U.I.C. Double Link Suspension. This was a proven design which was, and still is, in wide use on the Continent, but here again problems arose when operating at higher speeds and axle loads permitted in this country. These problems concerned the rapid wear of the links and saddles due to the friction necessary for lateral damping and spring failures caused by the torsion induced in the spring superimposed on the normal vertical loading.

HUNTING PROBLEM OF HIGH-SPEED RAILWAY VEHICLES WITH SPECIAL REFERENCE TO BOGIE DESIGN FOR THE NEW TOKAIDO LINE
This paper describes the preliminary experiment on hunting by means of a model vehicle; the hunting tests of an experimental bogie and the prototype bogie at the rolling stock testing plant; a considerable amount of various hunting calculations carried out in the design stage; running test, with casual hunting observed, of the prototype bogies on the test track section of the new Tokaido line; and the construction of a bogie finally designed--and gives a number of major results with some discussion on the points to be considered. Elaborate running tests of six prototype cars were carried out on the test track section of the new Tokaido line. In designing this bogie, special attention was paid to the following two points to prevent hunting: (1) Mode of axle-box support and its stiffness: (2) Combination of frictional and elastic restoring force against bogie rotation. According to the running test at 246 km/h this bogie exhibited a very high running stability.

SOME ASPECTS OF THE HUNTING OF A RAILWAY AXLE
Equations of motion are derived to describe the hunting mode of a railway axle running at constant velocity along straight track. It is assumed that the wheel and rail-head profiles take some arbitrary shape. This shape gives rise to non-linearities in the equations. The equations are first linearized, and approximate expressions derived for the frequency of the oscillation and conditions of stability. Asymptotic stability for all initial conditions of the non-linear system is then considered in the manner of Aiserman, and the equations are examined for stable limit-cycle by applying the first approximations of Kryloff and Bogoliuboff. It is shown that, when running at low velocities, the axle will execute limit-cycle oscillations even though the wheel's flanges do not contact the rails. Small increases in velocity, however, quickly result in flange contact.

THE TOLERANCE OF TRACK LONGITUDINAL LEVEL IRREGULARITY DETERMINED BY RIDING QUALITY
This investigation was concerned with the vertical vibration of bogie car which was caused by track longitudinal level irregularity. It delineated the characteristics of the longitudinal level irregularity which can occur on track and proposed a method to determine the tolerance of longitudinal level irregularity from the view point of riding quality. In addition, the study examined the relation between the riding quality, the car structure and condition, the running speed and the measuring method of track longitudinal level irregularity.

THE RIDING PROPERTIES OF BOGIE VEHICLES--1
This article discusses the problems of values assigned to ride quality as an indicator of the effectiveness of a suspension system of a rail vehicle. In order to find an index of such performance, a mechanical device such as the Askania Universal Vibrograph is recommended. The charts which are produced by the Vibrograph are evaluated and the application of the results to vehicle design is discussed. The instrument may be used to measure vehicle body oscillations. Vertical acceleration and resonance is included in the measurements. The article concludes with the reminder that the factors recorded by the vibrograph should not be used alone as parameters of vehicle design but should be used with the factors of noise and vibration also.

B2 037225
THE RIDING PROPERTIES OF BOGIE VEHICLES--2
The author explores various theoretical aspects of railway vehicle riding performance as an aid to the rationalization of bogie design. It was shown that low ride index values can be retained by minimizing the natural frequency and/or the amplitude of the oscillation. The importance of damping with respect to amplitude ratio is shown and it is pointed out that dampers are actually undesirable at speeds in excess of 1.41 of the resonance speed. It is also pointed out that damping is of relatively little importance with short swing links. In order to determine the ride index of a rail vehicle, the magnitude of excitation amplitudes, the natural frequency and the damping factor of the system must be known.

THE DESIGN OF RAILWAY BOGIES
In connection with bogie design research and development has led to the establishment of ten particular design features which cover primary and secondary spring deflection; primary damping; secondary spring disposition and damping; swing-link design and suspension; bolster anchorage by traction bars; bogie frame stiffness; rotational damping; secondary spring anchorage, and check stop clearances. It has been clearly established by investigation and testing that the inclusion of the recommendations on these ten points into a new bogie design will give a consistently good ride, which is relatively insensitive to tyre wear and to normal track irregularities.

HIGHER SPEEDS THROUGH CURVES
Investigation of rail friction (mu (sub y)), made on both wet and sanded rock, at speeds between 6 and 72 km/h, showed values ranging between 0.4 mu (sub y) and 0.5 mu (sub y) with banding leading to higher values. Values of mu (sub y) for lateral slip versus wheel-load are given as are values of mu (sub y) for a range of R(m) from 300 to 890 at speeds from 80 to 110 km/h. It was noted that the use of bogie intercouplers reduce rail friction (mu (sub y)) and flange wear.

BOGIE DESIGN FOR HIGH SPEED
Opinion holds that the line of demarkation between low speed and high speed operation, from the coach design point of view, is in the region of 80 to 85 mph. Bogies that have been tested in freight wagons have exhibited good riding qualities at 80 mph, or lower, but have shown themselves entirely unsuited to speeds above 85 mph, in some of the tests the shocks recorded were doubled in intensity as speed increased from 80 to 90 mph. Up to 80 mph the amplitudes of body swing were within reasonable limits, but at 90 mph the body of the box wagon under test was becoming unstable. Experiments proved that, given equal conditions of springing and of maintenance, a six-wheel bogie gives slightly better riding in both vertical and horizontal planes than a four-wheel bogie, and has better braking qualities also; but the gain is not considered to be worth the increase in weight, first cost, and cost of maintenance. In the design of passenger-car bogies, coil bolster springs perform the same duty as the swing hangers in the elliptic spring bogie. Another important requirement is that in wheels for high speed equipment the treads shall be concentric within 0-10 in. Experiment showed that one of the principal factors in causing bogies to "hunt" at speed, is a short and sharp taper close to the throat of the main flange of the wheels, even if the extent of the taper be no more than 1/10 in. No bogie design tried by the Milwaukee has given good riding at high speed if the wheels have been in this condition, and the only way to restore such wheels to good riding qualities is by re-turning or griding them.

"LRC" PROTOTYPE DEMONSTRATED--POWERED BANKING ON CURVES IS KEY FEATURE ON NEW CANADIAN FAST-TRAIN CAR
The prototype coach of Canada's high-speed "LRC" train has successfully undergone running tests at speeds in excess of 90 mph. When completed, the "Lightweight Rapid Comfortable" train would operate in pushpull service, with a locomotive at each end and up to 12 coaches, at speeds up to 120 mph on existing North American Tracks. LRC's most significant engineering feature is its "powered banking" system, built into the car suspension. The two-axle trucks, are basically of conventional design, but they have an additional bolster that can tilt the car body to compensate for up to 10 deg of unbalanced superelevation. Each truck has a sensor, which responds to centrifugal force and seeks a bank angle that will reduce this force on the passengers to near-equilibrium. The sensor activates a servo mechanism that causes the banking bolster to be rotated hydraulically until the car body meets the desired bank angle.

EVALUATION OF THE STABILITY OF THE M130 AND D1G CONTAINER CARS
The railroads have been experiencing difficulties with 100-ton cars having a high center of gravity. The results of the tests showed that the M130 Container Car and the simulated D1G container car were both sensitive in roll to track-induced inputs in the as received condition with standard D-3 springs. At 22 mph, the car roll amplitude reached 7.5 degrees and wheel lifts of e inches were retested. The rocking action was reduced substantially

but 2-in wheel lifts occurred within 1 mph of the critical speed of 22 mph. The addition of 8 Stucki HS-6 snubbers to the D-4 spring group eliminated wheel lifts up to 22.5 mph. The dynamic roll action of this 350,000 lb. car produced excessive track degradation in the as received condition. The hydraulic snubbers and D-4 spring modification reduced this track degradation by a factor of 4 to 1.

ON THE USE OF INDIVIDUALLY SUPPORTED FREE ROLLING WHEELS ON RAILWAY VEHICLES [ZUR FRAGE DER VERWENDUNG VON LOSRADERN IM SCHIENENFAHRZEUGBAU]
The kinematics of wheel-sets on railway vehicles is discussed in theory. The tests are reviewed which were made of individually supported, free rolling wheels in frames under vehicles without a rigid connecting axle from wheel to wheel. The conclusions of this study point out the following: free rolling wheels have no guidance capabilities along the rail; wear on the curves is not avoided by free wheels. Safety factor against derailments is less than with conventional wheel sets, since the free wheel cannot develop sine waves in its running, it runs free of such lateral vibrations and is therefore quieter. [German]

DB EXPERIMENTS WITH POWERED TILTING OF COACH BODIES
A three-car diesel train with air suspension has undergone field testing to develop an electro-pneumatic servo which tilts the body inward on curves. The three-car diesel train has been run experimentally at 130 km/h over a route that is largely limited to 105 km/h. If the train itself was capable of higher speeds it is claimed that 135 km/h could have been attained safely. Air springing provides the tilting mechanism, the servo system being arranged so that the air bellows on the outside of the curve are inflated and those on the inside deflated, thus tilting the body relative to the bogie towards the inside of the curve. The centrifugal force that can be tolerated without discomfort is taken as 0.067 g, which is equivalent to a cant deficiency of 100 mm.

PHYSICAL HAZARDS OF TRANSPORTATION
The interaction of shipping containers in the presence of shock and vibration during railway transportation is discussed. Vibration frequency measurements are reported for empty, half-loaded, and fully loaded cars travelling at speeds from 10 to 90 mph. The impact of containers on end walls is suggested as a more important source of merchandise damage than coupler forces or acceleration. Compartmentalization and load dividers are suggested to decrease damage. Variable rate springs for freight cars are being studied to narrow the frequency band of vertical vibration of the car. Test programs are being developed to further study impact in loaded cars.

STEERING CHARACTERISTICS OF BOGIES
This article, which is a description and analysis of the fundamental steering properties of four-wheel bogies, considers the limitations of bogie vehicles for high speed operation and compares their performance with estimates for the APT, the 250 Km/h advanced passenger train. Because bogies act to attenuate the effect of road bed irregularities, there are strong reasons to favor bogie vehicles whenever passenger comfort is a major consideration. A possible disadvantage is that bodies designed to be dynamically stable at high speeds may need a primary suspension which is too stiff for good steering properties. It is concluded from mathematical studies that a dynamically optimized bogie still provides satisfactory guidance, comparable with a four wheel vehicle with a very soft suspension, and bogies should not, therefore, be regarded as unsuitable for high speeds.

INTERACTION OF WHEEL AND RAIL WITH RESPECT TO TRACKING, WEAR, FREE ROLLING AND STRESS IN WHEEL SETS
The author examines the interaction of wheel to rail with respect to tracking qualities, wear of wheel tread and rail, free rolling and stress in the power wheel sets under power or braking. A picture is shown comparing the stress lines in the rail under a wheel with the flange away from the rail with that where the wheel tread and flange both exert pressure on the rail. The verification of the theoretical considerations of these conditions by actual measurements has been made by modern techniques, which are closing the gap between theory and practice.

TRACK STRESSES AND VEHICLE MOTION AT HIGH SPEEDS
The high speed test runs made with the locomotives E 10 299 and E 10 300 and 8 wheeled track recording cars and passenger cars are described. Extensive measurements were made of the stresses to which the track is subjected at train speeds of 140 to 200 km/h, and of the dynamic wheel loads and lateral pressures against the rail, as well as the effect of these forces on the roadbed. The results of these tests on curved and straight track are given and illustrated by charts. The present usual track structure will suffice for the high speed operation. The minimum radius of curvature should not be under 1890 meters. Continuous welded rail improves the riding qualities in high speed operation. A desirable riding comfort level is attained in the passenger cars at 200 km/h speeds.

ASSURING THE STABILITY OF THE BARTD LIGHTWEIGHT RAPID TRANSIT VEHICLE
The BARTD System will utilize lightweight cars about 800 lbs. per linear foot operating at higher average speeds than any other transit system in the world. These vehicles will be subjected occasionally, on 31 miles of aerial structures and 24 miles of at-grade construction, to high winds. Mathematical formulas were developed to determine the reliability of vehicle-track systems constructed to a range of gauges under various combinations of adverse conditions. As a result of these investigations, it is recommended that the BARTD System vehicle and track system be designed to a guage of 5'-6". Findings clearly indicate that this approach would assure the lateral stability and safety of the desired lightweight vehicle more effectively and economically than any other design approach.

LATERAL RAIL FORCES DUE TO VARIOUS LOCOMOTIVE AND TRAIN CONSISTS
A series of tests was performed to determine the lateral forces developed by various types of locomotives and train consists. Analysis of the data indicates that no excessive lateral forces were developed by any of the test consists. The maximum average force, 7,400 pounds was developed by the T.P.F.C. freight. The effect of roadway irregularities on lateral forces generated by normal consists remains largely unknown. Based on the results of this test series, it is concluded that light locomotive, passenger and freght consists generate relatively low lateral force on good roadway. There is a slight reduction in maximum lateral forces as training tonnage is increased. A study of the available research literature on the forces required to overturn rail shows that the maximum pressures measured were about 30% of the forces theoretically needed.

ROLL ACTION TESTS OF 100-TON HOPPER CARS ON THE GULF, MOBILE AND OHIO RAILWAY
The GM and O conducted extensive induced roll action tests on Commonwealth Edison 100-ton hopper cars being used in unit coal train service. The tests were conducted on tangent track, laid with 112-lb. rail. A target was placed on top of the car at its center and a transit was set up on an overhead bridge to measure the amount of lateral movement of the top of the car in inches. It was found to be possible to measure the car roll accurately in this manner. The amount of wheel lift was estimated. These cars are equipped with rotary couplers for unloading. A friction type gage was used to measure the maximum spring deflection. Variations were made in the type and number of springs, with and without various types of snubbing devices, bolster gib clearance, and side bearing spacing. The data sheets give a description of the truck arrangement and the results obtained. It was decided after these tests that the standard equipment provided initially on these cars was satisfactory for their operations.

ANALYSIS OF COVERED HOPPER CAR DERAILMENTS ON THE BALTIMORE AND OHIO RAILROAD
The derailment history of high-cube, covered hopper cars on the B&O Railroad was analyzed. The analysis showed that the in-service life of this type of equipment has a very noticeable effect on its derailment rate. About 80% of the derailments occurred during the first year of service. The statistics also show that rock-offs of foreign cars of the same type are also a serious and growing problem. The analysis shows that the operating restrictions on the PS-2-CD domestic and foreign cars are effectively reducing derailments of these high-cube, covered hopper cars. An extension of the PS-2-CD operating restrictions to all covered hopper cars with a capacity of 3000 or more cubic feet and less than one year old could provide an interim solution that could be quickly implemented.

A WHEEL PROFILE: FOR BETTER RIDING AND LONGER WHEEL LIFE
Riding qualities can be improved and wheel life can be extended by making rather modest modifications to conventional profiles. The present AAR profile has one major shortcoming in common with the conventional British profile, and one additional problem that is unique to railroading in North America. The common problem is that there are two points of contact between the wheel and the rail when flange guiding is required. The uniquely American problem is associated with the inward cant at a 1:40 angle whereas the angle of the tread face is 1:20. Because of the angle between the rail and the tread face, there is rapid tread wear immediately after wheels are turned and an attendant loss in lateral riding qualities. The proposed profile uses a basic taper of 1:40. A flange throat contour which at all points has a slightly larger radius than the head of the rail, and a short section of flange face at a 70-degree angle. The region of the tread face which gets the least use is relieved at a 1:10 tamper. Using a modified flange throat contour will improve the steering action of a wheel set lateral movement of the wheel will be opposed by a smoothly increasing lateral restraining force and on a curve the rolling radius of the outside wheel can increase much more than is possible with a conventional wheel set.

ROLLABILITY OF CARS
Potomac Yard tests were conducted with cars obtained from the yard which were hard rollers. The rolling resistance of the car as received in the yard was compared with that after certain changes were made for improvement. A total of 408 test runs were made, utilizing 7 freight cars. Observations made during the testing were skewed trucks on tangent track; dragging brakes; wind up to 12 mph; poor center plates; comby wheels; hollow wheel treads; wheel diameter difference of 3/8 in.; and side bearing clearance from tight to 1/2 in. Changes made intended to improve rolling resistance were: grease outer rail on curves; apply regular grease on center plate; moly grease on center plate; add liners for side bearing clearance; grease side bearings; add nylon moly content liners in center plate; add brass liners in center plate; and tighten brake rods for rod eccentricity. Significant differences in the average rolling resistance were reported following the changes.

CLEARANCE ALLOWANCES TO PROVIDE FOR VERTICAL AND HORIZTONTAL MOVEMENTS OF EQUIPMENT DUE TO LATERAL PLAY, WEAR AND SPRING DEFLECTION
A method for calculating lateral clearance requirements for passenger cars on curved track is presented considering the following factors: roll of car body, due to unequal spring deflections and play in side bearings; displacement due to swing-hanger movements and lateral play and wear in truck parts, and allowances for the effect of track irregularities and dynamic behavior of equipment. The results obtained are only as good as the basic information, such as degree of curvature and elevation. For best results, it is recommended that actual field conditions be determined by actual field measurement, determining curvature by string lining and elevation by cross levels. Variation of a few minutes in curvature should not be ignored.

VEHICLE DESIGN RELATED TO TRACK CONDITIONS
Recommendations which may influence improvements in the safety and comfort of passenger-train rolling stock are made in a paper, Vehicle Suspension and Bogie Design in Relation to Track Conditions, by Mr. R.M. Hancock of British Railways. The paper deals with the necessity of relating vehicle suspension and bogie design to the track conditions likely to be encountered in practice, particularly where lateral and crosslevel wave shape are concerned, as these are most likely to produce discomfort. The vehicle-response basis of systematic testing main routes as carried out with the Western Region track-testing car has provided much of the experience from which the illustrations in the paper are drawn. The effects of coning and track shape, in relation to the riding of four-wheel vehicles, are considered with reference to an investigation of their derailment in fast trains.

THE EFFECT OF TRACK GEOMETRY ON RIDE QUALITY
In this test, acceleration measurements were taken with one lateral and one vertical accelerometer attached to the floor of the test car. The sensitivity of ride roughness to changes in crosslevel during the negotiation of a curve is shown. Also shown is the change in ride response due to bolted to welded rail transition. The track geometry measurements used in this investigation were: centerline profile, the average profile of both rails; alignment; gauge; rate of change of gauge; and warp. The track and ride data were then sorted according to speed. The data for the 100-110 mph tests are plotted on scatter diagrams. Correlation coefficients were then computed for each of the six track exception densitites and the density of the sum of all exceptions with vertical, lateral, and mean lateral/vertical ride. The results are shown. Though sample populations are small, data correlation is sufficiently reasonable to lend support to the approach.

Paper recommended by IEEE Land Transport Committee of the IEEE Industry and General Applications Group for presentation at the joint IEEE/ASME Railroad Conference, Montreal, Quebec, Canada.

BODY ROLLING AS INFLUENCED BY BOGIE SUSPENSION--1
Considerations of design variables affecting the angle of roll of bogie vehicles is discussed. A standard Russian coach bogie with divided bolster swing links is shown. Tests carried out with modern coaches running through curves at a steady speed resulting in an unbalanced lateral force equivalent to 0.1 g show that the angular displacement varies between 0.019 and 0.032 radians. With some modern bogie locomotives using laminated bolster springs and operating at speeds of up to 90 mph the angle of roll on straight track was found not to exceed about 0.005 radians. Roll stiffness of coaches, railcars, diesel and electric locomotive bogie suspensions for British Railways stock and the angle of roll are tabulated.

NON-LINEAR SPRINGS
The problem of ensuring satisfactory riding characteristics with vehicles operating in suburban services is particularly difficult because, as far as the bolster springs are concerned, the rush-hour load can exceed the weight of the vehicle body. Consequently, a static deflection of 4 inches under tare load will mean a static deflection of 8 inches and more under overload. General design considerations make it often necessary to deviate from the constant frequency relation, particularly when dealing with heavy overloads. To ensure a non-linear characteristic, rubber cones are used inside helical bolster springs and use is also made of suitable rubber springs sometimes incorporating helical springs vulcanised in them also to prevent undue barreling out of the hollow rubber cylinders. The use of non-linear centering devices is beneficial by reducing the degree of coupling between bogie hunting and body nosing and swaying in the range of low amplitude and frequency oscillations.

B2 037699
THE SUPERELEVATION OF RAILWAY CURVES
The most suitable superelevation for a given curve is determined as follows: the average speed on a tonnage basis should be ascertained from the actual known speeds of all trains, and the curve given the full theoretical

superelevation corresponding to this average speed; and the maximum permissible speed on the curve should then be fixed as that corresponding to the above superelevation plus 4 inches. The first condition will result in equal loading of the two rails, and hence equal head wear and even maintenance of surface. The second ensures passenger comfort, and gives an ample factor of safety against derailment which is uniform for all curves, while at the same time it fixes an upper limit to the lateral forces acting on the track which is also the same for all radii. A table gives the superelevation for various radii for different average speeds, and the corresponding maximum permissible speeds.

B2 037700
BODY ROLLING AS INFLUENCED BY BOGIE SUSPENSION--2
The effective length of the swing links should be considered in terms of the natural frequencies of lateral and nosing oscillations, as well as swaying, frequently, the use of relatively long links is desirable to reduce the sensitivity of the suspension to lateral track irregularities and to achieve a low natural frequency of the lateral track irregularities and to achieve a low natural frequency of the lateral and body nosing oscillations. Particular attention must be paid to lateral displacement for this is determined by the effective link length and the lateral force. Another solution consists of pre-loading the bolster laterally, the centering springs action increasing usually in direct proportion with the displacement, a feature found with leading bogies of steam locomotives and some modern bogie electric locomotives. The natural frequency of oscillation for a British Railways coach is determined mathematically. Articulated swing links used in Switzerland are briefly described.

HYDRAULIC DAMPERS
As far as vehicle suspension incorporating steel springs is concerned, the number of damping characteristics can be limited to two; friction damping and viscous damping. Friction damping occurs in every system and is maintained by friction forces acting in opposition to the motion. With true (Theoretical)viscous damping the damping force opposing the oscillation is proportional to the velocity of the latter. Many hydraulic dampers meet this requirement over the lower range of their characteristic. The effect of damping on the pattern of vibration decay and the effect of damping on the force and displacement transmissibility and resultant acceleration are shown. The Askania hand vibrograph is illustrated, along with the vibrograph records of diesel-electric locomotives. Typical characteristics of various damping methods encountered with railway vehicles are graphed.

A NEW METHOD OF DYNAMICALLY STABILIZING RAILWAY BOGIES, FOUR-WHEEL WAGONS, AND ROAD-RAILERS AGAINST UNDESIRABLE LATERAL OSCILLATIONS
A new method is described of dynamically stabilizing railway bogies, four-wheel wapons, and road-railers so as to be proof against undesirable lateral oscillations. It is generally accepted that the root cause of all such oscillations is the inherent instability of the ordinary axle-set, i.e. the integral unit of live axle and two wheels. By seeking to eliminate this instability, the new method tackles the problem as its source. The principle relied upon in the method is that of the inertia-guided axle, i.e. an axle with a leading guiding arm that is integral with it in yaw and that is connected at its forward end, by means of a velocity damper, to a floating mass whose lateral inertia provides the necessary guidance. Alternate guiding arms come into action wherever the direction of travel is reversed.

CAR ROLLABILITY ON GRADES
This report discusses the various factors which decrease the rollability of railroad cars. These factors include: center and side bearings of trucks; broken, scored or unlubricated bearings; tolerance of axle bearing and truck bolster in side frame; plus dragging brakes. Findings suggest methods to increase rollability of rolling stock with related savings, such as improve center and side bearings with good lubrication; use of rust resistant materials; redesign brake rigging to minimize dragging of brakes resulting in locking of the truck; and creation of a device to free brakes with air is bled from the system.

CAR ROLL AND WHEEL LIFT, PROBLEM CHARACTERISTICS
The problem of car roll becomes more acute as the height of the center of gravity of the car body and lading is increased by greater car heights; and as car lengths are increased to the extent that the distance between truck centers approximates a standard rail length. While severe car roll is objectionable the most serious immediate consequences are wheel lift and resultant derailments. Commulative roll can develop very quickly to cause wheel lift. With rail joints 3/4-inch low, wheel lift can develop in four rail lengths at critical speed. Wheel lift can also be obtained on track with joints only 3/8-inch to 1/2-inch low if the joint stagger is midway and uniform, all joints are equally low, and the critical speed is maintained for about ten rail lengths. Fortunately, only a small percentage of wheel lifts result in derailments. When car roll is severe enough to cause wheel lift, there is a sizeable lateral force in the direction of the wheels staying on the rail, so that on tangent track, the wheels that are lifted simply come back down on the rail. In addition to the derailment hazard possibility there will be an increase in fatigue failures of journals, wheels and rail near joints as the result of the repeated high wheel loads being sustained due to severe rolling of heavier cars on track with less-than-perfect rail joint conditions.

CAR ROLL AND WHEEL LIFT, PROBLEM SOLVING APPROACHES
The author discusses the problem of derailment and larger hopper cars as a two step process, (1) problem definition and (2) the selection of possible solutions or alternatives. It is pointed out that not all 100-ton cars derail. Only a relative few derail and, those which do, derail at more or less predictable locations. In the rail-versus-car controversy, it is obviously not very reasonable to spend the money to overhaul every mile of railroad track, nor is it any more reasonable to condemn the 100-ton car since it is one of the major factors contributing to increased railroad business. One possible solution might be to correct the very bad areas of track where the rail joint conditions produce severe dip, and the track arrangement is such that roll is reinforced; then do enough to the car itself to make it tolerate the remaining track. A few solutions on which there has been some work during the last year or two include improvement of the track and roadbed, and control of operation of the train so that susceptible cars don't move over troublesome curves at the critical speed or under certain conditions of draft or buff. Most derailments occur with newer cars, and when substantial milage is accumulated so all contact surfaces are worked in and maximum freedom of movement is attained there is a distinctly lessened tendency toward derailment. However, work on hopper car derailments has not produced a generalized solution which is widely adopted.

CAR ROLL AND WHEEL LIFT TESTS ON SIMULATED SERVICE TRACK: TEST CONDITIONS AND RESULTS AT PRR ALTOONA TEST SITE
The class H-43, 100-ton hopper car began derailing at increasing rates beginning in the Spring of 1964 as more and more of these cars were placed in service. It was decided to set up a test track to simulate the rock-off phenomena and determine what modifications could be made to the car to reduce wheel lift and car roll. All cars were tested first on a tangent track with rails shimmed 3/4" to produce an 1-1/2" total change in cross level at each 39-ft. joint over a distance of ten rail lengths at speeds in the range of ten miles per hour to 22 miles per hour at approximately one mile per hour increments or until the critical speed was exceeded. The cars were then tested on a 3 degree curve having a 4-1/2" super-elevation with an 1-1/2" change in cross level superimposed at each joint over a distance of six rail lengths. Speeds on the 3 degree curve did not exceed 15 miles per hour. After testing, it was decided to adopt the following truck modifications:--1. Replace the 2-1/2" travel springs with 3-11/16" travel springs. 2. Add two friction snubbers to each spring group to absorb energy input into the spring group: 3. Move the side bearings in from 50" centers to 46" centers. 4. Machine the bolster gibs to permit more bolster lateral freedom. Even though a truck modification eliminate wheel lift on the test track, it was not certain just how close the wheel is to becoming unloaded.

CUSHIONING REQUIREMENT TRENDS IN NEW CAR DESIGN
The early history of cushioning and car design is reviewed. During the period from the early 1900's to the present, it is interesting to note the changes that were made in the couplers and yokes. The size of the head and shank of coupler was increased several times to what we now have, and the material was changed to high tensile steel several years ago. There has been quite a change in the yoke, too, from the old riveted type to the current designs in cast steel. During this period, the car structure was undergoing changes and modifications in an attempt to provide more strength and reduce or eliminate failures. Today, only a small percentage of impacts in classification yards occur below five miles per hour. Impacts at speeds from eight to ten miles per hour are not uncommon. The cushion underframes and end-of-car devices are doing a good job in affording better protection to the lading, and they have reduced the stresses substantially in the car structure, particularly the body bolster and ends of box cars. In the future the use of cushion underframes and end-of-car devices for fragile commodities will increase but not in general use.

BODY STRUCTURAL PERFORMANCE
When cracks begin to show up on cushion underframe castings of 70-ton cars, laboratory work was initiated to find and correct the problem. It was quickly determined the car rocking and rolling was causing cracking problems in the reinforcing ribs of the casting. A special casting was developed to provide for all rocking moments within the underframe coating itself. After running a number of laboratory tests measuring stresses at the critical areas, tests then were run on such a bolster that was built into a car. The car was loaded, detrucked, and supported at the ends of the bolster as had been done in the lab. Known loads then were jacked into the car and stresses were measured in critical areas. Field tests and lab data were compared, thereby permitting evaluation of the effect of the car structure on the bolster. It was found that the car structure does assist the bolster in resisting rock and roll and that top cover plate reinforcements were effective.

BENDING STRESSES IN A MOTORED AXLE ON ELECTRIC ROLLING STOCK--1

This article gives results of strain gauge tests on a motored axle both empty and loaded. Deductions from the results lead to an emphasis on the transverse friction between wheel and rail. This factor, neglected in axle stress formulae, is shown to be of major importance in the bending moment on the wheel seat of an axle, amounting to about 40 percent of the total on a curve with equilibrium cant. Support for the deduced theory is given by the correspondence between calculated and measured stresses, and also by the results of direct comparative tests. Additional stresses from cant deficiency, track irregularities, and acceleration or braking are discussed. The apparatus used in the test and the procedure of testing are fully described.

BENDING STRESSES IN A MOTORED AXLE ON ELECTRIC ROLLING STOCK--2

A further check of the theory that transverse friction is a major item in the stressing of axles was made by a series of comparative tests. While vertical differences in track level apparently affect the stress in the axle very little, it has been found that the test axle assembly is very sensitive to the condition of the running edge of the high rail on a curve. Contrary to expectation, passage over the toes of switches and the noses of crossings did not produce high stresses in the axle. Passage through the lead of turn-outs caused high values to appear, though no higher than those which occurred on some curves.

ASEA AND SJ TEST TILTING SUSPENSION WITH PANTOGRAPH ADJUSTMENT

An electronic pendulum or accelerometer senses the lateral acceleration in a curve, and the deflection of the pendulum determines the tilting angle of the coach. The air suspension raises one side of the coach body and lowers the other side; full tilting angle is obtained within 1.5 sec. The system is stable and unaffected by irregularities in the track; the air suspension itself provides a simple level control so that the relation between coach floor and platform height remains constant irrespective of whether the coach is loaded or empty. As well as practical tests, computer simulations of the equipment have been performed. The two-car electric unit used for the tests so far has a maximum speed of 120 km/h, but its gear ratio is to be altered to permit speeds up to 200 km/h.

DEVELOPMENTS IN WAGON BOGIE DESIGN

Cast-steel bogie frames and bolsters are being used for goods stock on many railways. Basically, there are two designs, one employing springs without friction damping and the other, springs which are friction controlled. The bogies can be of either the plank or plankless type, but the self-aligning spring plankless type gives better riding qualities with consequent reduction of wear on bogie guides and on wheel flanges and rails. There is also a reduction in cost and weight due to the elimination of the plank. Friction controlled bogies have long travel bearing springs, although they can be designed for short travel springs, with adequate reserve travel and constant control of spring action. Tests have shown friction controlled bogies give improved riding of wagons at all speeds with consequent reduction in wear and maintenance. Unit brake beams are described.

RUBBER SUSPENSION FOR BOGIES

The object of these experiments is to determine the practicability of suspending the whole bogie on rubber, and so bring about a reduction in maintenance costs by eliminating all wearing parts such as rubber plates, hanger pins, and bushes, as well as the steel springs. Such suspension would also go a long way toward reducing if not eliminating the running noises resulting from conventional type bogie suspension, particularly in tunnels. A preliminary investigation indicated that the cost per bogie was approximately 50 pounds more than for the standard arrangement. It is anticipated that the life of the rubber units will be approximately ten years, if not longer. The saving in maintenance would more than compensate for the extra initial cost.

RUNNING THROUGH CURVES

Economic considerations demand high average, rather than occasional high maximum speeds. Rapid acceleration and retardation are essential and vehicles must also be able to negotiate curves at high speeds, which is of particular importance for lines with many curves. The forces acting on a vehicle running in a curve are shown and the limiting valves of speed and the effect of axle load on speed through curves are established mathematically. Transverse flexibility is important in reducing dynamic forces at curve irregularities. Time-speed and time-distance curves for a single car and for a car and trailer are plotted for electric hydraulic and mechanical transmissions.

CONFINES OF BRAKING--1

Factors reducing braking rates below the limit imposed by adhesion between wheel and rail are discussed. Braking efficiency can be related to adhesion, but only when the braking is straight line from moment of application to standstill. This is never so in practice, and the braking efficiency can therefore be considered only as an average ratio, and not the adhesion value which is the limit in maximum braking. No braking starts at the maximum rate instantaneously, nor does it usually carry on to a stop at the maximum rate. The reasons are regard for passenger comfort and the speed of equipment response. Manufacturing inaccuracies and maintenance problems which cause differences in brake cylinder air pressure are mentioned.

IMPROVING THE SUSPENSION AND STABILITY OF RUNNING OF BOGIES

New coaches have been equipped with an improved Pennsylvania bogie, having reduced play about 1 mm. in new stock designed to take nearly 50 percent of the total load on the bogie. Coaches fitted with these new bogies have an excellent degree of stability in running, up to speeds of 100 mph and over. Double elliptical springs in the bogie were eliminated and were replaced by something flexible, able to damp all stock gradually. The design enabled the total vertical accelerative movements, measured inside the vehicle, to be reduced by some 50 percent, and the shocks caused by passing over the rail joints to be noticeably lessened. These bogies have a control device or system composed of longitudinal and lateral stay-bars, which dispenses with horn plates on the axle boxes, or guides at the ends of the swing bolsters.

DERAILMENT NEAR SITTINGBOURNE

The train comprising 24 empty continental ferry vans and a brake van, became derailed on plain track approximately one mile west of Sittingbourne Station. The train was running at 55-60 mile/h when it derailed, a speed substantially in excess of the 45 mile/h limit. Since the intermittent side-cutting of the high rail contributed to this derailment, the possibility of reducing it by making some change in train behavior over the curve deserved consideration. Train behavior itself should be altered if the cant were reduced to three-fourths inches at which equilibrium speed would be 39 mile/h. The fast trains which appeared to cause the intermittent side-cutting would then run more firmly against the outer rail and the intermittent side cutting would be checked.

HEUMANN TYRE PROFILE TESTS ON BRITISH RAILWAYS

A new tire profile, based on the studies of Prof. Heumann, was designed and is illustrated. This tire profile should assist in ensuring good riding qualities, increase the resistance against derailment and this in turn should reduce tire and rail wear, and ensure a favorable wear pattern. This can be done by ensuring one-point contact running and a gradual transition of the throat profile. The result of trials carried out with standard 32 ton British Railways coaches running on B4 type bogies with 3-ft. wheels, positive axle guides, 19-1/2 in. effectively long swing-links and helical springs throughout are shown. Ride index values during acceleration and wear patterns for the tires are given. The tests have shown beneficial results, although further tests are needed.

MANGANESE-STEEL AXLEBOX LINERS
Wear of axleboxes, more than any other single feature, is responsible for requiring locomotives to be returned to the workshop for repairs, and the mileage between shoppings is directly connected with the wear-resisting properties of the materials of which the axlebox rubbing surfaces are composed. It became clear that any considerable improvement in shopping mileage would require different material for the flat surfaces of the axleboxes, and the practice of fitting manganese steel liners to roller bearing axleboxes suggested a line of attack. Details for fitting axleboxes with new liners are presented. The leading features which were observed during examination in the shops and sheds following mileage runs average 80,000 miles shows. 1. The surfaces of the liners which are in contact with one another become work hardened in service and take on a high polish. 2. A very interesting feature has been that reduction of "knock" or wear in a longitudinal direction has had also a beneficial effect on lateral wear. 3. Bolts and rivets of the horn liners have remained tight. 4. Scoring of the liners has been negligible. The manganese steel liner has been adopted as standard and it has fitted to new construction of all types. Apart from the potential increase in shopping mileage, the liners already are proving of considerable value from an operating point of view in reducing development of rough riding.

AXLE-FATIGUE TESTING MACHINE
A testing machine, designed for investigating the fatigue strength of railway rolling-stock axles, has been installed in the new Central Research Laboratory of London Transport at Chriswick. The machine is of the resonant type driven by an electric motor through a slipping clutch which is incorporated to ease the starting and stopping conditions. The test specimen are of a typical axle size. The stress is measured by several resistance strain gauges, calibrated in position, and various protective devices are provided to enable the machine to be left running unattended

RUBBER-CUSHIONED RESILIENT WHEELS FOR MAIN-LINE RAILWAYS
Most types of rubber-cushioned resilient wheels, including those for tramways and for narrow-gauge railways, consist of three metallic discs. Between these discs are placed either circular rubber blocks, positioned in one or two concentric rows, depending upon axleload, or a single pair of large rubber discs, which may be divided into segments. The central metal disc is fixed either to the wheel or to the wheel hub. Several applications of rubber-cushioned wheels, both on tramways besides main and secondary railway lines, have shown considerable reduction of maintenance costs for the mechanical parts and electric equipment, particularly collectors, because of the radial and tangential flexibility introduced by these wheels. The reduction of the wear on tires and flanges with resilient rubber-cushioned wheels, must result in a corresponding reduction of the wear of the rails.

A CALCULATION OF THE LATERAL HUNTING MOTION OF A TRACKED VEHICLE
The lateral hunting motion of a vehicle running on tracks is not only prejudicial to riding comfort, but may also cause dangerous derailment. The initial step in the design of a safe high-speed train is a theoretical and experimental investigation of this lateral hunting motion and a practical method of preventing it. The usual railroad train may be idealized as a system consisting of a number of cars connected end to end like links of a chain. The transfer-matrix technique purports to be applicable to such a system, whereby once the transfer matrices of each component (car) are derived, it is only necessary to perform successive matrix multiplications to fit the entire system. It is demonstrated that the transfer matrix method may be applied successfully in a study of lateral hunting motion. The stability problem associated with this motion, and forced vibrations caused by irregularities and lateral distortions in the rails may also be investigated by the use of the transfer-matrix technique. WHEEL AND RAIL LUBRICATION
Remarkable increases in life of rails and wheel flanges through lubrication, by as much as 700 percent, are quoted by Dr. Fritz Birmann, in his paper "Lubrication of Rails and Wheels." The requirements of a lubricating system to reduce wear of rails and tires, are that the lubricant must be prevented from spreading to the running surface of the rail, thereby reducing traction; that the efficiency of the system must not be spoiled by dust, dirt or weather influences; that the lubricating devices and spray nozzles must be profile free on the rail and vehicle; and that lubrication must not start too late on the curve, so that it is preferable, where possible, to lubricate tires before entering the curve.

CARRIAGE-BOGIE DESIGN
Factors involved in determining the riding characteristics of coaching stock are numerous. By means of suitable formulae, the path of a wheel set, will be a sine curve. It is influenced by the profile of the rail head. The characteristics of springs are carefully considered as suggested that helical springs might be used to deal with both vertical and lateral forces or by arranging for bogie center to bear against large rubber pads disposed at an oblique angle, so as always to be in shear.

WHEEL HUNTING AND IRREGULAR RAIL WEAR
In addition to the "hunting" of rolling stock wheels, there is the constant side-to-side movement of individual pairs of wheels. The standard taper of coning of wheel-treads is at 1 in 20, so the tread of a new tyre may be at right-angles to the centre-line of the rails. Experiments have been tried in varying the angle of taper of the treads and the radius of the railhead, but the wear of tires and rails complicates the problem, and hitherto has made it difficult to come to any final conclusion as to how the hunting problem may be solved. Persistent bogie hunting can cause bogie stock to ride uncomfortably. Of even greater importance is the wear-and-tear of rolling stock and the damage to rails caused in this way.

PREVENTION OF DERAILMENT OF GOODS WAGONS ON DISTORTED TRACKS
A mathematical study is presented to determine the critical value of relative wheel unloading of the leading wheel of a freight car on a track twist. Also determined are the maximum track twist which can safely be negotiated by a vehicle and the measures which need to be taken to adapt freight cars to meet the standard without modification of the torsional stiffness. The standard adopted by the Specialists Committee B55 of the ORE is a maximum permissible relative wheel unloading equal to 0.6, at a maximum permissible track twist of 7 percent.

AREAS OF CONCERN FOR FREIGHT CAR ENGINEERING
The aims of containerization are to provide cheaper, safer and quicker transportation for commodities which can be placed in standard size boxes. To obtain maximum benefits, special equipment is necessary and economically justified. The size of the containers, loading and securing methods, and size and capacity of the cars are described. A series of tests were made to determine the source and methods to eliminate the poor ride qualities of 60 feet container cars used on the Canadian National Railways. The tests were run over the same track at a range of speeds. The acceleration was measured in the vertical and lateral directions. Track hunting was apparent above 45 mph. The results of the tests are shown.

ENGINEERING CRITERIA FOR FUTURE FREIGHT CAR TRUCK DESIGN AND PERFORMANCE
To establish the criteria for design and performance of freight car trucks, the environmental effects on the truck must be examined. These environmental effects are grouped as: external environment from track conditions, carbody and train speed; and internal environments which are induced by the truck design, the specialty components, such as roller bearings and the state of the art in developing the most desirable elements in the truck assembly. Each of these effects is described. The lack in the U.S. of a full-scale wheel-rail dynamics research facility to test trucks and tracking has hampered the efforts on truck design. A British Railways test using a U.S. truck design and their Freighliner test equipment is briefly described.

CARBUILDER'S APPROACH TO THE SOLUTIONS OF THE TRUCK--CAR BODY RELATIONSHIPS
Three failure modes for center plate areas are discussed and illustrated. Wear of vertical wall inboard and outboard has been reduced by the wear ring and harder center plate. By use of these modifications, the 50 and 70 ton service experience should be approached. Cracking of center plates was prevalent prior to 1967, and was a function of the center plate center filler contact area. Failures had not occurred at conference time of the solid forced plate designed to eliminate the cracking problem. Cracking of the cushioned underframe center plate is a function of the overall bolster design and with proper design and reinforcement, this mode of failure should not occur.

RESUME OF LONG CAR TRACKING PROBLEMS
It was necessary to employ a special coupler in the design of the 86'6" Hy-Cube box car for automotive stampings. To permit those cars to negotiate curves it was necessary to use a nonstandard 60-in. "F" shank coupler with a Type "E" head. The coupler carriers have been broken on several of the cars as they were passing over vertical curves of lesser radii than the cars were designed to negotiate. Coupler carriers on other cars coupled to Hy-Cube cars have been literally torn off while negotiating vertical curves. The most prevalent difficulty with the long couplers on cars with long overhangs, is caused by missed couplings. Accidents of this kind smash angle cocks, train line nipples, uncoupling mechanisms and in many cases causes much damage to the center sills, especially to sliding center sills. The answer to longer trains and reduced draw-bar pull may be automatically controlled locomotives spaced in trains.

THE FRENCH RAILWAY SPEED RECORD
As part of a study of the technical and economic aspects of high-speed operation, the SNCF conducted four days of trial runs at progressively higher speeds. The purpose of the tests was to investigate the margin of safety allowed by the speeds now regularly scheduled with normal types of locomotives and rolling stock. They were also regarded as a contribution to research into methods of improving the productivity of transport and reducing its cost, by showing how the building of vehicles able to run at ever-increasing maximum speeds can reduce maintenance expenditure on locomotives and track when operating at the speeds now normally scheduled. The test train consisted of three coaches of a recent design. Continuous records were made on all the runs by means of piezo-electric apparatus of the lateral forces exerted on the track by the first and third axles of the locomotive bogies. It was found that these did not exceed 4.2 tons.

EASIER MAINTENANCE CONTROL FOR RAILWAYS
A small Canadian railway has initiated a planned maintenance system to detect excessive maintenance costs. The system is designed to point out when equipment should be replaced rather repaired. This method is applicable to anything that has to be maintained: locomotives and rolling stock; roadbeds and tracks; machine-shop equipment; buildings and their components (floors and roofs); paving of roads, and so on. Tables are shown as examples of the system. A measure of operating conditions are established using a Table of Wear Points. This Table shows arbitrary values for various degrees of operating conditions. Multiplying these wear points by each other a wear factor can be arrived at. History cards are kept on each piece of equipment to accumulate the wear factors.
