TESTS OF HEAD END PASSENGER EQUIPMENT PERMANENTLY ASSIGNED TO FREIGHT SERVICE
Tests were made of three types of baggage cars which have been permanently assigned to freight service, equipped with trucks as described below: 1. Six wheel trucks with outside swing hangers. 2. Six wheel trucks with inside swing hangers. 3. Four wheel trucks with outside swing hangers. These tests were made in buff or squeeze to determine the stability of these cars before and after modification to reduce lateral truck frame to truck bolster clearance to plus or minus 3/8 inch. In the first case, the modified six wheel truck showed a reduction in lateral wheel force to drawbar force ratio of 79%. In the second case, the modified six wheel truck showed a reduction in this ratio of 73% and in the third case, the reduction was 54% for the modified four wheel truck. The modified six wheel trucks produced no skewing. The cars with four wheel trucks did assume a skewed position, but the L/V ratio did not exceed 0.66. All these cars with modified trucks had good stability under all these conditions.

TESTS OF F-70-25 MODIFIED AND UNMODIFIED BAGGAGE FLAT CARS
These tests were made to determine the modifications that would be necessary to improve the stability of flat cars redesigned for container service. Preliminary squeeze tests with unmodified trucks resulted in these cars skewing and derailing, indicating that the original 2-1/2 inch bolster to truck frame clearance on each side was too much and should be reduced to at most 1/2 inch on each side. Tests made with instrumented wheels and truck bolsters on both unmodified and modified trucks under these flat cars showed the following: On trucks with unmodified clearance, lateral force of wheel to rail reached 10,000 lbs. with 200,000 lbs. squeeze, resulting in derailment of test car, L/V ratio exceed 0.68. Further tests on unmodified trucks with 450,000 lbs. squeeze developed lateral force of wheel to rail up to 15,000 lbs., resulting in turning rail over and derailing. L/V ratio exceeded 0.68. On trucks with modified clearance, lateral force of wheel against rail reached a maximum of only 2,000 lbs., for an L/V ratio of 0.22. All unmodified cars assumed a skewed position, while all modified cars with restricted bolster to truck frame clearance remained straight in line with axis of track. It was determined that the limitation of the truck bolster to truck frame clearance did not adversely affect the curving ability of the modified car, and rendered the car stable under all tracking conditions.

DYNAMIC TESTS OF FREIGHT CAR TRUCKS UNDER MECHANICAL REFRIGERATOR CARS 70 TON CAPACITY
The objective of these tests was a comparison of the ride characteristics of the various designs of premium type trucks currently being marketed with the ride characteristics of the AAR standard friction snubbed truck. The trucks tested included: The AAR standard 70 ton, narrow pedestal roller

bearing truck. The XL-70 truck, the Rockwell Express truck, the National Castings Division truck, and the Chevron freight truck. The following conclusions were reached: Vertical forces received by the car body floor were not adequately snubbed or controlled by any of the five trucks tested. Lateral force levels at the car body floor were at a low amplitude with all of the trucks tested with new wheels with the exception of the GSI Chevron truck. Lateral car body force reactions to rail joints and other track irregularities increased materially at higher speeds and when worn wheels were substituted for new wheels, especially with the AAR standard truck and the XL-70 Syminton Wayne truck. The spring plank swing motion arrangement on the National Swing Motion truck showed excellent control of car body lateral force levels, while the Transom linked side frames of the Rockwell Express truck showed acceptable control of these force levels. Vertical and lateral force levels were lowered when speed was reduced, but they did not reach acceptable levels until below 50 mph.

DYNAMICS OF A STANDARD CAR DURING IMPACT

The purpose of this report is to present data that may be used for comparing rubber type draft gears versus friction type draft gears under identical conditions of impact speed, car structure, and lading. These data also may be used for establishing minimum requirements for affording adequate protection against end shock to freight cars of all types and their lading. Another purpose of this report is to call attention to the fact that the cushioning capacity of any of the A.A.R. certified draft gears, regardless of type, is not sufficient to afford adequate shock protection to freight cars and their lading under the severe conditions of hump yard service. In view of the fact that a limited survey of impact conditions in local hump and flat switching yards showed that 50% of the observed impacts occurred at 6 mph and above, and 28% at 8 mph and above, it can be concluded that neither the friction type draft gear nor the rubber draft gear investigated in this report has adequate cushioning capacity to properly protect freight car and their lading under the severe conditions that are encountered in switching service. The rubber draft gear has considerably more cushioning capacity than the friction gear. Top and bottom bolster cover plates are stressed excessively by impacts above 6 mph. The improvement in cushioning capacity and smoothness of action of the rubber draft gear is due to the elimination of metal-to-metal over-solid limiting stops.

REPORT OF TEST OF WELEX HYDRAULIC DRAFT GEAR

The purpose of this test was to determine the cushioning qualities of the production model hydraulic draft gear manufactured by Welex Jet Service. The new Welex draft gears have a self-aligning socket plate on the end of the piston rod, which is designed to eliminate any bending forces on the piston rod. A car equipped with Welex draft gears, was used as the striking car throughout the test, being empty for one series of runs and loaded to 169,000 pounds gross weight during the remainder. Car AT-64999, also equipped with Welex draft gears, was used as the struck car during part of the test, and car AT-75377, equipped with reconditioned Minor A-22XL friction draft gears, was used during the remaining runs. Both struck cars were loaded to 169,000 pounds gross weight, and were backed up by six loaded cars with the brakes set, except in a few runs in the series when the striking car was loaded to 169,000 pounds, when the struck car was standing free to roll. A Hathaway electronic oscillograph and amplifier unit were used to record the coupling force, draft gear travel, speed, and longitudinal acceleration during the various impacts. A 16-mm Wollensak Fastax high-speed camera was used to show the draft gear action at impact. It was concluded that the Welex hydraulic draft gear has very desirable characteristics in buff, in that it brings about a marked reduction in coupling forces and accelerations in the equipment at impact. It is not felt, however, that equivalent protection is afforded by the gear in draft or run-out. The Welex gear would give adequate protection to the lading and equipment at switching impacts of 10 miles per hour.

WIND-TUNNEL STUDY OF STREAMLINER PASSENGER TRAIN

In the subsonic wind tunnel of the University of Michigan, tests were made in which the six components of aerodynamic force acting on a 1/12 scale model of a car of Train X were measured. The purpose of the tests was to obtain data for calculation of the stability of the train in high winds. Tests

were made on the car by itself and in the presence of other cars. Tests were made with and without rails, and with and without a raised roadbed. Parameters varied in the tests were: (a) angle of yaw of the train to the wind; (b) angle of lateral rail of the car to the horizontal; (c) height of car above ground; and (d) wind-tunnel speed. Tests were also made on a 1/12-scale model of a standard boxcar, to obtain a standard of comparison. The results of the tests are presented in tables and figures.

STUDY OF FREQUENCIES AND ACCELERATIONS PRESENT IN RAILROAD FREIGHT CARS

A series of tests was conducted to obtain data on vibratory conditions in a freight car and its effect on damage to lading. This type of data is helpful in establishing lading damage index and as a criterion for packaging against vibration. The tests indicated that the vibrations present in the freight cars can be divided into three groups: (a) Those, caused by excitation of the suspension system, (b) Those, caused by excitation of major structural members, (c) Noise and resonance of the structural components. The damaging effect is probably in the same order as mentioned above. It was definitely shown that the accelerations in the cars equipped with A.A.R. 1915 trucks are by far the largest.

IMPACT TESTS CONDUCTED ON: A. HULSON HIGH CAPACITY CUSHION UNDERFRAME B. ALL AAR APPROVED FRICTION DRAFT GEARS AND C. ALL AAR FREIGHT RUBBER DRAFT GEARS

The purpose of these tests was to evaluate the various cushioning means available for protecting freight cars against longitudinal forces of impact. All gears were new and taken from stock except one rubber type and one friction type, both of which were shipped direct from the manufacturers. The outstanding performer in this series of tests was that of the Hulson High-Capacity Cushion Underframe. Studies of the detail test records show the average of friction draft gear closure was at a coupling speed of 3.9 mph and all gears were closed at 5 mph when used in fully loaded cars. No closing point was found for the freight rubber draft gears. They continued to operate during the entire range of coupling speeds. It is to be noted that these are the results for new gears and might properly be followed with similar tests on gears that have been in service over a period of years.

PASSENGER RIDE COMFORT ON CURVED TRACK

The objective of this study was to obtain data for formulating recommendations on (1) the permissible speed of rolling stock on curves, (2) the length of transition curves for passenger comfort, and (3) the clearance requirements on curved track. The first test was run on the L&N Railway using the C&O track inspection car and making use of 20 observers to obtain a correlation between passenger reaction and the amount of unbalanced centrifugal force on curves as determined by measurements of the lateral acceleration. Results of this test indicated the importance of the tilting of the car in reducing the effective elevation of the track insofar as passenger comfort was concerned. Results from a second series of tests made it possible to establish a very satisfactory relationship between passenger reaction and the amount of lateral acceleration so that in subsequent tests it was not necessary to use passenger observers. Tests on permissible speed have indicated that for the types of modern equipment having soft springs and no provision for restricting the roll of the car body on curves the present AREA limitation of 3 in unbalance should be continued. Upon this basis the permissible speed on a curve is equal to the calculated equilibrium speed for the actual elevation of the curve plus 3 in. For cars having stiffer springs, outside swing hangers or roll stabilizers reducing the amount of roll with unbalanced elevation, the tests have shown that a permissible unbalance on curves of as much as 4-1/2 in. can be tolerated by the more favorable types of equipment. A new and different procedure is recommended for determining the length of transition curves. The formula recommended, L(sub min) = 4.88 V, gives a minimum length of spiral about 2/3 of that of the present AREA recommendation. However, this should be considered as a minimum length and a longer length is desirable if practical. With respect to clearance the test data gives displacement characteristics due to tilting of the car body on the springs of the various types of passenger cars included in the tests as related to the unbalanced elevation. A method for determining the angle of lean from static measurements of any particular type of car is also explained.

TRAFFIC IN A CURVE WITH RAILWAY COACHES FITTED WITH INCLINABLE BODIES

Further tests of the pendular type coach have been effected, during which the body has been given a boost to speed up the time taken for it to get the correct inclination when negotiating connecting transition. This is done by means of a hydraulic ram monitored by a accelerometer detecting, permanently, the non-compensated acceleration. Another arrangement is being worked out with a coach for which the axis of oscillation is below the center of inertia of the body. Tests are described which show that it is possible to get a coach to negotiate a curve with 0.3 insufficient cant, which is considerable, by employing assisted pendular motion. The first tests have shown that the assisted pendular motion gives considerably improved smooth riding while negotiating the transition as compared with natural pendular motion.

CAR ROLLING CHARACTERISTICS DATA DEVELOPED BY USSR RAILROAD

The USSR Railroad collected data on car rolling characteristics on two hump yards. Results are expressed in W-Kilograms/Ton resistance and were analyzed in the following groupings: by car weight; by speed of cars; by type of car; by ambient temperature; by weather conditions; for wind velocity. Table I gives effect of wind on rolling resistance for various kinds of cars. The larger discrepancy in flat cars is explained by the varieties of loads carried that would affect frontal area. The tests established that the effect of weather on rolling resistance is not significant. Since variations due to wind and weather were small, these variables were eliminated in development of distribution curves and evaluation of the other variables. By use of statistical methods a mean value and standard deviations were calculated, extreme values eliminated, and a new mean determined. Fig. 1 gives a distribution curve for both yards studied during the summer months. The major number of cars have an average rolling resistance value.

B2 040078
DYNAMIC LOADING AT RAIL JOINTS--EFFECT OF RESILIENT WHEELS

This study of a simplified vehicle model passing over an idealised dipped rail joint using values applying to a BR Class 86 locomotive shows that resilient wheels give an equivalent reduction in unsprung axle mass of 2,500 kg. The following conclusions were made: The suggested model for a broadened analysis of the vertical response of vehicle and track at a dipped rail joint is workable and produces dynamic wheel load values which are in full agreement with observed data. Fitting a Class 86 locomotive with resilient wheels will have the effect of reducing the dynamic wheel load increment at severe dipped rail joints by some 40 percent. The effect of resilient wheels on a Class 86 locomotive--based on the dynamic loading at rail joints--is equivalent to a reduction of the unsprung mass from 4,200 kg to 1,700 kg on the leading axle. Thus the results of the analysis suggest that a power-unit comprising axle-hung motors and resilient wheels is a highly competitive alternative to conventional, mechanically complicated and expensive arrangements used to obtain fully-suspended traction motors.

OBTAINING A SMOOTH-RUNNING BOGIE--2

An approach to improve the conventional type truck as used on multiple-unit and locomotive-hauled stock by considering its faults is suggested. The tendency of the bogie to snake can be greatly reduced by guiding both axles rigidly in the frame and so forcing them to remain parallel, i.e., within 0.04 in. by using roller bearings. The second method of attacking hunting is to prevent the whole bogie frame from snaking by deliberately introducing friction to discourage it from rotating slightly about its pivot. The sidebearer friction will rise in step with tire wear and snaking tendency if the sidebearers are greased only once when the tires are profiled.

B2 040083
CARRIAGE AND RAILCAR BOGIES: THEIR DESIGN AND DEVELOPMENT--IV

Design factors considered in this part include brake ratios; axle fatigue; adhesion, and P.D. More effective braking will require ratios 1:1.5 to 2.2 of the tare weight, cut back to 0.8 at lower speeds. A routine method of axle fatigue calculation indicating the influence of such design variables as fillet radii, type of vehicle, speeds, whether four-wheeler or bogie, and so on, relating to dynamic load allowance and other factors is long overdue. Adhesion improvement through truck linkage to the body at low level requires care that bogie pitching will not cause high stress peaks at the kingpin or cause intense shuttle of the body.

CARRIAGE AND RAILCAR BOGIES: THEIR DESIGN AND DEVELOPMENT--V

The determination of bolster-spring oscillation amplitudes, swing-link displacements, and their phasing using oscillographic instrumentation can be used for definite assessment of riding qualities. Vibrograph wedge tests permit determination of damping factors. The frequency of lateral/swaying oscillations can be determined by placing the vehicle on a transfer table and imparting an impulse by suddenly stopping the moving table. Similarly, body-nosing can be excited by placing the vehicle on a turntable, the center of gravity of the body being in line with the center of rotation. A sudden stop

of the turntable will then excite body-nosing oscillations at their natural frequency. It should be stressed, however, that as far as vertical body oscillations are concerned wedge tests are not fully representative of road conditions.

B2 040085
SOME ASPECTS OF THE THEORY AND PRACTICE OF DAMPING--II
When mounting dampers across the secondary suspension of a vehicle body pitching and swaying oscillations must be accounted for. The lateral motion on the swinglinks can be damped without difficulty, however, rolling on the bolster springs is difficult to damp with hydraulic units since the frequency of the oscillations is often low (about 0.5 to 0.8 c/s) and the moment arm short. Resonance conditions in the swaying mode must if at all possible be avoided at the operationally important speeds since control by hydraulic damping is unlikely to prove an acceptable solution.

SOME ASPECTS OF BOGIE PITCHING
The desire to increase passenger comfort makes it necessary to pay careful attention to the effects which bogie pitching can have on body oscillations. The general aim is to use dampers between axlebox and bogie frame which would be equally effective in compression and expansion because pitching takes place symmetrically and regularly about the lateral axis. Proprietary hydraulic dampers are theoretically the most suitable to deal with these oscillations provided the correct characteristic has been determined, produced, and maintained. Body and bogie primary suspension oscillations with and without auxiliary friction dampers are shown for a passenger coach travelling at 70 mph. The beneficial effect of the friction damper reducing the magnitude of the fore and aft accelerations is apparent.

RUNNING THROUGH CURVES
Simple methods for the determination of forces and wear are discussed. Flange forces are determined by constructing a Heumann Minimum Diagram of the friction moment curve. A Vogel diagram is plotted to show the center line of the vehicle in a curve. The center of friction is located mathematically in the Vogel diagram. Axlebox clearance values are determined from the diagrams and corresponding force diagrams are plotted.

PRACTICAL RESEARCH INTO VEHICLE DYNAMICS
Stability theory is evaluated by running an experimental car, HSFV-1, on a roller rig and on the track. The underframe and drawgear is standard, and the suspension is designed for an unladen weight of 10 tons and a laden weight of 35 tons. The wheel profiles conform to the RD6 profile. The first tests consisted of vertical and lateral damper tests; vertical and longitudinal spring stiffness tests; accurate turning and measurement of wheel and roller rig profiles; measurement of masses, moments of inertia and centres of mass;

and, re-assembly of vehicle, checking and correction of dimensions. The next step was to measure the natural modes and frequencies of the vehicle, again with wheels fixed, in the frequency range 0 to 10 c/s. The longitudinal springs were modified for stability tests. The vehicle was completely stable up to a speed of about 100 mile/h, where wheelset instability occured. The purpose of initial track tests was to confirm that the lateral stability of the vehicle on the track was satisfactory and consistent with the roller rig tests, and to measure the response of the vehicle to track irregularities. The results and techniques established by the work on HSFV-1 are applicable to all railway vehicles.

THE TORSIONALLY STIFF BOGIE WAGON

Torsional stiffness is an important factor bearing on the ability of vehicles to run over twisted track. Results of British Railways tests of tank cars with tare of 26 to 28 tons and 41.75 ft. truck centers are described. Track twist varied from 1 in 400 to 1 in 150. The design limitations for wheel load is calculated. Suspension changes to eliminated derailment tendencies are discussed.

RELATION BETWEEN TRACK IRREGULARITIES UNDER TRAIN LOADS AND NO LOAD

Track irregularities were measured under train load conditions using a new high speed inspection car, Maya 341. The sizes of the irregularities were compared with the sizes measured under no load conditions with a light weight, Yoshiike type, inspection car. A unique rule connecting measurement under load versus no load conditions could not be formulated. Relationships are established for load versus no load conditions in a mathematical model.

THE DYNAMIC STABILITY OF RAILWAY VEHICLE WHEELSETS AND BOGIES HAVING PROFILED WHEELS

The dynamic instability of railway vehicle bogies and wheelsets is caused by the combined action of the conicity of the wheels and the creep forces acting between the wheels and rails. The instability is investigated in the important case where the wheels are profiled rather than purely conical. Equations of motion are formulated and stability criteria obtained which indicate the effect of varying the various parameters of the system. The nature of the motion at the critical speed is investigated and the mode of energy conversion between the forward motion of the vehicle and the lateral motion of the bogie or wheelset is explained.

THE DYNAMICS OF RAILWAY VEHICLES ON STRAIGHT TRACK: FUNDAMENTAL CONSIDERATIONS OF LATERAL STABILITY

Existing and recently developed theories of the lateral motion of railway vehicles are discussed in relation to experimental work on both models and full-scale vehicles. It is shown that a realistic theory taking into account flexibility between the wheelsets and the frame in the longitudinal, lateral, and vertical directions, and the influence of wheel and rail profiles, yield values for the critical speeds which are consistent with experimental results. The influence of various parameters on stability is discussed and it is explained how railway vehicles can be designed for stable running at high speeds. Examples of suitable choices of suspension and other parameters are given and experiments carried out in order to verify these concepts are described.

COMBINED EFFECT OF FRICTIONAL AND ELASTIC MOMENTS AGAINST TRUCK TURNING UPON HUNTING OF TRUCK

The hunting of a truck is analyzed theoretically and a numerical calculation for an actual example is made to provide the data on truck design. By a numerical example, combined effect of friction and rigidity against truck turning upon the hunting speed was investigated and was checked by analog computation. The spring action against truck turning plays the leading role to increase the hunting speed and the frictional resistance plays an important supporting role to make the spring action effective to the range of a large amplitude though the friction itself has no action to prevent truck hunting. In order to determine appropriate magnitudes of these factors, the supporting stiffness of the axle with respect to the truck frame should be taken into consideration.

TESTS OF EFFECT OF BALANCED WHEELS ON PASSENGER CAR RIDE PERFORMANCE

The test of balanced wheels in Car 20 of the Pere Marquette Steamliner indicated that the ride can be improved by using balanced wheels. Actual balancing of the wheels and the tests on the road show that if new wheels are statically balanced after they are finish-bored and ready to be pressed on the axles, they will give a good ride up to 100 m.p.h. For higher speeds closer balancing will be required. The amount of unbalance of new wheels should not exceed 3 ft. lbs. Closer balancing is not economically justifiable and will not improve the ride comfort. The ride quality was measured with accelerometers at train speeds of 40 to 90 m.p.h.

THE DRAG OF RAILWAY CARS OF NEW DESIGN

The air resistance characteristics of two train configurations, one of modern, conventional design and the other aerodynamically designed to reduce drag, were determined from train models. The lower drag of the new design was due to the reduction in total surface area, to the important improvement in underbody design including the recessing of trucks and wheels, to the removal of the many appurtenances on the tops and sides of the cars, and the reduction of wake drag. Not only was the absolute drag reduced, but the tests showed that the rate of change of drag with velocity was considerably less for the new design than for the conventional train.

ADAPTING THE AUTOMATIC COUPLER TO FUTURE DEVELOPMENTS ON THE RAILWAYS
Consideration is given to certain desires and requirements of the railways for the development of the fully automatic coupler, which will not only serve as a coupling, but also will absorb the buff between cars, and make the pneumatic and electrical connections as well. This coupler must be adaptable to use with other designs of center couplings. the opening and closing of cut-out cocks on the air lines is to be automatic, actuated by coded signals from the locomotive or the train yard. Consideration must be given to operation with container cars, where overhanging must be limited. The desired coupler travel will have to be determined. A description of the "Eurocoupler 1968" is included. [German]

STUDIES ON INTERVAL DISTANCE BRAKING WITH PRIMARY AND SECONDARY RETARDERS IN THE HUMP INSTALLATIONS IN TRAIN YARDS
One important problem of the automation of train hump yards is the automatic control of the speed of all cars in the distribution track zone between the hump and the last of the distribution switches. The results of the studies of this problem are described, which the Swiss Federal Railways researched with the aid of their Computer-Program. The basic observations of the free-running of cars in the distribution zone were considered, which required the distinction between "free-rollers" and "hard-rollers". To equalize this situation, the "hard-rollers" required acceleration and the "free-rollers" required deceleration or braking. In addition, the basic considerations of braking in the distribution zone required studies to attain the desired speed interval braking of the various types of rolling cars. A detailed description of the programmed braking is given, as well as its application to these hump yard operations. [German]

TRUCK TO DETERMINE TRUCK ACTION
Static effects of warped track surface in causing derailments under varying truck conditions are measured. The tests were confined to the determination of the amount of depression or super-elevation in the outside rails of curves, measured in terms of track warp in a distance equal to that between the truck centers, required to cause derailment of a box car of rigid body construction which had a total weight of 82,000 lb., and to the determination of the turning resistance of trucks under various conditions. The results of the tests are shown in the table. They indicate that center plate resistance is not the major factor in the resistance to turning, which must be overcome by rail pressure at the flange, under the truck conditions prevailing when such turning is normally required. The flange pressure required to turn the truck on level track ranges approximately from 600 to 1,000 lb. with center plates greased. Forces greater than these are the result of side-bearing friction caused by the tilting of the center plate in the bearing as the side bearings on one side of the truck are brought into contact. The results do not indicate that the presence of graphite or grease on these center bearings had any consistent influence on total truck resistance under track conditions which bring the side bearings into action.

LATERAL OSCILLATIONS OF BOGIE BOLSTERS
It is imperative to break away from the adherence to general recipes regarding spring rates and swing link angles of inclination often regarded as a universal panacea against ailments generally diagnosed as "bad riding." Vertical leaf springs succeed only in increasing the lateral centering force thus reducing the effective length of the swing link arrangement and increasing its natural frequency, inadvertently acting as swing link spoilers. So far as design layouts are concerned detail components should be used along rational lines, each component being allowed to perform the basic function allotted to it. Thus swing links should be permitted to swing and dampers used to ensure damping. Excessive body amplitudes sometimes encountered with some designs can be controlled with the aid of lateral centering springs preferably with a non-linear characteristic and here suitably shaped rubber units can be of great help.

PERMISSIBLE SPEED OF FREIGHT CARS ON CURVES
In Part I, the dynamic effects due to lateral roll motion of a freight car are analyzed and the position of the resultant dynamic force with respect to center line of track for cars having 71, 85 and 99 inches combined center of gravity heights is calculated. These calculations use data on the amplitudes of the lateral roll motion of a fully loaded 70-ton 55-ft gondola which were measures during an extensive series of running tests on the Lackawanna Railroad in 1955. In Part II, calculations, based on extensive tests with freight cars having center-of-gravity heights of 71, 85 and 99 in with 3 11/16 in travel springs and conventional snubbing, were used to establish the

elevation for curves and maximum permissible speeds for the operation of freight trains.

DYNAMIC TEST OF 10TH SCALE "TRAIN X" CAR MODELS
Test were run to establish the type of vibrations that could be expected in the full scale cars at various speeds and to control those that would be considered undesirable. The tests proved the undesirability of using parallel tie-rods as originally proposed and indicated that a 4 degree toe-in is desirable as it prevented any self-excited vibrations. Use of lateral damping to prevent resonance due to forced vibration produced by rail joints was also indicated. These features were then incorporated in the designs of full scale cars.

IMPACT TEST OF C.&O. RY.CO. 70-TON GONDOLA CAR WITH FLOATING PALLET CAR NO. 218924
The object of these tests was to determine reduction in end shock transmitted to lading, obtained with installation of floating pallet and rubber draft gears in a standard gondola car. The test car was loaded with 95,840 pounds of rolled steel sheet to a total car weight of 170,140 pounds for all tests. The striking car was a 70-ton gondola loaded with heavy steel scrap to a total weight of 210,940 pounds and was equipped with friction draft gears. Impacts were started at 2 mph and speeds were increased in 2 mph increments. Tests were continued in each series to a point where the shocks on the pallet attained a force approximately equivalent to six times that of gravity. Peak acceleration records with the peaks corrected for frequency were used to intrepret accelerometer shock records. It was found that the shock transmitted to lading in a gondola car with floating pallet and rubber draft gear was approximately the same at 8 mph as the shock in a standard car with friction draft gear at 4 mph, thus four times as much energy was absorbed by the experimental car.

VEHICLE SUSPENSION AND BOGIE DESIGN IN RELATION TO TRACK CONDITIONS
The relationship of vehicle suspension to track conditions is expressed analytically. Significance of coning lies in its property to transmit and magnify the effects of track misalignment to the vehicle body. This effect will become greater as tread wear develops. In the event of build-up of wheel movement, flang-climbing and bogie hunting oscillations may occur. The effects of conicity can be reduced in new designs by the provision of positive guiding of axles by means of telescopic or other guides, together with roller bearing boxes and wheels having a minimum of coning, to avoid running against one rail. Frictional effects of laminated springs and suspension links transmit shock vertically and laterally from the track, and the elimination of such friction is desirable and beneficial. Suspension link length is important, and an increase in length will diminish the transmitted shock. A relationship has been established between track shape and vehicle response, which may be applied by a special application to an analog.

HOW HIGH CAN TRAIN SPEED BE INCREASED? A REVIEW OF PRESENT AND FUTURE
The effect of wave propagation in air and on the rail is discussed as a theoretical limit for train speed. As practical limits to speed, the deflection by the pantograph to the wire at point of contact is described. By this principle the critical speed of the New Tokaido Line (NTL) train has been calculated as 400 km/h. Adhesion force is plotted versus tractive resistance for a 12-car NTL train, which gives the limit to speed as 370 km/h. Vibration limits speed to 230 km/h on straight track due to passenger comfort. The problems concerning curved track are also briefly discussed.

WHEEL, AXLE, AND RAIL STRESS PROBLEMS RELATED TO HIGHER CAPACITY CARS--PART IV-EFFECT ON RAIL
Those items that have been found advantageous in reducing shelling caused by higher capacity (85 to 100-ton) cars are wheel loads should be limited in proportion to wheel diameter. Higher strength material in the rail will greatly reduce shelling but not entirely eliminate it (under the wheel loading conditions existing with 70-ton capacity cars before the allowable load was increased 5%). Modified rail head contours in today's modern rail sections which approach the average worn wheel condition, have been helpful in reducing shelling. Rail lubrication on curves extends the rail life but results in the removal of more rails for shelling rather than abrasive wear.

A COMPUTER PROGRAM FOR DETERMINING THE EFFECT OF DESIGN VARIATION ON SERVICE STRESSES IN RAILROAD WHEELS
Two computer analyses have been prepared relating service stresses in railroad wheels to wheel shape and dimensions. One program computes the temperature distribution and stresses due to heat input by brake shoe friction at the wheel tread. The other computes stresses due to lateral, vertical, and tractional forces between the wheel and rail. Both programs have been validated for certain known conditions using theoretical solutions and are in agreement with available design and experimental stress data to the degree that differences in wheel geometry and loading conditions permit a comparison with experimental stress data. The next step contemplated is better experimental confirmation by computations for specific wheels and loadings for which test results are available and use of the programs to study trends resulting from changes in wheel geometry and dimensions. This work is directed toward optimization of wheel design, and elucidation of the nature and specific effects of excessive service loads.

THE TRANSPORTATION ENVIRONMENT
Rail shipping is compared to truck shipping. In both cases the over-the-road environment is characterized by a continuous low amplitude vibration with random and periodic shock type inputs superimposed. The basic periodic inputs are rail joints for rail transportation and expansion joints for highway transportation. The random inputs for rail transportation are road crossings, bridges, switches, railroad crossings and the like. For highway transportation, the random inputs are railroad crossings, bridges, pot holes, etc. The continuous low level input is what creates resonant damage to products. The shock inputs create the dented, crushed, and broken hinge type of damage. Both types occur in both modes. The environment is divided into natural frequencies of vibration, vertical accelerations, shock spectra, impact forces and lateral acceleration, the magnitude of which is displayed graphically.

COOPERATIVE FREIGHT CAR TRUCK AND SNUBBER RESEARCH PROGRAM
This item consists of the conclusions and four appended reports to MR114. It was found that in trucks with all-coil springs without snubbers, the best performance was obtained with 1 5/8" spring travel. All snubbing devices tested provided definite improvement in riding quality over that provided by

unsnubbed springs. None of the fifteen Unit Snubbers tested provides performance considered satisfactory to a speed of 65 mph. Five of the eleven Package Snubbers tested provide performance considered satisfactory ("fair") to a speed of 90 mph. Two of the three Modified Conventional Trucks tested provide performance considered satisfactory ("fair") to a speed of 90 mph. These two trucks are as follows: HOLLAND RS-8 with 2 1/2" springs and HOLLAND RS-8 with CESD springs. Twenty-eight of the thirty-five High-Speed Trucks tested provided performance considered satisfactory to a speed of 90 mph. The appendices includes reports of studies on the performance of solid-type journal bearings, roller bearing research, lateral action of freight car trucks and accelerometer performance and side frame stress.

REPORT TESTS OF STABILITY OF 100 TON CAPACITY HOPPER CARS UNDER VARIOUS TRACK CONDITIONS HOLLIDAYBURG, PA.

Tests were started in June 1966 and completed in January 1967. No. 14 track, approximately 3600 feet in length, including 1000 feet of two degree curve, was selected as a suitable test site. Tangent track test runs were made with the track warped successively at intervals of 19'-6", which is normal joint stagger for 39 foot rails, and intervals of 31 and 39 feet. Curve track tests were made with the track warped at 19'06" and 15'-6" intervals. The modified H43 loaded hopper car and the H46 loaded covered hopper car should satisfactorily negotiate an indefinite succession of cross level changes in opposing directions of 1-1/2 inches in tangent track, 1 inch on curves with no more than 5 inches of superelevation and 1/2 inch where the superelevation exceeds 5 inches, regardless of speed. Continuous succession of cross level changes limits speed to 15 mph. The unmodified H43 loaded hopper car should satisfactorily negotiate an indefinite succession of cross level changes in opposing directions of 1 inch in tangent track, but not more than 1/2 inch on superelevated curve track regardless of speed. Continuous succession of cross level changes limits speed to 10 mph.

SPECIFICATIONS FOR TESTING SPECIAL DEVICES TO CONTROL STABILITY OF FREIGHT CARS

These specifications cover testing and performance requirements for trucks or other special devices to control car stability for application to freight cars with 4-wheel trucks having 6.5" times 12" journals or larger with loaded center of gravity 84" or higher above top of rail. The tests shall be conducted using a 100-ton high center of gravity hopper car on 4-wheel trucks. This test will be run over a track section with a superelevated curvature especially prepared with low joints. Instrumentation for the test car is described.

A VIBRATING RIG TEST FOR RAILWAY BEARING GREASES

A test rig utilizing a standard reaction type vibration test machine was developed to determine the consistent stability of grease lubricants in anti-friction bearings. This program was undertaken in view of the ever increasing demands upon greases in railway service and also the lack of direct correlation among performance characteristics obtained through existing standardized bench tests, full scale rotational tests lacking vibration, and those characteristics displayed in the field. General performance of the products tested appeared to be insensitive to the parameters of vibration within the range of parameters occurring in service. A 48 hours test which subjects the test cartridge to 4 G's at 38 cps with the grease bulk temperature thermostatically controlled at 180 F emerged as the condition which yielded results duplicating field service conditions.

WHEEL-RAIL DYNAMICS OF LOADED ORE CARS ON THE Q.C.M. AND B. AND L.E. RAILROADS

This study was initiated to determine the possible cause and to recommended a practicable remedy for excessive wear and damage to rails on the

Quebec Cartier Mining Company Railroad. Using instrumented car trucks and trackside rail deflection indicators, measurements of wheel-rail dynamics were made during test runs on the Bessemer and Lake Erie Railroad to evaluate the effect of different cars, car-truck combinations, and track structures on the forces between the wheels and the rails. The primary causes of the severe rail damage and rail corrugation experienced by the Q.C.M. are the unit train method of operation in conjunction with the undesirable car behavioral traits inherent in the design of the trucks of the standard Q.C.M. car. The effects of "bouncing", "rocking", "hunting", and "oscillation" of cars on tangent track, and of the "skewing", and "unbalance" on curves were measured quantitatively.

CONSIDERATIONS FOR THE DESIGN OF LONG CARS FOR IMPROVING CURVE NEGOTIABILITY

Graphs derived from theoretical considerations are presented in this report to show the effects of applying 60-in. couplers to long cars and to indicate the extent to which truck centers require increased dimensions to provide acceptable flange forces. For purposes of illustration, calculations are based on an 85-ft. car coupled to two 31-ft. cars with all cars operating on a curve of uniform degree and with variously applied drawbar forces. The following is recommended: whenever possible, cars of 85 ft. and over should be equipped with 60-in. couplers; when cars cannot be equipped with 60-in. couplers truck centers should be spaced to produce a reduction in lateral forces.

STUDY OF VIBRATION FREQUENCIES UNDER IMPACT CONDITIONS

A study is presented of vibration frequency characterisitcs under impact conditions for typical friction type draft gears used on railroad freight cars of a comparison of typical instrumentation records showing force-closure clutch action of typical and of representative electronic equipment used to measure these vibration forces. When determining the reaction-force characteristics of draft gears during closure, careful selection of instrumentation must be made. Instrumentation having a flat frequency response of 0 to 600 cycles is prefereed in order to attenuate the higher frequencies encountered in friction-draft-gear characterisitcs. Instrumentation having higher frequency response can be used but this usually results in confusion in interpreting the records to determine the fundamental force measurements.

ROLL ACTION OF HOPPER CARS INDUCED BY STAGGERED RAIL JOINTS

Loaded hopper cars were tested on a test track at elevations of 3 and 6 inches and low joints from .25 to .75 inches. The suspension system was varied to determine the effect on car rocking. Some tentative conclusions drawn from the tests are as follows: if joints are not more than 1/2 in. low in the loaded condition, wheel lift and derailment are not likely to occur; derailment is less likely to occur with 3 inches elevation than with 6 inches elevation; the use of 3 11/16 in. travel springs, widened gibs and supplemental snubbers, substantially reduces the likelihood of wheel derailment from roll action; and the hydraulic snubbers between the underside of the car body and the spring seat on the truck frame were effective in eliminating car roll and flange climbing; and provision of 2000 lb. friction resistance between the underside of the car body and the spring seat on the truck frame was effective in reducing the roll amplitude but did not prevent derailment.

STUDIES TO ELIMINATE HARMONIC ROLL OF HEAVY CARS

The purpose of this study was to observe controlled tests and fine solutions for harmonic roll in 100-ton hopper cars during low speed operation on staggered joint track which initiated wheel lift and subsequent derailment. These studies indicated that lower spring rates, extended center of the spring nests, applied swivel center plates, and preloaded laminated side bearings can be attenuated but not fully eliminated. Also, some improvement has veen obtained by permitting more lateral between the side frame and the bolster, in the bearing system, and by reducing the distance between the centers of the side bearings. Experimental truck arrangements are being developed which will permit the truck to follow the irregularities of track and which will prevent the introduction of the forcing frequency into the body of the car at such a phasing as to cause harmonics in the car rolling. Also, snubbing and energy absorption are being studied from a theoretical standpoint and practical applications of snubbers have been made which help to reduce the incidence of wheel lift when the snubbers are applied in combination with other changes.

LABORATORY INVESTIGATION OF THE EFFECT OF COLLAPSED SPRINGS OF LONG TRAVEL DESIGN ON CAR CLEARANCES

This investigation was made as a result of concern that serious trouble might be experienced with car clearances especially on gondola and flat cars

equipped with springs of long travel design particularly when springs are in a collapsed condition. A seventy-ton drop end gondola, equipped with 3-11/16 inch travel springs in A.S.F. design A-3 Ride Control trucks, was furnished for this investigation. Using the measured car lean of 8-1/4 inches for empty car on 6 inch superelevated track with all springs in place as a base line, the static lean increased for the different conditions tested as follows: car empty--4 springs removed 5/8 increase; car loaded--all springs in place 3/4 inch increase; and car loaded--4 springs removed 1 inch increase. These data indicate that the effect of broken springs with this type truck and spring arrangement may increase car lean up to 1 inch with the type load we were able to place in the car.

IMPACT TESTS OF HOPPER CAR LOADED WITH FERROMANGANESE ORE
This report describes impact tests made on a four pocket hopper car loaded with ferromanganese ore in order to determine whether or not it is safe to ship such a product in hopper cars. Tests were made on both the A and B ends of the hopper car at speeds up to 11.3 miles per hour, and measurements and observations were made to check for any permanent deformation in major structural members of the car and for adequacy of the experimental wood bracing arrangement. It was included that hopper cars can be employed safely for the transportation of ferromanganese ore if adequate bracing is applied to the doors of the loaded hoppers. Only approved methods of bracing should be used and wood wedges should be used to secure the locking pawls of the door latches.

IMPACT TESTS OF BALTIMORE AND OHIO RAILROAD TWO-POCKET FIFTY-TON HOPPER CAR LOADED WITH FERROMANGANESE
This report covers the results of a series of impact tests with a two-pocket fifty-ton hopper car loaded with ferromanganese. The purpose of this series of impact tests was to determine the safety of shipping this dense commodity in a standard hopper car that has auxiliary bracing between the hopper doors and also to determine the extent of the damage that can normally be expected on the hopper pockets and door equipment when the car is subjected to over-solid impacts. The following conclusions were made. The Baltimore and Ohio two-pocket hopper car, Class N-44, is representative of equipment that can be safely used to transport ferromanganese if the hopper doors are properly braced in the same manner used in this series of tests. The results of this test show that it is reasonable to expect a certain amount of bulging and distortion to the hopper doors, frames, and the hopper sheets adjacent to the door when ferromanganese is transported in this type car when the car is subjected to impacts at speeds of 6 mph or greater. The impacts in this series of tests were as high as 10.9 mph, which is higher than would be expected in normal service.

A COMPUTER STUDY OF DYNAMIC LOADS CAUSED BY VEHICLE-TRACK INTERACTION
Computer analyses of vehicle and track are producing enlightening results regarding actual dynamic loads and the manner in which various parameters of vehicle and track structure affect these loads. Using this information, it is possible to decide more intelligently how to alleviate the high wheel-rail stresses caused by today's unique traffic and track conditions. Possible solutions range from better track maintenance to different wheel rail geometries to changes in stiffness and damping of trucks and the track structure itself.

B2 040381
THE RELATION BETWEEN THE SWAYING OF HOPPER CARS AND THE STAGGER OF RAIL JOINTS IN TRACK
Freight cars with high-center-of-gravity loads sway considerably, especially on tracks with low joints. To produce synchronism, the time of swaying must have a definite relation to the speed of the train. A principle that maybe used to destroy cumulative swaying is that the stagger of rail joints must be such that a car must hit, simultaneously, a pair of joints, the joints being in opposite lines of rails. A second principle is that the stagger should be unequal in such a way that enough joints occur at suitable phases of swaying to neutralize the effects of the other joints. Frictional resistance helps in this principle. The amplitude of swaying may be increased by a series of low joints, provided that the swaying of cars synchronizes with the impulses given by the joints.

INVESTIGATION OF THE TRUCK HUNTING INSTABILITY PROBLEM OF HIGH-SPEED TRAINS
The problem of trucking hunting instability and the design implications for high-speed trains were investigated. Linearized theoretical analyses were made to identify the most important design parameters for speeds of 125 to 200 mph. Truck wheelbase, truck mass, wheel coning ratio, and springs to oppose yaw and transverse motions of the truck relative to the car body--all have large effects on the critical speed for secondary hunting instability. It appears probable that lightweight passenger cars could be designed for stable operation of speeds considerably in excess of 200 mph.

UNDERSTANDING WHEEL-RAIL ADHESION
The terms of wheel-rail adhesion are defined. An extensive review of the problems associated with adhesion and the attempts to solve these problems

is presented. The results of experiments conducted by the author on scale equipment show that creep is present as long as there is adhesion demand. As the adhesion demand increases, the percentage creep increases until creep becomes slip and eventually slide. It is shown that true adhesion varies with velocity. Suggestions are given for means of approaching true adhesion values on the railroad. The danger of wheel damage caused by high adhesion could offset the advantages.

THE EFFECTS OF JUMBO (HEAVY AND HIGH CUBE) CARS ON THE M OF W EXPENSES

Studies research and field observations show that the heavier wheel loads imposed on the rail today cause higher rates of rail failures, severe flaking, spalling, pitting and shelling. Track geometry also deteriorates faster. The two remedies are stronger rail material and stiffer track. But these are quite costly and economically not always possible. Instead, it is more likely that the movement of heavy loads will be continued on the present track at the expense of higher maintenance costs. This paper presents estimates and approximations with regard to the magnitude of the penalty M of W departments must pay in the area of track maintenance as a result of operating jumbo cars.

B2 040418
PROBLEMS OF INTERACTION OF VEHICLES AND TRACK--WORN PROFILES OF RAIL HEADS AND WHEEL TYRES

As a result of a large number of tests it has been proved that service wear on wheel tires and rail heads leads to definite profiles. These worn profiles are to a large degree independent of the initial profiles of tires and rail heads. In the worn condition the profiles maintain their form and are not subject to any further change. The worn profiles are characterized by good mutual conformity and thus by little increase in wear. The worn profile of tires results in a shortening of the wave length of the periodical wheel set motions (hunting) in the track clearance. It was concluded that to wear new profiles of rail heads and tires should be adapted as much as possible to the worn profile. The use of special wheel tire profiles promise no lasting influence on the riding quality of vehicles. Therefore other design measures on the vehicles should be preferred to control the hunting motion.

PROBLEMS OF INTERACTION OF VEHICLES AND TRACK--MEASUREMENTS MADE WITH RAIL VEHICLES DURING 1961 TO ASSESS THE CLEARANCE GAUGE ALLOWING FOR ROLLING MOVEMENTS OF THE VEHICLES
The purpose of these measurements was to shed light onto the behavior of the bogies, their position on the track, and to assess the lateral and rolling motions of the moving vehicles, caused by the forward traveling speed, the curve radii, and superelevation in curved track. The values so determined were to be taken as a basis for the setting up of a kinematic vehicle gauge. One of the most important results of the experiments is the linear dependence which was confirmed, for all vehicle types, between the angles of rolling, or between the transverse displacement of the sprung masses and the excess transverse accelerations respectively. This seems to indicate that the magnitude of the quasi-static angles of rolling can be precalculated, provided that the mathematical layout of the problem is sufficiently accurate. This would, however, entail complex conditions, because it would be necessary for all force effects of the connecting members between the individual masses to be incorporated in the process, with reasonable accuracy.

TESTS CONDUCTED ON CURVE OF THE SANTA FE RAILWAY NEAR ARGENTINE, KANSAS, TO DETERMINE THE CAUSE OF DERAILMENT OF PASSENGER TRAIN NO. 17 ON FEBRUARY 3, 1968
A test was made of four classes of diesel locomotives, followed by a baggage car and 12 additional cars. The train consists simulated the passenger train which derailed February 3, 1968. The maximum lateral and vertical rail forces and lateral to vertical ratios are tabulated for each consist. No L/V values were measured in the tests that were high enough to indicate a derailment condition was being approached. Tests were made at various speeds and throttle positions and a few runs with dynamic braking. Large variations in axle thrust were measured along the track, so it is unlikely the track measurements were made at a location that would give maximum L/V values.

DERAILMENT OF A PASSENGER TRAIN CONSISTING OF A DIESEL LOCOMOTIVE WITH SIX-WHEEL TRUCKS, A BAGGAGE CAR, AND A COACH
Three letters discuss the derailment of June 7, 1968. A sketch of the derailment area and photographs of sections of the track involved are included. This derailment is characteristic of a number of derailments that have occurred on curves at or near permissible speed of passenger trains having locomotives with six-wheel trucks, derailment apparently occurring first of the rear truck of the locomotive unit or the lead truck of the baggage car following. In each case the high rail of the curve was overturned. A high ratio of L/V is required to overtrun a rail and it is unlikely that this high a L/V ratio would be developed in track unless there is some unusual condition such as a jack-knifing of couplers between cars, an unloading of the lead wheel of the truck on the high rail, or some severe wedging action of the truck between rails due to a malfunction of the truck components.

COMPARISON OF EFFECTIVENESS OF FREIGHT CAR ROLL CONTROL DEVICES
The expected cost of derailments attributable to excessive car roll over a period of time can be reduced by various modifications to the car purporting to restrain wheel lifts and stabilize the car in roll. The decreased derailment cost over this period can be traded-off against the installation and maintenance costs of the modifications over the same period to find an optimum balance, i.e. maximum rate of return on investment in roll control

devices. For open top hopper cars, double Barber side coils or stiffer A-3 springs were found to be most economic. For covered hopper cars, the Roll Stabilizer or 2 Holland snubbers per spring group were found to be the optimum solution.

ANALYSIS OF COVERED HOPPER CAR DERAILMENTS ON THE BALTIMORE AND OHIO RAILROAD
Covered hopper car derailments on the B&O system during 1967 were analyzed to update previous work. The analysis confirmed and strengthened the conclusions found earlier. The conclusions reached were that (1) in-service life has a significant effect on rock-off derailments, and (2) the April 1964 speed restriction was effective in reducing early age derailments of the cars covered. For the year 1967, it was found that derailments of C&O-B&O covered hopper cars that generated L&D claims were nonexistent. The B&O series 602000 cars have made it through their critical first-year period with only two minor derailments, neither of which generated L&D claims. This fact tends to indicate that the increased snubbing in the trucks under this series of cars has reduced their early life derailment susceptibility. Based on these results as well as on the fact that all new 100-ton covered hopper cars in AAR interchange service must now have increased snubbing, it is recommended that the April 1964 speed restrictions be expanded to cover all covered hopper cars built in 1967 which have not been modified to control the roll problem. The restriction could be withdrawn in January 1969, when all cars of this type either will have completed their "wear-in" period or will have been equipped with additional snubbing.

ULTRASONIC TESTING OF RAILWAY COMPONENTS
Ultrasonic testing has expanded to the stage where it is a vitally important inspection method for two major railway components, axles and rails. It is likely that the use of the method will extend in many other fields. The success with which ultrasonic testing is now practiced is dependent upon three factors. They are: a thorough understanding of the type and position of flaws likely to occur in the component and the significance of flaw size; a sound knowledge of the principles underlying the use of ultrasonics for this purpose; and, a testing organization which can put sound techniques, well-trained men, and well-maintained instruments of the right type to work.

COMPOSITION BRAKE BLOCKS AND TYRES
This paper describes some of the problem which have arisen from the use of composition brake blocks in the past. For at least two of these, wet stopping performance and thermal cracking, there is now an understanding of the problem and possible solutions. Present-day production has also resulted in blocks free from the other difficulties. Other methods of avoiding the dangers associated with thermal cracking have been indicated: these involve moving away from the classic wheel and tire arrangement and the materials which have persisted for many years.

A METHOD FOR ESTIMATING BRAKING DISTANCES
This method allows for a time delay in the development of full brake power after a brake application has been initiated at the driver's cab, by taking note of the actual pattern of this development during this period. Thereafter, the distance traversed with full brake power before coming to a stop can be computed. Allowance has also been made of the brake power development characteristics of the motive power units. The method is suitable for application to all brake systems, compressed air standard AVB, and AVB with Quick Application valves--in fact, for any system where the brake power development curves can be established.

IMPRESSIONS ON THE NEW TOKAIKO LINE, JAPANESE NATIONAL RAILWAYS. BASED ON A RECENT VISIT TO JAPAN
The trains are made up of 12 coaches, but can be expanded to 15 to 16 as demand increases. The track is designed for high speed running. Track centers are widened to lessen the air impact effects as trains pass. Gradients are limited to 1.5 percent, minimum radius of curved track is 220 years, and maximum cant is 7.08 inches. Welded rail is padded by rubber and fastened to concrete cross ties with spring clips. Signals controlling train speed and operation are transmitted from a Central Train Control Office to the cab. Train brakes and speed are automatically controlled to eliminate collisions. The driver can assume control to counteract adverse environmental conditions. Revenues are described.

HYDRAULIC DAMPERS AND DAMPING
After brief review of the influence of viscous damping on free and forced oscillations of mass-spring systems, and its effect on response to impulses, suitable damping factors are quoted for control of body and truck oscillations on the suspension. This is followed by discussion of the most suitable forms of force-velocity characteristics for railway applications, and a section dealing with damping calculations. The influence of damper flexible mountings is then examined, with particular reference to impulsive suspension response and response to sinusoidal in deal with excitation. Experimental work relating to vehicle damping requirements and the recently issued B.R. specification with stipulates the requirements for dampers for use on British Railways' vehicles is discussed. Difficulties in the manufacture of dampers with linear symmetrical force-velocity characteristics are then pointed out with special reference to the tendency for current damper designs to result in S-shaped characteristics.

PASSENGER RIDE COMFORT ON CURVED TRACK
Tests were carried out to obtain data for making recommendations for the permissible speed on curves and the length of transition curves for passenger comfort, and for establishing clearance requirements on curved track. The first test was run on the Louisville and Nashville, May 10, 1950, using the Chesapeake and Ohio track inspection car and making use of 20 observers. Results of this test indicated the importance of the roll of the car body in reducing the effective elevation of the track insofar as passenger comfort was concerned. A second test on the Kansas City Southern developed gyroscope and recorder techniques to show the angle of the car body from the vertical. From the results of these tests it was possible to establish a very satisfactory relationship between passenger reaction and the amount of lateral acceleration so that in subsequent tests it was not necessary to use passenger observers. To obtain data on the various types of modern passenger cars being used, running tests were subsequently made on 7 railroads. The tests have indicated that for types of modern equipment having soft springs and no provision for restricting the roll of the car body on curves the present AREA limitation of 3-in. unbalance should be continued. For cars having stiffer springs, outside swing hangers (and springs) or roll stabilizers reducing the amount of roll with unbalanced elevation, the tests

DISCUSSION ON "THE ENGINEERING ASPECTS OF HIGH-SPEED TRAINS" (1) MOTIVE POWER: (2) PASSENGER ROLLING STOCK; (3) BRAKING AND SIGNALLING; (4) PERMANENT WAY
This paper surveys the engineering aspects of high-speed trains in terms of motive power, passenger rolling stock, braking and signaling, and permanent way. In developing high-speed trains there is clearly a need to examine all aspects of vehicle performance on the track, and also a need to subject every item of traction equipment to the closest secrutiny to ensure that it is suitable for onerous high-speed duties. The car of the future will probably be lower and smoother, and with smaller windows than present-day cars. It will be pressurized and adjacent body ends will be closer to incorporate peripheral coupling and improve passenger access. It will also cost more. A basic consideration in obtaining the best brake performance of high-speed trains is the maximum braking retardation. When high retardations are used and as the maximum speed of trains increases from about 100 mph to 120 mph (or even 150 mph) two problems of braking which become increasingly important are adhesion and heat dissipation. Both necessitate modifications to present braking practice when higher speed stops are to be made. It is generally agreed that at high speeds some form of cab signaling is essential, and systems in use vary from the relatively simple A.W.S. as used in this country to apparatus which starts, controls, and stops the train automatically. There is every justification to believe that, from the point of construction, modern track would be quite suitable for speeds up to 160 mph--possibly more--where it is straight or flat-curved.

EFFECT OF NON-LINEAR CHARACTERISTIC ON HUNTING OF CAR--EFFECT OF SIDE PLAY BETWEEN AXLE AND BEARING METAL
The equation of motion for a two-axle car was introduced when there was side play between the axle and the bearing metal, and an observation on the value of side play was made. Non-linearity of the elasticity and the side play was treated by the describing function method, linearizing of the equation of motion, and then the characteristic equation of the two-axle car was derived and the sinusoidal hunting velocity was calculated. A one-fifth sized model of a two-axle car was used in order to verify the theoretical treatment of hunting of a two-axle car experimentally. The experimental results and the theoretical calculation coincided closely and qualitatively and moreover when the damping of the supporting device for the car body was selected properly, the above results also coincided quantitatively. It was proved that the side play not only prevented the body hunting effectively but also lessened the side thrust experimentally.

TRUCK BOLSTER DYNAMIC LOADING MEASURED UNDER HARMONIC ROLL CONDITIONS
In service, two general types of fatigue loading conditions are imposed on railroad freight-car truck bolsters. Both types of loading involve a relative rolling or rocking motion between truck and car body bolsters but differ in amplitude and frequency of the motion. One condition, the lateral harmonic roll motion action possible with large and high center of gravity freight cars, is associated with low train operating speeds and operation on track of periodic low joint conditions. This paper illustrates the truck-bolster dynamic loadings measured under the extreme harmonic roll condition on a specially prepared test track and describes the methods of instrumentation developed to measure such loadings.

STUDY OF ACTIVE VIBRATION ISOLATION SYSTEMS FOR SEVERE GROUND TRANSPORTATION ENVIRONMENTS
An investigation is conducted to evaluate the application of active mechanisms for the protection of equipment and/or personnel from the severe dynamic inputs characteristic of ground transportation vehicles. For the purposes of the study, dynamic loads and isolation system performance are defined in terms of the maximum expected vertical excitations associated with the suspension system of high speed ground transportation vehicles, and conservative levels of allowable passenger acceleration. Selected configurations employ available hardware, and consist of a static load support fluidic spring in parallel with a 0.2 Hz resonant frequency electrohydraulic isolator, which: a) provides the desired degree of isolation from both discrete frequency and broad-band vibration excitations; and b) limits the payload deflections to within plus or minus 6 inches under conditions of combined vibratory and transient dynamic loads. Rigid and flexible payloads of 1,000 3,000 and 10,000 pounds per isolator are considered. The response of the selected isolation systems is presented in terms of absolute and relative transmissibility; payload acceleration; and relative displacement between the payload and the source of excitation for the vibratory, transient, and combined excitations. In all cases the effect of increasing the payload weight by twenty percent is shown. The results indicate that the selected active isolation systems are capable of protecting a range of payloads from severe vibratory and transient dynamic loads. Systems stability, estimates of flow and power requirements, system weight, reliability, and failsafe criteria considerations are shown. Recommendations are made regarding extension of the techniques to provide isolation in the combined vertical and lateral directions. (Author)

EFFECT OF COUPLING DEVICES ON LATERAL VIBRATION OF 951
The experiment investigation of the effect of coupling devices on the characteristics of lateral vibration of 951 type test electric car is described. The dominant component of lateral body vibration is forced body hunting with both modes of rolling and yawing with a wave length of 40-50m. The lateral relative motion around the position of action of coupling devices decreases markedly and the restricting force is preferably enlarged in the range of value tested. (Author)

'MILLION MILE' FREIGHT CAR SUSPENSION SYSTEM
A freight car suspension system has been introduced by American Steel Foundries. The T-11 system is designed expressly for 100-ton capacity freight cars. It combines an advanced snubbing system to absorb and dissipate energy and a design change such that longer travel load-carrying coil springs can be used. The system is warranted for a million miles or 10 years of life. The T-11 system also includes the Simplex side bearing which uses controlled friction to reduce rock and roll motion at critical speeds and to control the high speed swiveling of the truck. Recent tests indicate that the T-11 reduced the damaging effects of lateral shock to an unloaded freight car by as much as 75 percent at speeds above 50 mph. It also reduces the damaging effects of vertical shock inside of a loaded car by as much as 60 percent. Comparisons are to a conventional truck. Better riding qualities should result in longer life for truck components. The life expectancy is rated at 2.65 times that of a conventional truck.

ACCELERATION AND COMFORT IN PUBLIC GROUND TRANSPORTATION
Conventional transportation systems such as subway trains and buses are now designed to accelerate at about 4 ft/sec/sec (3 mph/sec). Electrically powered rapid transit cars of the last 10 years have an initial-acceleration range of 2.5 to 3.2 mph/sec (0.11 to 0.14 g). This performance will accelerate a vehicle to a speed of 30 mph in 10 seconds. Crucial to the longitudinal acceleration level that can be accepted by passengers is the preparedness of the passenger at the onset of motion. When the traveler is seated and expectant, the smooth takeoff of a jet airliner is not at all uncomfortable, although at 0.5 g some difficulty would be found in leaving the seat. Nevertheless, when the trains in the Paris metro system were fitted with rubbertired wheels and acceleration was increased, complaints forced a return to the previous standard of about 3.3 mph/sec that had been used with steel wheels. Sudden jerks on starting or stopping are especially objectionable, since they can cause an unwary standee to lose his balance. Longitudinal accelerations and decelerations judged comfortable and acceptable on the basis of rider ratings were in the range of 0.11 to 0.15 g, and lateral accelerations were in the range of 0.06 to 0.22 g. However, existing data are inadequate for specifying acceleration limits for future systems. Since the acceleration values found are about 0.10 g lower than those that are accepted by automobile users, it may be worthwhile to investigate methods for making higher accelerations acceptable to mass transportation passengers.

HUMAN SENSITIVITY TO WHOLE-BODY VIBRATION IN URBAN TRANSPORTATION SYSTEMS: A LITERATURE REVIEW
The survey indicated that a majority of relevant data came from only a few sources whose results were frequently divergent. That is, no reliable guidelines for passenger comfort were yielded by the data; rather several conflicting results were obtained which did not provide any satisfactory basis for choosing any one of the recommended comfort limits in preference to another. The literature survey revealed two basic data sources: (1) those obtained on "shake tables" in the laboratory; and (2) those obtained in field testing. In both cases, testing considered vertical, horizontal, and sinusoidal vibrations on standing and seated vehicle passengers. The data proved either contradictory or non-correlative, widely divergent testing methods and procedures further impaired reliable correlation of the data. Appended material includes a full bibliography of sources used, relevant details from selected reports, ride indices recommended by various investigators, and selected data and analysis of anatomical and physiological effects of vibration.

DYNAMICS OF A MODEL VEHICLE RUNNING ON AN IMPERFECT ELASTIC TRACK
Theoretical analyses of both longitudinal and lateral dynamics of a scaled model subway vehicle were performed to identify design parameters and the relationships among different system components and conditions. The longitudinal analyses assumed both rigid and elastic trackage to estimate critical speeds. Effects such as the eccentricity of the wheel, track imperfections, curvature in the track plane, and the coupling between rotary and translation vibration due to asymmetry of the center of gravity were considered in the analysis. Lateral dynamics were also investigated, with particular attention focused upon both wheel shimmy, which involved solid and viscous friction, and the stability of the "snake" type motion of the vehicle on a rigid imperfect track. All critical speeds in the dynamic analysis exceeded the maximum required normal operations of subway vehicles (65 miles per hour).

EFFECT OF FLAT WHEELS ON TRACK AND EQUIPMENT
Under present AAR rules governing removal of flat wheels, flat spots are limited to 2-1/2 in. length for one slid flat and 2 in. each for adjoining spots on freight car wheels and 1 in. on passenger car wheels. These limitations have been established from the experience and judgment of those concerned with the operation and maintenance of equipment and track. To date mathematical solutions to evaluate the impact effects from flat spots have not been adequate. Until recent years, instruments of sufficiently high frequency response to accurately measure the rapid stress changes have not been available. Tests made on the New York, New Haven, and Hartford RR. in 1942 established the characteristics required for reliable instrumentation. Suitable stress measuring instruments were obtained and a comprehensive test program to determine the effects of flat spots on both the track and equipment was conducted on the Chicago & North Western Railway during the summer of 1947. A special test train was used consisting of a locomotive, a passenger car carrying the measuring and recording instruments for the measurements on the test car, and a flat test car having a flat wheel and loaded with rails.

This report was prepared by the Joint Committee on Relation Between Track and Equipment.

RECENT RESEARCH ON ADHESION
The various studies and contributions are drawn into a coherent statement of how wheel/rail friction varies. Surveys of a number of track sites have identified the contaminants present in the wheel/rail interface, and measurements have been made of the adhesion which is experienced by railway traffic. A principal contaminant is a surface active oily fluid spread by the passage of wheels which forms a bonded surface layer on the wear band. A simple relationship has been found between the amount present on the surface and the resulting friction.

METALLOGRAPHIC OBSERVATION OF THE TREAD OF WHEELS SUBJECTED TO VARIOUS SERVICE CONDITIONS
The present paper reports the results of the metallographic observation of the tread of wheels subjected to various service conditions. Wheels in the present investigation are classified into those with on-tread brake and those without it, and the former is further divided into two groups according to the brake shoe, either castiron or composition (synthetic resin base). Work hardening of the tread region due to rolling contact with rail is observed. Heavily deformed cementile lamella in pearlite is frequently observed in the surface region. When using an on-tread brake, heat affected layers develop. There are many varieties in the heat-affected microstructure; martensite, tempered martensite, various incompletely hardened structures, and spheroidized carbide structures. Defects observed on the tread are heat-checks, spalling, flaky surface, skidding marks, fused deposits, thermal cracks, shelling, and growing.

DRAFT-GEAR ACTION IN TRAIN SERVICE
In order to investigate the most desirable characteristics of a draft gear by mathematical analysis, a study has been made of the mechanics of an elastic bar, which is subjected to external forces that correspond to those acting in trains under various service conditions. The results of this study, including the derivation of the various equations governing the behavior of an elastic bar, solid or with free slack, are given in another paper by the author. The present paper contains substantially the same equations but transcribed so as to apply to railway trains. Numerical examples are given showing the applications of these equations to assumed test trains.

This paper appeared in Anthology of Rail Vehicle Dynamics, Volume 2: Effects of Train Action and Rail Car Vibration. The anthology was sponsored by the Rail Transportation Division, ASME. Presented at Semi-Annual Meeting, Pittsburgh, Pa.,-June 19-22, 1944.

EVALUATION OF FREIGHT CAR CUSHIONING DEVICES TROUGH SIMULATION OF TRAIN DYNAMICS
The paper describes a means of evaluating freight car draft-gear designs through analytical studies of train action. New designs and design variations may be tested through simulation at an early stage in their development. The simulation approach described in the paper should be of interest to draft-gear manufacturers as well as to railroads. Although a manufacturer

may experimentally develop a draft gear to provide a desired characteristic, the simulation approach described will permit selection of the most promising characteristic before component design has started. In turn, the railroad may select on the basis of simulation the draft-gear device best suited to its operating conditions. Included in the paper along with a brief description of the analytical approach are examples illustrating how data required for the input to simulation programs may be developed. A form of performance evaluation for draft-gear devices is suggested. Also included for comparison purposes are results of typical train simulations along data from real-life tests of trains equipped with end-of-car hydraulic draft-gear devices.

This paper appeared in Anthology of Rail Vehicle Dynamics, Volume 2: Effects of Train Action and Rail Car Vibration. The anthology was sponsored by the Rail Transportation Division, ASME. Presented at Winter Annual Meeting and Energy Systems Exposition, Pittsburgh, Pa., Nov 12-17, 1967.

LATERAL OSCILLATIONS OF RAIL VEHICLES

The authors point out in this paper that lateral oscillations, which either do not occur or are negligible at slow train speeds, are of vital importance at the high train speeds now demanded by the railroads in order for them to complete successfully with the swiftly moving automobile and the much swifter airplane. Aside from collisions and broken rails, practically all railroad accidents result from lateral derailments, since vertical derailments occur only on those rare occasions when a bridge or trestle collapses from flood or storm. Lateral derailments are caused by lateral pressure of wheel flanges against the rail Therefore, the prevention of lateral derailments requires a knowledge of both the conditions which cause high lateral forces and of the conditions which must prevail in order to keep the lateral forces below some indicated safe value.

This paper appeared in Anthology of Rail Vehicle Dynamics, The anthology was sponsored by the Rail Transportation Division, ASME. Presented at the Annual Meeting, New York, N.Y., Dec. 2-6, 1935.

DYNAMIC ANALYSIS OF ROLLING FREIGHT

The dynamic equations of motion describing car rocking are presented. These equations are then simplified and used to determine car-body roll frequency and its dependence on roll amplitude. As a result of the analysis, a graphical technique was developed which shows the rail disturbance as a function of truck-center distance for any desired rail length, wheel base, track profile, and rail stagger. In addition, a brief account of the experimental history is presented.

This paper appeared in Anthology of Rail Vehicle Dynamics, Volume 2: Effects of Train Action and Rail Car Vibration. The anthology was sponsored by the Rail Transportation Division, ASME. Presented at the Winter Annual Meeting, Chicago. Ill., Nov. 7-11, 1965.

INVESTIGATION OF THE TRUCK HUNTING INSTABILITY PROBLEM OF HIGH-SPEED TRAINS

The problem of truck hunting instability and the design implications for high-speed trains were investigated. Linearized theoretical analyses were made to identify the most important design parameters for speeds of 125 to 200 mph. Truck wheelbase, truck mass, wheel coning ratio, and springs to oppose yaw and transverse motions of the truck relative to the car body-all have large effects on the critical speed for secondary hunting instability. It appears probable that light-weight passenger cars could be designed for stable operation at speeds considerably in excess of 200 mph.

SUSPENSION DYNAMICS BY COMPUTER SIMULATION

An analytical study of the effect of changing the design parameters of a two mass, six-degree-of-freedom suspension system was made. Rail cars with coil and air springs were analyzed by analog and digital computer. Spring stiffness, spring spacing, damping rates, height of center of gravity, and total mass were varied. The effect on frequency and response were determined.

GENERAL ASPECTS OF THE LATERAL DYNAMICS OF RAILWAY VEHICLES

Recent developments in research into the lateral dynamics of railway vehicles are reviewed with particular reference to dynamic stability, dynamic response, and curving. Two engineering aspects of this work are stressed-namely, the advantages of applying linear theory to a comprehensive study of vehicle dynamics, and the choice of basic assumptions required to make such studies realistic for design purposes.

B2 047433
THE EFFECTS OF THE LATERAL INSTABILITY OF HIGH CENTER OF GRAVITY FREIGHT CARS

High center of gravity freight cars experience extreme weight shift from side to side as a result of lateral resonance on track with cross-level differences from alternately staggered joints, as well as soft or other local variations in either rail. Dynamic measurements from tests made on test track with controlled 3/4-in. cross-level difference changes illustrate the force and motion magnitudes resulting from resonant and near resonant operating speeds; side bearing loads of 138,000 lb and spring group loads of 100,000 lb, accompanied by center plates separating and wheels lifting. The rotational energy input to the car body can be approximated for a given motion cycle and is proportional to the product of the amplitudes of the track profile and the car body motion. The high lateral (horizontal) forces on the truck at the side bearing and center plate make the truck unstable and cause wheels to lift off the rail on one side. This lateral force at a given end of the car is proportional to the corresponding vertical side bearing load. Freight cars traveling at resonant speed are especially prone to derail on curved track under high wheel-rail friction conditions. Forces and motion generated between the car body, truck, and the track, cause high cyclical stresses and severe wear between components that can shorten equipment life and cause severe track maintenance problems.

THE HYDRACUSHION CAR

It is the object of this paper to outline briefly the unique constructional features of the Hydracushion car and to report manufacturing, operating, and maintenance experience with such cars. The damage to lading occurring in freight cars equipped with standard friction draft gears is so well recognized that many attempts have been made to develop draft gears with softer response characteristics. In any such effort the major problem is that of dissipating the energy of impact while transmitting to the contents of the car only that portion of this energy which is necessary to accelerate such contents smoothly to the final speed of the car underframe. In the Hydracushion car a hydraulic buffer has been combined with a sliding-sill cushion-type underframe to control the flux of energy to the car lading.

IMPACT AS RELATED TO FREIGHT-CAR AND LADING DAMAGE

Damage to railway cars and ladings resulting from end impact is responsible for direct and indirect losses to the American railroads probably exceeding $100,000,000 annually. The subject of impact as related to freight-car and lading damage was therefore chosen by the author's company for research study and exploration on the impact tack as a basis for the development of efficient car-cushioning products. The first part of the paper provides an analysis of the physics of impact. Next the paper reports railway-car impact studies which were made to determine the relation between car cushioning and disturbances to cars and ladings during impact.

This paper appeared in Anthology of Rail Vehicle Dynamics, Volume 1: Freight Car Impact. The anthology was sponsored by the Rail Transportation Division. ASME. Presented at the Annual Meeting, Atlantic City, N.J. Nov. 29-Dec. 4, 1959.

CUSHIONING REQUIREMENTS FOR ADEQUATE LADING PROTECTION

The problem of lading damage is approached from the standpoint of what is required to eliminate coupling impact damage to a critical class of lading under present railroad operating conditions. A series of full-scale exploratory impact tests were conducted in which a wide range of load subdividing and underframe cushion travels were studied using removable bulkheads and an adjustable cushion fixture in the test cars. The results show that to evaluate the lading protection ability of cushioned cars on the basis of the percentage reductions in coupler force or car-body accelerations alone, or because some seemingly high cushion capacity has been provided, can be very misleading when resilient types of lading are considered. Also, when 30 in. of cushion travel are used, the optimum potential of cushioning is realized and load subdividing and other means of securement are unnecessary.

This paper appeared in Anthology of Rail Vehicle Dynamics, Volume 1: Freight Car Impact. The anthology was sponsored by the Rail Transportation Division, ASME. Presented at the Annual Meeting, Atlantic City, N.J., Nov. 29-Dec. 4, 1959.

PERFORMANCE TESTS OF LONG TRAVEL CUSHION UNDERFRAMES

The concept developed in the past few years that cushion travel of at least 20 in. and preferably 30 in. is required for lading protection at impact speeds of 10 mph or more and the confirmation of this in actual practice has led to the need for further investigation of the phenomena associated with this longer range of cushion travel. In 1962 it was decided to evaluate experimentally the order of difference to be expected from sliding center-sill cars having sill travel of 20 in. and sill travel of 30 in. Also, the possibility of developing new criteria for judging the comparative performance of freight cars during impact was to be studied. The results of this investigation are reported in the paper.

B2 047444
SHOCK AND VIBRATION ON RAILROAD MOVEMENT OF FREIGHT
One of the more pressing problems concerning rail movement of freight is the cost of securing lading to the car and protecting it properly from impact shock. The highway truck has an advantage in this regard because friction between rubber tires and pavement govern the maximum longitudinal forces developed, except for dock impacts. Rail, however, has the advantage in vertical and lateral shock and vibration control and, with proper design and operation, can meet the truck's longitudinal conditions. Adverse criticism has been received by the railroads because of their past reluctance to take the necessary steps to reduce lading damage. We now have the hardware to provide this protection, and the rail industry as a whole is rapidly applying it to its more critical loads. The purpose of this paper is to acquaint the shipper with the railroad environment and with the characteristics of the equipment available for controlling it.

ANALOG-COMPUTER SIMULATIONS OF END IMPACT OF RAILWAY CARS
Description is given of attempts to simulate, on an analog computer, the impact of two railway cars. It is found that considering each car as a single lumped mass gives results nowhere near those measured from physical tests. Considering each car to consist of two lumps, structure and lading, allows reasonably accurate results to be obtained, as shown by various comparisons of simulated and physical results. The complication involved in making better representations of railway cars is discussed in relation to the problems of simulating the overall motions of trains.

PERFORMANCE OF TOFC-COFC ARRANGEMENTS IN YARD-TYPE IMPACT TESTS
As shipment of trailers and containers by rail continues to increase, there is a growing tendency not to provide special handling, and, ultimately, complete mixed service through hump yards is desirable. For this reason the cushion arrangements to provide protection to the lading during impact are of growing importance. There is a variety of arrangements available, but until recently no direct comparison had been made by tests of cushion effectiveness. The purpose of this paper is to present this factual comparative test data, to relate this to the normal railroad operation, and to indicate cushion requirements, limitations, and related problems in moving toward unrestricted handling of piggyback and container cars.

DYNAMIC ANALYSIS OF LONG-TRAVEL, HIGH-EFFICIENCY SHOCK ABSORBERS IN FREIGHT CARS
A dynamic analysis is presented relating the principle design parameters of a constant force type, dissipative shock absorber to the forces experienced by a resilient lading. The analysis, which correlates the effects of coupler force, lading force, cushion travel, closure time, impact speed, and friction, represents an application of classical mechanics to a dynamical system with sliding friction (Coulomb damping). Although a lumped-parameter analysis forms the basis of the derivation, a procedure is described which takes into account the mass-and compliance distribution within the lading.

CUSHIONING PERFORMANCE-AN IN-SERVICE EVALUATION
Freight car cushioning equipment has been exhaustively tested over the years by railroads and railroad suppliers alike. This effort, however, has been generally limited to physical testing of the equipment performance under impact conditions. Little work has been reported in terms of the cushioning equipment effect on commodities transported in freight cars. This effect can be evaluated in terms of loss and damage claim prevention. This report relates one railroad's in-service experience with the loss and damage performance of cushioned freight cars. The statistical data upon which the evaluation is based was analyzed thoroughly to ensure that the results accurately depicted the differential utilization, commodity value or susceptibility, loading practices, yard handling practices, etc. Based on the results of this evaluation it was concluded that cushioning equipment reduces loss and damage claims but the reduction is insufficient in itself to justify the application of cushioning units to all cars.

OPERATING DYNAMICS--AN EMERGING BASIS FOR EQUIPMENT DESIGN
It is improbable that the rate of improvement in car utilization achieved in the 1960's can be duplicated by the same factors in the 1970's. The cost per freight car is steadily rising. Utilization and serviceability of new and existing cars must increase to meet the performance required in projected demands. In April 1925 the American Railway Association published Appendix A of Circular No. D.V. 400 on fundamentals of car design. In September 1964 the railroad industry adopted "Specifications for Design, Fabrication, and Construction of Freight Cars." Car technology can be characterized as evolutionary. To upgrade existing freight car standards, and to provide for equipment of the future, recourse is necessary for incorporating dynamic inputs into freight car designs and tests.

PASSENGER RIDE COMFORT ON CURVED TRACK
This report gives the results of tests carried out to obtain the necessary data for making recommendations for the permissible speed on curves and the length of transition curves for passenger comfort, and for establishing clearance requirements on curved track. Present speed limitations were established in 1914 by mathematical analysis, personal observation and experience. Since that time changes have been made in track, increases in operating speeds, and the introduction of modern-type passenger equipment with markedly different truck and springing arrangements: In addition, electrical measuring equipment is now available permitting a more exact and scientific evaluation of quantities related to ride comfort. From the results of these tests it was possible to establish a very satisfactory relationship between passenger reaction and the amount of lateral acceleration so that in subsequent tests it was not necessary to use passenger observers. To obtain data on the various types of modern passenger cars being used, running tests were subsequently made on the New York, New Haven & Hartford, the Lackawanna, the Pennsylvania, the Milwaukee, the Santa Fe, and the Burlington Railroads. These tests included not only measurements of lateral acceleration and car body roll on many curves and many miles of track under operating speeds, but also included static lean measurements of the car to determine data on the relationship between car body roll and unbalanced elevation. From a comprehensive study and analysis of these data as presented in the accompanying report, conclusions and recommendations have been formulated.

ON THE MEASURING METHOD OF THE CREEP FORCE BETWEEN WHEEL AND RAIL
When a wheel runs on a rail, there occurs a small slip at the contact surface between wheel and rail. When slip is very small the tangential force is in proportion to the slip. The proportional constant is so called creep coefficient. An experiment to measure the creep coefficient was carried out with one-fifth scale model. As the results, the following facts were obtained: 1. The value of creep coefficient increases in proportion to the wheel load to the two-thirds power, that value is nearly close to $F = 1/\pi \times$ area of ellips x Young's modulas. 2. The longitudinal creep coefficient is larger than the lateral one. 3. As slip increases, non-linear characteristics appear. 4. The value of creep coefficient is in inverse proportion to the displacement of wheelset, that is, as the displacement becomes large, the value of creep coefficient becomes small.

WEAR AND REPAIR--SHOP PROBLEMS IN THE CASE OF OVERSEAS HIGH PERFORMANCE FREIGHT RAILWAYS [VERSCHLEIS UND WERKSTATTPROBLEME BEI UBERSEEISCHEN HOCHLEISTUNG-GUTERBAHNEN]
With the help of details of the experience acquired by railways in America and Africa, in connection with the transport of minerals, a group of experts has examined the conditions which are necessary for achieving an optimum balance between the wear on the running gear of rolling stock and that on the rail, and the cost of maintenance. They have established the technical and economic criteria showing the effect of the weight per axle on wear in the case of the different track gauges, and in relation to the diameter of the wheels, the profile of the rail tread, and the radius of curve of the track. This study has enabled it to be established that rail-wheel wear is directly proportional to the weight per axle, and inversely proportional to the diameter of the wheels, and that resistance to traction increases with the track gauge and the wheelbase. INFLUENCE OF SOME PARAMETERS OF THE RAILROAD ROLLING STOCK ON ITS VERTICAL DYNAMICS [VLIYANIE NEKOTORYKH PARAMETROU ZHELEZNODOROZHNOGO EKIPAZHA NA EGO VERTIKALNUYU DINAMIKU]
Analytical relations are obtained permitting an evaluation to determine to which oscillations--hopping or galloping--a particular railroad vehicle is most likely to be liable. It is shown that the inertia radius of the superstructure above the carriage spring, the number of axles and distance between them have an effect on the kind of the prevailing oscillations. A solution is found for carriages with any number of axles. It is noted that carriages with an odd number of axles are more liable to galloping oscillations. [Russian]

THE CONTRIBUTION OF TRIBOLOGY TO THE DEVELOPMENT AND OPERATION OF RAILWAYS
The contributions of the railway pioneers to the development of tribology is reviewed. The numerous locations within a modern electrified railway wherein surfaces interact in relative motion are listed and discussed from the point of view of reduction in maintenance and enhancement of reliability. In particular, recent work on adhesion between wheel and rail is reviewed.

ADHESION AND THE CONTACT SURFACE BETWEEN WHEEL AND RAIL [SILOVE A GEOMETRICKE POMERY VE VZTAHU K ADHEZI VYVOZENE PUSOBENIM KILOVEHO TLAKU]
The article contains a description of the history of research into adhesion, and deals with the position in the area of contact between wheel and rail. It also contains observations concerning the correlations between the different principal factors which affect the form and dimensions of the contact surface between wheel and rail, and which determine them in cases when the normal effort is the only outside force. This simplifying hypothesis provides a possibility of constructing mathematical relations on the basis of which it is possible to develop considerations concerning the contact surface under the simultaneous effect of the adhesive weight and the tangential effort. Finally, the author describes the method of establishing, on the one

hand, the area of the surface of contact of the wheel and the rail, in the case of a used, and an unused, rail head, and, on the other, the rate and strength of the pressure in the wheel. [Czechoslovakian]

PRESENT KNOWLEDGE OF ADHESION AND ITS UTILISATION
The phenomenon of adhesion has since become the vital problem, representing the principal limitation to the increase in the magnitude of the tractive and braking forces at low speed as well as at medium speed. Scope and nature of the investigations concerning adhesion and its utilization have obviously developed in parallel to the importance attached to the problem itself. During the last decades, research on the subject of adhesion has not only developed considerably but its nature has also undergone a remarkable development. These different research programmes have already enabled several countries to achieve substantial improvements in the values of the adhesion coefficient which were applied in connection with the calculation of maximum train loads.

ANALYSES OF RAIL VEHICLE DYNAMICS IN SUPPORT OF DEVELOPMENT OF THE WHEEL RAIL DYNAMICS RESEARCH FACILITY
The development of experimental facilities for rail vehicle testing at the DOT High Speed Ground Test Center is being complemented by analytical studies. The purpose of this effort has been to gain insight into the dynamics of rail vehicles to guide the equipment development and to establish an analytic framework for the design and interpretation of tests to be conducted at the facility. The mechanics of rail vehicle lateral guidance are reviewed on the basis of linearized models. Computer programs are developed for predicting stability and general lateral response characteristics. Computer programs for predicting vertical and pitch vehicle response to track irregularities are included. (Modified author abstract)

TRANSIT CAR RIDE QUALITY: PREDICTION, TEST AND IMPROVEMENT
Techniques for evaluating rail car vibratory accelerations against various forms of ride quality criteria are discussed. The development of a computer program to predict these vibratory accelerations is described, and the results obtained from the program are validated by comparison with field test data and data obtained from laboratory vibration tests on a full-scale truck. An active suspension concept to improve ride quality is described, and laboratory test results of several candidate active suspension systems are presented.

ABBREVIATED REPORT ON FREE LATERAL OSCILLATIONS IN LONG FREIGHT TRAINS
This report is an abbreviated form of a full report which has been prepared describing a study of lateral vibrations in long freight trains. A mathematical model for investigating the dynamic stability of cars in long freight trains was developed which takes into account the effects of coupler forces. The model was used to investigate the stability characteristics of a specific three-container car employed by Canadian National Railways for which dynamic stability data is available, and the model was able to predict the behavior of this car accurately. Groups containing up to sixteen cars were investigated, and the results indicate that the range of train velocities for which a long freight train will exhibit stable behavior can apparently be determined with satisfactory accuracy by consideration of individual cars free of coupling forces. The model includes the effects of creep and spin forces at the rail-wheel interface, spin forces being found to have an important effect on the determination of dynamic behavior. The lozenge stiffness of freight-car trucks was shown to be an important parameter with regards to dynamic stability. It is possible to define an optimum value of lozenge stiffness for which freight trucks of the type used in North America would be stable for all speeds of interest for freight trains. More importantly, this optimum value would also result in a well damped response of freight trucks to track irregularities in nominally straight track.

EFFECT OF SPRING TRAVEL, HEIGHT OF CENTER OF GRAVITY, AND SPEED ON FREIGHT CAR CLEARANCE REQUIREMENTS ON CURVED AND TANGENT TRACK
Two fully loaded 70 ton cars used to determine the effect of spring travel, the height of the center of gravity, and speed on freight car clearance requirements on curved and tangent track. Car A had 5/8-inch travel springs; Car B, 3 11/16-inch travel springs. Static lean tests and dynamic tests were performed. The longer travel-springs gave a softer ride, and when used in conjunction with a damping device resonant vertical oscillations were greatly reduced. The vertical ride was improved, but lateral stability, especially in roll was much less. The average total lateral displacement on Car B with the long travel-springs was about twice that for Car A with short springs. Therefore, use of cars with long travel-springs requires careful considerations of clearances in locations where they tend to be critical. Car B also required higher vertical clearances. The larger displacements for Car B were mostly due to its larger roll angle. Speed was a factor in the dynamic action of the freight cars. Oscillations at lower speeds were sustained, indicating a resonance of the roll mode with some periodic disturbances. There were some large roll amplitudes for the higher speeds at entrances and exits of curves. Only low speeds, such as 5 mph, were free from these oscillations.

PRELIMINARY TEST TO CORRELATE PASSENGER RIDE COMFORT ON CURVED TRACK WITH LATERAL ACCELERATIONS
A description and results of tests made on the Louisville & Nashville Railroad to obtain data for re-examining the present practice of establishing maximum comfortable speed on curved track on the basis of 3 in. unbalanced elevation was given. Accelerometers were applied to the Chesapeake & Ohio track inspection car on a regular inspection run. Measurements were obtained on sections of the L & N main line containing many curves of various degrees of curvature. Twelve observers rode in the test car and recorded their impressions of the riding conditions on each curve. These observations were correlated with the measured lateral acceleration and calculated unbalanced elevation for each curve. This was a preliminary test with the objective of establishing methods of measurements and correlation of ride impressions to form the basis for securing more extensive measurements. The important conclusions are: 1) The 3-in. unbalanced elevation gives a very satisfactory riding condition. 2) The tests demonstrated that the amount of tilting of the car body on the springs is a very important factor because it reduces the effectiveness of the elevation and increases the acceleration on the passenger. 3) The tests have greatly clarified the future course that needs to be followed to establish a satisfactory method of speed limitation based on scientific measurements.

BEHAVIOR OF THE METAL OF RAILS AND WHEELS IN THE CONTACT ZONE. EXPERIMENTAL STUDIES: 1) WORK-HARDENING SPEED WITH THE EMS 60 MACHINE (ADDITIONAL MEASUREMENTS), 2) RESIDUAL STRESSES IN HARD-GRADE STEEL RAILS (ADDITIONAL MEASUREMENTS) 3) CHECKING OF FATIGUE CRITERION PROPOSED BY MR. DANG VAN
This report is in three parts: 1) Work-hardening speed examined with the EMS 60 machine: The development of the two principal residual stresses produced on the running surface of rails made of different grades of steel has been studied as a function of the repeated passages of a loaded wheel. It has been shown that this development ceases at about approximately 1 million cycles. 2) Residual stresses in hard-grade steel: These stresses have been measured inside 2 rails of hard-grade steel, one new and the other work-hardened in service. The use of the rail in the track produces severe longitudinal and transverse compressive stresses at the surface. The stress field is affected strongly throughout the height of the rail-head. 3) Checking of fatigue criterion proposed by Mr. Dang Van: The fatigue limits of a rail steel have been determined for different cases of stressing. The results have enabled the validity of the fatigue criterion proposed by Mr. Dang Van (see Report C 53/RP 7) to be confirmed.

STANDARDISATION OF WHEEL PROFILES. RECOMMENDATIONS CONCERNING A UNIVERSAL WHEEL PROFILE ADAPTED TO WEAR (UIC/ORE PROFILE) VALID REGARDLESS OF THE WHEEL DIAMETER AND THE TYPE OF VEHICLE

Following the studies carried out by a special group of "Rolling Stock" and "Track" Specialists, a "standard profile adapted to wear" has been developed. This profile, called the "UIC/ORE profile", does not constitute a compromise but, on the contrary, combines the best elements of the existing profiles. Together with the appropriate justifications and arguments, the present report gives the geometrical values recommended for the shape of the flange and for the outer part of the tread, the mathematical representation of the standardized profile, and the recommendations for its practical application. The "UIC/ORE profile" is valid regardless of the wheel diameter (ranging from 1000 mm to 330 mm for trailer stock) and the type of vehicle. In the opinion of the Specialists, it permits speeds of up to 140 km/h to be attained for old types of non-bogie vehicles and bogie vehicles, and 160 and even 200 km/h for vehicles equipped with modern bogies. The adoption of this "adapted wear profile", combined with the use of wheels with treated rim (see Report B 98/RP 9), should permit the greater part of the Administrations to achieve substantial economies (materials, staff, machine-tools, vehicle stoppages,...) due to the reduction in the number of re-profilings and the elimination of flange-wear.

BEHAVIOUR OF THE METAL OF RAILS AND WHEELS IN THE CONTACT ZONE. CALCULATION OF THE COMPLEX STRESS CYCLES IN THE RAIL SUBJECTED TO ROLLING LOADS. ASSESSEMENT OF THE DANGER OF DAMAGE (CONTINUED)

This study deals with new calculations of the composition of the residual stresses and the stresses induced in the rail during the passage of wheels, for different loading values, wheel diameters and wheel-tyre transverse curvatures. One thermal stress and three residual stresses have been considered. The latter have been calcuated and then measured with the help of an original strain-gauge method. The danger of rail damage has then been evaluated by means of the damage line criterion proposed by Mr. Dang Van (see C 53/RP 7 and C 53/RP 8). It has been possible in this way to define the danger factor for each loading case. It has been shown that two types of danger exist, namely, fatigue and plastic deformation.

ESTIMATION OF MULTIVARIABLE RAILWAY VEHICLE DYNAMICS FROM NORMAL OPERATING RECORDS. LABORATORY OF APPLIED MECHANICS DELFT UNIVERSITY OF TECHNOLOGY, THE NETHERLANDS
This paper discusses a procedure developed in order to estimate the parameters in a mathematical model describing the generation of the lateral motions of railway vehicles from measurements under normal operating conditions. Computations for a cyclical least squares model reference technique are carried out on a hybrid computer. In an illustrative example for a second order system it is shown that the use of two models in parallel can substantially improve the convergence, especially if the system output is disturbed by additive noise. The first results of experiments on vehicles, which are presented, show an encouraging correspondence between the important responses of the model and the actual bogie.

PROBLEMS CONCERNING THE INTERACTION BETWEEN VEHICLE AND TRACK [PROBLEME DES ZUSAMMENWIRKENS VON FAHRZEUG UND FAHRBAHN]
A report submitted at the 14th meeting dealing with "Modern railway rolling stock", held in Graz. The German Federal Railway, Munich Technical University, Krauss-Maffei-Krupp, Rheinstahl and Mak, have founded a Company for the Study of the limits of use of the "Vehicle on rail". The report consists of a wide synthesis of the methods used, and the results obtained, in the case of the numerous works to which reference is made. The author shows the manner in which it is possible to make use of simple models, which are linear in the case of the vehicle, and reduced to periodical irregularity in the case of the track, in order to obtain data concerning the structural parameters of the vehicle and the track, and estimates of the behaviour of the vehicle based on the values of these parameters. Although these models are far from according with the reality, the estimates which they make possible are close to the results of measurements carried out during tests. It is necessary to continue this research, although it is already agreed that the limits of the system "Vehicle on Rail" are far from having been reached. [German]

B2 054692
THE EFFECT OF TRACK AND VEHICLE PARAMETERS ON WHEEL/RAIL VERTICAL DYNAMIC FORCES
The railway track and vehicle combination comprises heavy rigid wheels running on heavy rails. Imperfections in either will give rise to dynamic effects which increase with speed. These will supplement the contact forces which, on perfect track with perfect wheels, are basically the static wheel loads. The commercial necessity for higher speeds and greater axle loads has been established and this historical trend will probably continue. Forces and stresses will therefore become more severe unless technical progress is made in track and vehicle design. In this context, close co-operation between the Civil and the Mechanical Engineer is essential. Track must have a high standard of alignment and level and maintenance quality must be improved as far as practicable. The forces that the rails and track structure will withstand must also be specified. New vehicles, particularly those for high speed operation or with heavy axle loads, must not generate excessive track forces.

IMPROVEMENTS OF MAINTENANCE CRITERIA COVERING THE RUNNING GEAR OF SHIN-KANSEN RAILCARS BY MEASURING THE TRANSVERSAL ACCELERATIONS OF THE BODY [SHIN-KANSEN DENSHA SOKO KANRI SHIRYO SEIDO UO KOJO NI KANSURU KENKYU]
Osaka engine shed officials measure, under 200 km/h on line conditions, the body accelerations of Shin-Kansen railcars each time the wheels are re-profiled (every 70,000 km). Following these measurements, an index is calculated in accordance with an empirical formula that is a linear combination of the acceleration occurrence frequencies classified by section (linear combination of the values of the acceleration distribution analysis). Bogie overhaul is scheduled in accordance with the value of this index. In applying this method, the JNR encountered difficulties due to the effect of 3 factors on transversal accelerations: the state of the track, the speed (the index is very sensitive to speed variations of only a few km/h), weather conditions (transversal stability is distinctly improved in rainy weather). The article describes how corrective laws were worked out to eliminate the effect of the first 2 factors. For the 3rd factor, it was decided to limit measurements to periods of wet weather. [Japanese]

NONLINEAR WHEELSET DYNAMIC RESPONSE TO RANDOM LATERAL RAIL IRREGULARITIES
The nonlinear equations of motion for a railway vehicle wheelset having profiled wheels and contact of the wheel flange with flexible rails are presented. The effects of spin creep and gyroscopic terms are included. The rails are considered to have random lateral irregularities which are described by prescribed power spectra. The equations of motion are integrated numerically and the effects on the dynamic response of quantities such as speed, track roughness, wheel wear, flange clearance, and lateral stiffness of the rails are investigated.

ON THE EFFECT OF TRACK IRREGULARITIES ON THE DYNAMIC RESPONSE OF RAILWAY VEHICLES
The steady state response for models of a six-axle locomotive running on a sinusoidally irregular track has been investigated. Two mathematical models have been set up, a full model for the stationary vehicle in which creep between wheels and rails was neglected, and a full model for the moving vehicle in which creep forces gravity stiffness effects and wheel tread profiles were considered. The use of the generalized method of complex algebra to obtain the steady state response of the railway vehicle components to varying input frequencies was used. The results given in this paper are for the case of sinusoidal lateral track irregularities only, but the method is general enough to allow also for vertical track irregularities. The analysis may be used to check the response of any proposed design for a railway vehicle to economically attractive track irregularities. It may also be used to adjust geometry, spring rates and damping characteristics in order to maximize operating speeds while providing optimum damping for the trucks and body motions.

VIBRATION DYNAMICS OF RAIL AXLES [Dinamica vibrazionale delle sale ferroviarie]
First, the dynamic configuration of an axle, generated by forced vertical excitation of the two wheels, is considered. A mathematical model of the vehicle and the axle vibrations is derived and analyzed. The frequencies of the axle are determined with the variation of the characteristic parameters of the vehicles and of the axles themselves. In the second part of the article, the dynamic stresses are sought, generated by typical excitation of the line and acting on the axle with the variation of the speed of the vehicle, in order to achieve optimum design. INTRODUCTION TO THE APPLICATION OF THE DYNALIST COMPUTER PROGRAM TO THE ANALYSIS OF RAIL SYSTEMS DYNAMICS
DYNALIST, a computer program that extracts complex eigenvalues and eigenvectors for dynamic systems described in terms of matrix equations of motion, has been acquired and made operational at TSC. In this report, simple dynamic systems are used to define the DYNALIST terminology. Input parameters required to model a rail vehicle are described. Preparation of a card deck to run the program is detailed. The program output is examined in terms of an application to a hunting analysis of a rail vehicle.

STABILITY AND RIDING QUALITY OF RAILWAY VEHICLES
The so-called critical speed of a linearized railway vehicle is shown to be no useful measure for the stability of the system in practice. The important interaction between vehicle and track can be taken into account by the riding quality for a certain vehicle on every particular piece of track. The riding quality is determined by the accelerations transmitted to the payload, weighted according to comfort standards, and the relative displacements between wheel and rail. From the riding quality demands both for vehicle design and for maintenance of the track can be derived.

MINIMAX OPTIMIZATION OF RAILWAY VEHICLE SUSPENSIONS
The minimax response of a complex dynamic system, such as a railroad vehicle, can be obtained by choosing certain (optimum) values of the stiffness and damping elements in the system. The railway vehicle is mathematically modeled as a linear, stable, strictly dissipative multi-degree of freedom dynamic system. The system is excited at more than one point by synchronous harmonic forces. A minimax principle reduces the problem to that of finite dimensional optimal design problem. Non-linear mathematical programming techniques are used to minimize the non-linear objective function representing the maximum resonant response at a point of the system, and subjected to linear or non-linear constraints, over a certain frequency range. The frequency range may be finite or infinite. Dynamic response of the system before and after optimization is shown, and three-dimensional plots for the constrained and unconstrained objective function versus the two most important design parameters are illustrated.

DAMPING REQUIREMENTS TO CONTROL VERTICAL AND ROLL MOTION OF FREIGHT CARS
Compression dampers located in the freight car spring group can effectively control the car body in the roll and vertical motion modes resulting from the more common track surface variations. Computer drawn traces show the motion and forces between car body, truck components and track resulting from a multi-degree of freedom, three-dimensional, mathematical model of a 100 ton freight car traversing track with defined surface variations. Comparisons of response resulting from hydraulically controlled springs and a conventional spring group suspension controlled only with coulomb friction shows generally that conventional suspension with only friction damping, results in a severe resonance for both vertical and roll modes with extreme weight shift and high reactions between freight car components and track-a resonance limited only by the system non-linearities. Single acting hydraulic damping can be defined with sufficient energy absorption that can limit forces and motion at each given resonance, reducing weight shift and derailment jeopardy, as well as, equipment and track damage.

RAILWAY TRUCK RESPONSE TO RANDOM RAIL IRREGULARITIES
This paper discusses the random response of a seven degree of freedom passenger truck model to lateral rail irregularities. Power spectral densities and root mean square levels of component displacements and contact forces are reported. The truck model used in the study allows lateral and yaw degrees of freedom for each wheelset, and lateral, yaw and roll freedoms for the truck frame. Linear creep relations are utilzed for the rail-wheel contact forces. The lateral rail irregularities enter the analysis through the creep expressions. The results described in the paper were obtained using frequency domain techniques to solve the equations of motion. The reported results demonstrate that the guidance force needed when traveling over irregular rail at high speed utilizes a significant portion of the total available tangential force between wheel and rail.

WHEELSET STEERING FOR BOGIES OF RAILWAY VEHICLES
Examined are steered wheelsets as a means of reducing tread, flange and railhead-contact wear and of minimizing derailment tendencies. Longitudinal and lateral sliding resistances of leading and trailing wheelsets are discussed and the moving of the friction force center to coincide with the trailing wheelset is shown to reduce lateral sliding resistance to zero. Described are wheelset pivoting arrangements which greatly reduce flange wear and are reported to be highly satisfactory in service.

STEADY-STATE MOTION OF RAILWAY VEHICLES ON CURVED TRACK
A simplified linear theory of steady-state curve traversing is developed for truck and two axled vehicles. The approach is based on providing guidance by creep forces in conjunction with wheel conicity, so that flange contact is normally avoided. It is shown that this approach is realistic for a wide range of vehicle and track parameters. However, steering by creep forces is limited by the onset of wheel slip. Representative experimental results for a two-axled vehicle are presented.

CONTACT VIBRATIONS
When a wheel rolls on a rail with a randomly wavy surface, the random waviness gives rise to a displacement input to the wheel and rail with a significant high-frequency (f greater than 100 HZ) spectral content. This displacement input excites the contact resonance of the system, wherein the mass of the wheel and an "equivalent mass" of the rail vibrate on the nonlinear contact spring. The purpose of the paper is to develop an analytical model for these high-frequency contact vibrations. The wheel is assumed to undergo only rigid-body motions, apart from the localized elastic deformation near the contact region. The rail is modeled as an infinite beam on a continuous, point-reacting foundation. With the rail roughness being assumed to be a locally stationary, Gaussian random process, a complete solution is presented to the linearized problem. Three phenomena of interest are investigated in detail: plastic deformation, loss of contact, and the formation of corrugations on the rail. The effects of various wheel and rail parameters on these phenomena are explored.

PROGRESS REPORT–DEVELOPMENT OF AN ASSOCIATION OF AMERICAN RAILROADS DYNAMIC BOLSTER TEST
Preliminary work was completed on the analysis of the strength of truck bolsters relative to possible service type loadings. Measurements were made of maximum tensile and compressive stresses occurring in a bolster specimen under laboratory conditions simulating predicted service imposed loadings occurring with cyclic frequency. The results of the full study are expected to lead to a laboratory fatigue test for use in an acceptance specification for bolsters. The stress measurements were made for two general types of loading conditions considered to be the principal types of cyclic fatigue loadings imposed on truck bolsters in service. For both type loadings, stress measurements were made at a number of load levels. The basic procedures used in this study are presented in this report. There were some deviations required from these procedures that are explained in the report.

RIDE QUALITY-AN INCREASINGLY IMPORTANT FACTOR IN TRANSPORTATION SYSTEMS
A portable data acquisition system has been developed and used to obtain field test data on a number of air and ground vehicles. Automatic data reduction techniques have been utilized, and developed where necessary, to present the measured data in useful, concise form. The vibration data parameters found to be of significant value include power spectral density distributions and frequency-of- occurrences of given levels of vibration. Vibrations in the lateral and vertical degrees of freedom appear to have significant influence on ride comfort at vibration levels as low as, or lower than, 0.1g acceleration. Vibration environments for the various type vehicles tend to be random in nature with the vibrational energy concentrated in the frequency range below 15 Hz and with a significant amount below 1 Hz, which is the region generally associated with motion sickness. For a train, subjective ride discomfort observations could be reasonably well correlated with peak lateral vibrations. This correlation formed the basis of a trial program of using vibration measurements as a quantitative index for identifying sections of rough track which could benefit from maintenance. Of all vehicles studied, the jet transport had the lowest vibration environment.

FINAL REPORT ON THE EVALUATION OF CUSHIONED UNDERFRAMES

This report covers a study and evaluation of special cushioning devices under impact conditions. The types of devices tested included sliding center sill, end of car hydraulic draft gears and column connected draft gears. Each device was evaluated with both canned goods and steel lading which respectively represented a resilient type of lading and a heavy rigid type of lading. This study indicates that the commodity protection needs under impact are not entirely a function of the special cushioning device but are also related to loading methods and types of packaging. In these tests the indications of cushioning protection provided by different shock absorption systems as summarized from the conclusions made in this report are: 1. Sliding sill type cars with 18 to 30 in. travel gave the highest degree of protection of lading through reduction of body force and resultant acceleration, followed in descending order by end of car hydraulic draft gears, column connected draft gears and standard draft gears. 2. The non-continuous or "split" design of sliding center sill provided the maximum protection to the car structure under dynamic squeeze, followed in descending order by end of car hydraulic draft gears, conventional continuous or through designs of sliding center sills and column connected draft gears. 3. Length of travel of sliding center sill is not an absolute indication of overall performance, particularly under dynamic squeeze conditions. 4. Small differences in sliding sill travel do not significantly change the performance characteristics. 5. Floating loads shift excessively, even with sliding center sill cars. 6. Energy absorption means are needed at the couplers in sliding center sill cars. 7. Sliding sills require high column strength to prevent bending.

SPECIFICATION OF RIDE QUALITY CRITERIA FOR TRANSPORTATION SYSTEMS: THE STATE OF THE ART AND A NEW APPROACH

The current state-of-the-art of ride quality criteria is reviewed. In particular the existing technique of describing the guideway in terms of its spectral density and of defining the ride quality standard as the acceleration spectral density is outlined. By utilizing linear system theory an alternative deterministic approach is presented. A deterministic ride quality standard is proposed and an analytical technique to design vehicle-suspension systems to meet this standard is presented.

ANALYSIS OF THE DYNAMICS OF A RAIL CAR FROM ITS RESPONSE TO RANDOM INPUT

The parameters which define the dynamic behavior of a physical system can be determined by analyzing the response of the system to a random input. Application of the random process technique to one of the U.S. Department of Transportation's rail research cars is described. One of these railcars was instrumented, operated over selected portions of mainline track between Washington and Baltimore, and analyzed for its dynamic properties. The theory and experiment are described, and the dynamic model of the railcar which was used is briefly presented. Results including natural frequencies for the car system, mode shapes for the principle modes, and revised values for important parameters are presented.

ELASTIC-PLASTIC ANALYSIS OF A WHEEL ROLLING ON A RIGID TRACK

A consistent finite element model for a circular wheel is developed based on triangular and quasi-triangular domains and a piecewise linear displacement field. The minimum stress-rate principle of plasticity is used to obtain the solution of this two-dimensional continuum problem with internal unloading. A piecewise approximation of the Tresca yield condition is used. Elastic-plastic solutions of a wheel rolling on a rigid track under its own weight and a hub load are obtained for the first few revolutions until a steady state condition is reached. Shake-down conditions for the wheel are demonstrated.

THE TRIBOLOGY OF WHEEL ON RAIL

The functioning of wheels and rails as a supporting and guiding system depends on a Hertzian contact of 1.2 x 10 to minus 4th power sq m (0.2 in sq) area. In addition to its supporting function, this area must withstand tangential forces to enable the functions of traction, braking and guidance to be fulfilled. Such traction forces are accompanied by a deflection known as 'creep' and classical estimates of this quantity are compared with measurements made on the track. Modes of wear of wheel and rail are described and alternative systems which avoid contact are discussed.

PROCEEDINGS OF THE SECOND INTERNATIONAL CONFERENCE ON VEHICLE MECHANICS
This volume reports the simultaneous technical sessions that were held on four major subjects--automobile dynamics, rail-vehicle systems, off-the-road vehicle systems, and ships and hovercraft. Presented are manuscripts and abstracts of the lecture presentations. The railway engineering topics include: Basic Theory on the Torsional Strength of Freightcar Body and Container; Modern Trucks for Very High Speeds (in French); Metro on Rubber Tires (in French); Development of a Computer Model for Simulating Railroad Track Structures; Statistical Analysis of Track Defects and their effects on Vehicle Ride (in French); Vertical Dynamics of a Rail Vehicle (in French); Theoretical Study of Transverse Stability of Rail Vehicles and Initial Experimental Results.
Conference held at Paris VI University, September 6-9, 1971.

STABILITY AND RIDING QUALITY OF RAILWAY VEHICLES
The so-called critical speed of a linearized railway vehicle is shown to be no useful measure for the stability of the system in practice. The improvement interaction between vehicle and track can be taken into account by the riding quality for a certain vehicle on every particular piece of track. The riding quality is determined by the accelerations transmitted to the payload, weighted according to comfort standards, and the relative displacements between wheel and rail. From the riding quality demands both for vehicle design and for maintenance of the track can be derived.

ON THE EFFECT OF TRACK IRREGULARITIES ON THE DYNAMIC RESPONSE OF RAILWAY VEHICLES
The steady state response for models of a six-axle locomotive running on a sinusoidally irregular track has been investigated. Two mathematical models have been set up, a full model for the "stationary" vehicle in which creep between wheels and rails was neglected, and a full model for the "moving" vehicle in which creep forces, gravity stiffness effects and wheel tread profiles were considered. The use of the generalized method of complex algebra to obtain the steady state response of the railway vehicule components to varying input frequencies was used. The results given in this paper are for the case of sinusoidal lateral track irregularities only, but the method is general enough to allow also for vertical track irregularities. For the "stationary" vehicle the input frequency is increased from zero to 3 cycles per second. For the "moving" vehicle the input frequency is a function of the track wave length and the vehicle forward speed and is given in terms of the vehicle speed. The frequency response curves are computer plotted in each case. For the "moving" vehicle, responses for the cases of both new and worn wheels are obtained. The natural frequencies for the full model are also calculated. The results obtained show the effect of the creep forces and the condition of the wheels on the steady state response. It is recommended that slip and corresponding creep forces, wheel tread and rail profiles, and the gravity stiffness effect be included in the steady state response analysis of railway vehicles to track irregularities.

COMPARATIVE ANALYSIS OF DYNAMICS OF FREIGHT AND PASSENGER RAIL VEHICLES
This comparative analysis was an examination of the vehicle-track interactive dynamics where several types of trains are required to operate over the same route at different speeds. Two areas of concern were examined: the effects of track geometry (surface, crosslevel and alignment) on vehicle

response and track loads, and the effects of lateral force components acting on curves. A linear, 14-degree-of-freedom computer model was used to simulate a number of rail vehicles on a conventional track structure of rails, ties and ballast, including the Metroliner, passenger and freight cars, TurboTrain, and several locomotives.

SIMULATED OPERATING STRESSES IN 28-IN.-DIA WHEELS
An analytical stress analysis of B-28 and CB-28 wheels of various designs is presented. Simulated service inputs of vertical, lateral, and brake shoe forces producing thermal loads from emergency braking are used. Octahedral stress mapping is used to display the stress fields generated in the wheels under combination of the above loading conditions. The results show that both wheels have low octahedral stresses when only vertical or vertical and lateral loads are applied, but under combined loading conditions including tread braking the stress levels in the B-28 contour exceed those in the CB-28 wheels.

VERTICAL ACTION OF FORCES BETWEEN WHEEL AND RAIL WHEN CROSSING A RAIL JOINT
An example serves to determine the maximum dynamic vertical wheel force when a modern coach crosses a rail joint. The problem is described mathematically by a system of ordinary differential equations and is solved by means of an analog computer. The high dynamic vertical wheel forces obtained linearly increase with the travelling speed. As a result, the demand of more elastic wheels is made for railway vehicles travelling at high speed, besides that of a high quality of the permanent way. [German]

STRESSES IN THE TREADS OF RAILWAY WHEELS
The stresses arising in and below the tread of a rail vehicle wheel are very complex. The wheel material, which is in no way of a homogeneous nature, is subjected to greatly differing forces varying in magnitude, as well as to frictional forces, thermal stresses, manifold tensile stresses and wear mechanisms. Because of the great many imponderabilities, resulting from the track position and riding quality of the vehicle, a prediction of the expected life or anticipated mileage is practicable to a limited extent only. Nevertheless, it is possible to picture the complex stresses acting on the wheel tread. For practical use, a new factor is proposed, permitting an estimate of the permissible axle load for wheel sets dependent on the wheel diameter. [German]

INSTRUMENTATION FACILITIES FOR DYNAMIC TESTING OF RAILWAY ROLLING STOCK
A wide variety of instrumentation facilities are used for dynamic testing of railroad rolling stock. For evaluating stability, measurements of the lateral force and vertical load on the wheel are required. The former is measured with the help of a load cell and the latter by measuring spring deflections using a linear variable differential transformer. For determining riding quality the average ride index is calculated and acceleration is measured using a seismic accelerometer. A transducer system is used to convert the physical parameters to electrical signals. As the electrical signals generated by the transducer are in the range of microvolts they are amplified by amplifiers which feed the signal to the recorder where the signals actuate pens, which trace out the signals in ink on paper.

A REVIEW OF RAIL-WHEEL CONTACT STRESS PROBLEMS
From its earliest days, railroad technology has been limited by an inadequate understanding of the mechanics of load transfer between wheel and rail. It is the purpose of this paper to indicate the major problems in this area, and to review the progress made to date in the solution thereof. Attention is focussed upon investigations of the stresses (normal pressure and tangential shear) on the contact patch, rather than upon studies of bending stresses in the rail. The physical basis of Hertz's widely used analysis is outlined, and the assumptions and limitations of that analysis are indicated. The need is shown for the development of solutions to important non-Hertzian problems such as: coformal contact (e.g. between worn wheels and track), contact of rough bodies, rolling friction, adhesion, and creep. The literature on these problems, as well as work in progress, is reviewed. A detailed mathematical treatment is avoided, but the principal results of much of the theory are illustrated through geometrical and physical descriptions. Recent works on the effects of surface waviness, plastic deformation, and residual stresses in rail, are reviewed.

This paper was presented at the Railroad Track Mechanics Symposium, Princeton University, 22 April, 1975.

MODIFIED THREE-PIECE TRUCK REDUCES HUNTING AND IMPROVES CURVING
Analysis of dynamic truck oscillations shows that hunting can be controlled by elastic links which connect the diagonally opposed journal boxes of the two wheelsets of a truck. Yaw constraint of the wheelsets in relation to the truck frame can then be minimized and full advantage taken of the ability of conical wheelsets to align themselves radially on curved track. This stability ensures that tread profile conicity does not change as wheels wear and stability can be maintained for long periods. South African Railways has incorporated such a diagonal suspension truck with encouraging test results. Although sharp curves are prevalent on the track where tests were conducted, flange wear has been negligible.

THE FREIGHT CAR TRUCK "CAPABILITY GAP"
The freight car truck is discussed as background to the question of what can be done about it. Because of the greater demands of today's freight service, a capability gap has developed between the truck performance required and that provided by contemporary running gear. The evolution of the three-piece truck, from the archbar design through stages to the contemporary arrangements, is illustrated. Some other car problems are covered and the possible end of cut-and-try design in running gear is foreseen. The possibility that a premium truck might be cost effective is suggested.

CORRUGATION AND PITTING OF ROLLING SURFACES-ARE THEY CONTINGENT UPON ULTRASONICS?
This article is an abridged version of essay number 28/1973 held in the Archiv fuer Eisenbahntechnik. Rail corrugations, which were a familiar phenomenon in the 1890's and similar periodic forms of wear occur in other rolling contact combinations. An attempt is made in this paper to explain these manifestations. It is suggested in conclusion that it would appear that troublesome corrugations and perhaps damaging pitting could be avoided if, besides the attenuation of low-frequency oscillations, a means could be found to prevent the agitation and propagation of intensive ultrasonic fields within the area of the running surfaces.

EFFECT OF WAGON-BOGIE SUSPENSION CHARACTERISTICS ON DYNAMIC LOADS
Recent British Railways tests show total forces induced by track joints, frogs and crossings are influenced by the square root of unsprung mass as well as other criteria. Sprung and unsprung mass accelerations call for careful damping. Load deflection characteristics examined show the need for closer scrutiny and suspensions must be designed to give satisfactory ride in normal speed ranges. Ride index and rotational resistance are important.

EFFECTS OF LONGITUDINAL IMPACT FORCES ON FREIGHT CAR TRUCK BOLSTERS
The design of truck bolster center plate rims was investigated as a result of increased reports of their failure on 100-ton capacity freight cars. The damage occurs when cars are coupled at moderate to high speeds, since the rapid deceleration of the truck causes high loads between the truck and body bolsters. Test measurements were made on an unloaded 100-ton hopper car impacting a string of loaded cars. The forces between the truck and body bolsters on the moving car were determined at impact speeds from 2.9 to 9.2 mph. Tests were made with two different energy absorbing capacities of draft gear. Loads at the truck-bolster/body-bolster interface averaged approximately 40,000 lbs for impact velocities up to 5 mph and reached 100,000 lbs at 7 mph. A peak load of 160,000 lbs was measured at 8.4 mph. Within the lower speed range there were no significant differences in load associated with the two draft gear, but at 6.7 mph the loads with the higher capacity gear were 25 percent less. Strain gages placed near the center rim indicated yielding on the first impact at 2.9 mph. Additional yielding continued as the impact velocity was increased. A finite-element stress analysis showed that loads of the magnitude measured on the test would cause severe stresses in the center plate rim and that yielding of the material would be expected. Several potential modifications of the truck bolster center plate rim were analyzed which showed that significant improvements could be obtained by making the rim wider and by increasing the radius of the fillet at the inside of the rim.

The project was sponsored by US DOT, Federal Railroad Administration's Office of Research and Development. IIT Research Institute was under contract to US DOT, Transportation Systems Center.

LONGITUDINALLY FLEXIBLE OR RIGID WHEELSETS FOR GOODS WAGON BOGIES? [Bewegliche oder in Fahrzeuglaengsrichtung starre Radsaetze fuer Gueterwagen-Drehgestelle]
In connection with the planned standardization of bogie wagons, the DB has carried out comparative tests on bogies specially equipped for measurement purposes. The results of these tests are represented by the cross stresses recorded both for the outside wheel on curves and for the inside wheel and in relation to the curve radius. They confirm that longitudinally rigid wheelsets cause inadmissible rail wear on curves with radii of less than 700 m. [German]

ECONOMIC IMPACT OF TRIBOLOGY
Friction and wear-caused mechanical failures and maintenance normally have their roots in phenomena based on tribology, the science and technology of interacting surfaces in relative motion. Developments in tribology since the publication of the "Jost Report" have utilized existing and new knowledge from physics, chemistry, mathematics, statistics, engineering, etc. As a result, advances in diverse fields, from metalworking to medicine or space technology, have been produced. The economic benefits that may accrue to industry can be substantial; in the case of the U.S. the savings obtainable through tribology could amount to as much as $16 billion per annum. Some of the means used in the United Kingdom in order to reap the benefits attainable by application of the principles of the multi-disciplinary subject of tribology, and some of the results obtained, are described.

ANALYSIS OF RAILROAD CAR TRUCK AND WHEEL FATIGUE. PART I-SERVICE LOAD DATA AND PROCEDURES FOR THE DEVELOPMENT OF FATIGUE PERFORMANCE CRITERIA
The development of fatigue performance standards for freight car truck components and wheels requires a knowledge of the fluctuation service load environment, and a basis for stating the conservatism of the design with respect to the environment. On this program special emphasis was given to determining the load environment by analyzing data from 53 test runs conducted on the Erie Branch test track of the Bessemer and Lake Erie Railroad. A number of test parameters were varied, such as speed, type of truck, modifications to the suspension system, etc., to determine those parameters having the greatest influence on the severity of the load. Vertical loads were measured at the side-frame-pedestal/roller-bearing-adapter interface and lateral loads were determined at the wheel/rail interface. The cyclic load data are summarized in a series of load spectra. Factors which must be considered in the development of fatigue performance standards from these spectra include reliability goals, the statistical spread of both load and fatigue strength data, and the philosophy followed in the design of the truck itself.

RESEARCH INTO THE OPTIMIZATION OF THE AXLE OF ROLLING STOCK ON FRENCH NATIONAL RAILWAYS [Recherches sur l'optimisation des essieux-axes de la S.N.C.F.]
The research work described is intended, among other things, to study how far in particular it would be possible to reduce the unsprung weight represented by the axle, a parameter whose influence increases with the speed of the vehicles. Various investigations, which are explained in detail as well as their results, were conducted in the following specific areas: more specific approach of the conditions with which the gear connections wedged on the axles must comply; possibilities provided by certain special steels; improvements to be expected from superficial mechanical treatments; and influence of different types of anti-corrosion methods. In French with English abstract. [French]

STABILITY AND RIDING QUALITY OF RAILWAY VEHICLES
The so-called critical speed of a linearized railway vehicle is shown to be no useful measure for the stability of the system in practice. The important interaction between vehicle and track can be taken into account by the riding quality for a certain vehicle on every particular piece of track. The riding quality is determined by the accelerations transmitted by the payload, weighted according to comfort standards, and the relative displacements between wheel and rail. From the riding quality demands both for vehicle design and for maintenance of the track can be derived.

WHEEL/RAIL ADHESION. THE INFLUENCE OF RAILHEAD DEBRIS
Evidence that rust is a major source of railhead debris, is presented. Particles are observed to spread on the wear band in wet weather and to be worn off in the dry. Laboratory experiments show that debris has little effect on friction except when mixed with an oil. Friction is then reduced depending on the quantity of oil and the surface area of the particles. A considerable proportion of oil is needed to reduce friction to its lowest value. Water can also substantially reduce friction on debris covered surfaces. A correlation is demonstrated between friction and humidity in which the friction coefficient is shown to be a simple function of the amount of water absorbed.

HARMONIC ROLL SERIES: FREIGHT CAR MODELS, DESIGN PARAMETER STUDY: FREIGHT CAR SIMULATION SERIES. VOLUME 3
To present the findings related to the primary objectives of Task 13, it was decided to present a series of harmonic roll related documents to the industry to be used as reference material in a similar manner to that of the Track-Train Dynamics Bibliography. The document presents technical information about computerized mathematical models used to simulate the dynamic response of freight cars to various operating conditions. Particular emphasis is placed on studying changes in certain basic freight car design parameters and how these changes affect the dynamic response. It is hoped that this information will be used as guidelines by the AAR Mechanical Division for establishing car design specifications and setting maintenance standards that insure the dynamic stability of freight cars.

RAILWAY DYNAMIC TESTS
The verification of running safety and the quantitative assessment of the comfort of railway vehicles involves the taking of many dynamic measurements. The author first lists the range of the main recordings required and explains how they are taken: fitting of gauges, isolation of the phenomenon to be studied and transformation of the results into readings that can be interpreted more easily (usually an electric process), amplification, filtering, remote transmission of this data, reception and recording. The complex behaviour of a moving vehicle means that numerous phenomena must be recorded simultaneously and continuously by a whole series of measuring instruments. The author describes and explains in three sections the techniques used for measuring stresses and wheel-rail interaction, the series of measuring instruments, and the interpretation of the many and varied experimental results obtained, particularly with the TGV 001 trainset and the Z 7001 railcar. These results are very close to those obtained by calculation; they show the high value of the method using an analogue computer. [French]

HUNTING STABILITY OF RAIL VEHICLES WITH TORSIONALLY FLEXIBLE WHEELSETS

The effects of torsionally flexible wheelsets on the hunting stability of rail vehicles have been investigated by solving the eigenproblem. The primary model is that of a single truck with two torsionally flexible wheelsets. Results for a complete car model consisting of the car body, two trucks and four torsionally flexible wheelsets are also presented for comparison. This study shows that the hunting critical speed of rail vehicles is reduced significantly by the use of torsionally flexible wheelsets.

VERTICAL MOTIONS DURING RAILCAR IMPACTS

In yard type impact situations, railcars strike other railcars producing car body pitching and vertical bounce. This vertical motion, if large enough, can cause vertical disengagement of couplers which could explain the penetration of tank car ends observed in accident situations. Preliminary investigation of vertical motions during impact, using a mathematical model, has successfully reproduced simulations of impacts in the elastic range. Examples confirm the possibility of coupler disengagement or center plate disengagement of railcars undergoing high speed impact. The computer program developed will solve for horizontal and vertical coupler force, vertical motion at the trucks and couplers, and slippage between adjacent car couplers. This work was sponsored by the RPI/AAR Tank Car Safety Research and Test Project Committee and represents one phase of the overall RPI/AAR study of means to improve tank car safety in accidents.

This paper was contributed the Rail Transportation Division of the ASME for presentation at the Winter Annual Meeting, Houston, Texas, November 30-December 4, 1975.

AN INVESTIGATION OF CONTAINER FLAT CAR RIDE QUALITY

This paper contains summaries and analyses of data recorded during a two-phase program, run between 1970 and 1974, which investigated the ride quality of a container flatcar. The program was undertaken because certain wear conditions found in the wheels, trucks, container pedestals, and trailer hitches on intermodal flatcars appeared to be related to their ride qualities. Phase I showed the importance of such basic variables as length of containers, rigidity of lading, amount of lading, speed of train, position of container on car, condition of wheels, and design of friction damping. Phase II showed the importance of truck design, side bearing design, and track condition.

This paper was contributed by Rail Transportation Division of the ASME for presentation at the Winter Annual Meeting, Houston, Texas, November 30-December 4, 1975.

PROPOSED SOLUTIONS TO THE FREIGHT CAR TRUCK PROBLEMS OF FLANGE WEAR AND TRUCK HUNTING

This paper reports on the progress of a development program whose objective is to devise cost effective solutions to the problems of excessive flange wear and truck hunting. It is expected that later papers will deal with separate aspects of this program in greater detail. Three solutions for freight cars are proposed: (1) a retrofit steering assembly kit for application to the trucks of existing roller bearing cars, (2) modification of the side frame and bolster castings to incorporate a more cost effective steering assembly for new trucks and (3) a completely new truck design incorporating improvements in car suspension as well. All three designs include a steering feature which will reduce wheel and rail wear in curves and elminate truck hunting. The second and third designs also provide better brake shoe/wheel alignment for additional savings in wheel wear. The appendices define the terminology used and identify the design characteristics of conventional trucks which lead to the present high cost of ownership.

This paper was contributed by the Rail Transportation Division of the ASME for presentation at the Winter Annual Meeting, Houston, Texas, November 30-December 4, 1975.

INVESTIGATION OF A TORSIONALLY FLEXIBLE FREIGHT CAR

With the introduction of a new design wood chip gondola car on the Seaboard Coast Line Railroad, problems arose which defied attempts at solutions by analytical methods and laboratory testing. To positively identify the source of these problems and at the same time analyze the effects of rigidizing the car body, Seaboard Coast Line in a joint effort with Pullman-Standard conducted tests in the actual operating environment of a car. The results of these tests, which are herein discussed, led to the conclusion that "truck hunting" action on the empty car was the primary source of structural problems. The test results are presented in graph form followed by a discussion and conclusions. A summary of the ongoing efforts to determine the most economical solution to the problem is also presented.

This paper was contributed by the Rail Transportation Division of the ASME for presentation at the Winter Annual Meeting, Houston, Texas, November 30-December 4, 1975.

ANALYTICAL AND EXPERIMENTAL DETERMINATION OF NONLINEAR WHEEL/RAIL GEOMETRIC CONTRAINTS

The wheel/rail geometric constraint relationships for actual wheel and rail profiles are generally nonlinear functions of wheelset lateral displacement. Two of these relationships which strongly influence the lateral dynamics of railway vehicles are the effective conicity and gravitational stiffness. An algorithm for the digital computer is presented that calculates these nonlinear relationships for arbitrary wheel and rail head profiles. An experimental apparatus was developed to determine the location of the wheel/rail contact points as a function of wheelset lateral displacement for arbitrary profiles. Experimental data obtained with this apparatus are presented for various cases which validate the results of the analytical procedure.

To be presented at the Winter Annual Meeting.

FREIGHT CAR TRUCK DESIGN OPTIMIZATION. LITERATURE SEARCH. VOLUME I

This document serves as an introduction to the literature known to be available and relevant to rail freight car trucks, their components and performance characteristics. In connection with the Federal Railroad Administration sponsored research in Truck Design Optimization a literature search was conducted to review and assemble all relevant publications, papers, and articles. The collected documentation has been organized into five sections: (1) The History of the Freight Car Truck; (2) Truck Design; (3) Truck Compaments; (4) Track-Train Dynamics as Related to Truck Performance; and (5) Truck Performance. Each section contains; an introduction dealing with literature selected for reprinting, reprints of articles judged particularly representative or salient, and a bibliography alphabetized by author. The five sections have been organized into three-volumes. Volume I contains the sections entitled: "The History of the Freight Car Truck" and "Truck Design." Volumes II and III will complete the compilation. It is expected that supplements to the three initial volumes will be published at a later date as additional information becames available.

This interim report represents the first of a three volume set. Volume II (RRIS 02 129105) and Volume III (RRIS 02 129106) bear the same report number with B and C suffixes respectively.

FREIGHT CAR TRUCK DESIGN OPTIMIZATION. INTRODUCTION AND DETAILED TEST PLANS-SERIES 1, 2, AND 3 TESTS-PHASE I
This document serves as an introduction to the Freight Car Truck Design Optimization Project (TDOP) and presents the detailed test plans for Series 1, 2, and 3 Tests of a contemplated group of four series for that project. Some of the background of the project is given, the development of the test method is described, a description of the instrumentation on the test track and test car and of the facilities of Southern Pacific Transportation Co, (SPT Co.) are given, a data collection and processing plan and analytical procedures for comparing test results with predicted values are presented. A description of the Series 1, 2, and 3 Tests, the contemplated test schedule, and the management structure for the project are also given. In the appendix, the tasks required to be performed by the statement of work for Phase I are outlined.

This is a prerequisite to the forthcoming interim report covering the test plan for Test Series 4, FRA Report FRA-OR&D 75-60. This document supersedes issue of July 1975. Sponsored by FRA.

FREIGHT CAR TRUCK DESIGN OPTIMIZATION. SURVEY AND APPRAISAL OF TYPE II TRUCKS
This report serves as an introduction to the family of truck designs known as Type II that will be studied in connection with the Federal Railroad Administration's Truck Design Optimization Project. An investigation was made of existing trucks and truck designs qualifying as Type II trucks and this investigation considers features which would be of interest in selecting candidates for testing and evaluation of such trucks under Phase II of the Truck Design Optimization Project. Type II special service designs embody new concepts that utilize current wheel set and journal bearing assemblies and braking arrangements compatible with current air brake systems. Car coupler height is maintained but car body support other than center plates can be employed. Ride quality and minimum maintenance cost are of major importance to Type II designs.

This project was sponsored by the Federal Railroad Administration, DOT.

THE GUIDANCE OF RAILWAY VEHICLES
World-wide the consensus is generally towards the use of rather low conicities for high speed vehicles. Whether the improvement of understanding and prediction techniques will alter this trend remains to be seen. For lower speed vehicles the consensus is less general. Some freight vehicles already succesfully use a high-conicity approach with good linear curving, and the authors expect to see this trend continued. They also expect to see improvements in the design of commuter vehicles to increase the linear curving regime and therby reduce flange and rail wear problems.

COUPLED VEHICLE/TRACK DYNAMICS
Dynamic coupling occurs between a railway vehicle and the track due to the reaction forces acting between the wheels and the track, and the elasticity of the track and the foundation. It has become apparent that track elasticity can influence the dynamic behaviour of the railway vehicle, yet in most of the research work in the area of railway vehicle dynamics reported so far, the track is regarded simply as a rigid structure, providing the reactions to the loads of passing vehicles. In this paper the models used for the analyses of the vehicle dynamics (on rigid track) and for the coupled vehicle/track dynamics are described. The equations of motion are derived, and the results obtained for the coupled vehicle/track model are presented and compared with those obtained for the case of an infinitely rigid track. Particular empahsis is on the lateral stability and the response to vertical track irregularities.

INFLUENCE OF THE CONCRETE CONDITIONS OF CONTACT BETWEEN WHEEL AND RAIL ON THE RUNNING OF VEHICLES OVER RAILWAY LINES [Einfluss konkreter Rad-Schiene Beruhrungsverhaltnisse auf das Laufverhalten von Schienenfahrzeugen]
The authors speak of the effects of a number of different wheel, and rail profiles on the stability of rolling stock, and also of the influence on such stability of the wheel/rail friction coefficient. From the studies carried out, it transpires that a wheel profile close to the shapes created by natural wear between wheel and rail is more advantageous than conical profiles as regards maintenance and running stability. LATERAL DYNAMICS OPTIMIZATION OF A CONVENTIONAL RAILCAR
The attempt to develop a railway vehicle that can operate in the 150 to 300-mph (240 to 480-km/h) speed regime is seriously hampered by the problems of ride comfort, curve negotiation, and "hunting." This latter phenomena involves sustained lateral oscillations that occur above certain critical forward velocities and cause large dynamic loads between the wheels and track as well as contributing to passenger discomfort. This paper presents results of an initial effort to solve these problems by utilizing optimization procedures to design a high speed railway vehicle. This study indicates that the problem is more easily treated as a constrained optimization problem than as an unconstrained problem with several terms in the objective function. In the constrained optimization problem, the critical "hunting" speed was maximized subject to constraints on (1) the acceleration of the car body, (2) the suspension stroke length, and (3) the maximum suspension stroke while negotiating a curve. A simple, three degree- of-freedom model of the rail vehicle was used for this study. Solutions of this constrained problem show that beyond a minimum yaw stiffness between truck and car body the operating speed remains nearly constant. Thus, above this value, the designer may trade off yaw stiffness, wheel tread conicity and stability margin.

A REVIEW OF RAIL-WHEEL CONTACT STRESS PROBLEMS
Nearly 200,000 defective rails were located on U.S. railroads in 1972 Rail failures are one of the largest single causes of derailments, ranking somewhat ahead of the next most substantial contributor: wheels and axles (bearings). Furthermore, a high degree of correlation was observed between the rail-related accidents and the ton-miles carried, suggesting that a higher utilization of the rail system may lead to yet higher accident rates. The defective rails and rail-failure-related accidents occur in spite of a massive inspection effort and the installation of over 700,000 tons of new rail annually. Not all defects are equally likely to cause derailments. Rail-end failures (bolt-hole cracks and head/web separations) occur most frequently, but are not proportionately the largest cause of accidents. Transverse defects, which are less frequent, can account for a disproportionately high number of accidents.

STRESSES AND BEHAVIOR OF RAIL TRACKS DURING THE PASSAGE OF TRAINS TRAVELLING AT VERY HIGH SPEEDS; STANDARDS ADOPTED BY THE SNCF FOR ITS FUTURE VERY HIGH SPEEDS LINES (250/300 KM/H)
On the Paris-Madrid line in Southwest France, between Bordeaux and Dax, there is a section on which there are two straight stretches of 20 to 45 km, separated by a curve with a radius of 2850 meters. This SNCF line allows tests to be carried out at speeds of over 250 km/h. Since August 1972, two prototype trains, the TGV 001 turbotrain, and the Z 7001 electric motor train, have been traveling four times a day at speeds between 250 and 320 km/h. This paper summarized the knowledge acquired in France as the result of systematic tests carried out at those speeds in anticipation of the new Paris-Sud-Est line on which trains will travel at speeds of over 250 km/h. Although the problems are not yet completely solved, they are at least now defined very clearly, and none of them is of a fundamental type. The doubts raised a few years ago now appear to be baseless, at least for speeds of up to 300 km/h.

TECHNICAL STABILITY OF THE LATERAL VIBRATION OF A SINGLE WHEEL SET MOVING ALONG A TRACK WITH A NONLINEAR TRANSVERSE ELASTICITY [Statecznosc techniczna drgan bocznych pojedynczego zestawu kolowego poruszajacego sie wzdluz toru z nieliniowa sprezystoscia poprzeczna]
The technical stability of a mechanical system with a single degree of freedom, a nonlinear elasticity characteristic, free play, and damping by dry fricition, is considered. This system performs forced lateral vibrations produced by a harmonic force. The system is acted on by constantly acting perturbations of the elasticity and damping characteristics. The regions of

the stability were considered from the practical point of view. The problem is analyzed by means of the second method of Lyapunov. The relations obtained for the stability conditions contain the elasticity coefficient, the damping, and the rate of lateral motion of the body. [Polish]

FREQUENCY DOMAIN COMPUTER PROGRAMS FOR PREDICTION AND ANALYSIS OF RAIL VEHICLE DYNAMICS. VOLUME 1-TECHNICAL REPORT
Frequency domain computer programs developed or acquired by TSC for the analysis of rail vehicle dynamics are described in two volumes. Volume I defines the general analytical capabilities required for computer programs applicable to single rail vehicles and presents a detailed description of frequency domain programs developed at TSC in terms of analytical capabilities, model description, equations of motion, solution procedure, input/output parameters, and program control logic. Descriptions of programs FULL, FLEX, LATERAL, and HALF are presented. TSC programs for assessing lateral dynamic stability of single rail vehicles are also described. Volume II contains program listing including subroutines and card-by-card descriptions for inputing data for the four TSC frequency domain programs described in Volume I.

EFFECT ON TRACK OF HEAVY AXLE LOADS
The author recalls and makes reference to numerous studies on the problems of damage to rails caused by heavy axle loads. He quotes recommendations developed by AREA with regard to permissible axle loads in relation to wheel diameter and vehicle speed, and the ultimate tensile strength of rail steels. He mentions the experience of Australian Railways operating meneral lines with block- trains made up of very heavy wagons. He then gives formulae and tables in which the track maintenace cost, as per traffic unit, is expressed in relation to various variables and parameters: speed, axle weight on rail, age of ballast, linear weight of rail, curve radius, etc.

CRITERIA FOR EVALUATING RAIL VEHICLE DYNAMICS BY COMPUTER MODELING TECHNIQUES
The problem is tackled by means of a 14-degree-of-freedom computer model excited by two track geometry errors: a deterministic input based on bolted-rail track, and random geometry power spectra based on continuous welded rail. The model is not described, and the paper is devoted to the study of possible criteria and the results obtained from application of these criteria to various types of rolling stock. The authors review the classical ride-comfort criteria of JNR, ISO, BR and devise complex criteria combining vertical and cross vibration, and characterising: the maximum permissible weight of the vehicles; the stability of the track/vehicle system; comfort in curves; the ride quality.

SOME RELATIONSHIPS BETWEEN DYNAMIC PERFORMANCE OF FREIGHT CAR TRUCKS AND WORN WHEEL TREAD
Stability of flanged wheels on steel rails involves wheel tread and rail head contours. But after 150 years of railroading, the merits of various tread profiles are still being debated. To fix the importance of wheel profile on lateral stability of the freight car truck and riding qualities of the car, extensive tests were conducted by Southern Pacific on 89-foot flat cars used in container service. It was found that wheel contours have overriding influence on truck stability. While asymetrical wear patterns may develop

from external influences, not all such uneven wear produces unstable operation. Hollow treads seem to stabilize a wheel set. Further investigations, assisted by computer analysis, are needed to understand the dynamic performance of car trucks as influenced by worn wheels. Brake shoe wear has an influence on wheel wear which can affect wheelset stability but this is not understood fully.

B2 131639
WHEELSET SUSPENSIONS DESIGNED TO ELIMINATE THE DETRIMENTAL EFFECTS OF WHEEL WEAR ON THE HUNTING STABILITY OF RAILROAD VEHICLES

Traditionally, railroads use wheels having conical wheeltreads, the conicity being 1/20 normally. In practice it has been found that wheeltreads tend to wear hollow. There is also considerable wear to wheel flanges. Such wheel wear changes the effective conicity of the wheeltread and railroad practice has shown that worn wheels frequently excite the vehicle, often to violent oscillations in the lateral plane at certain critical speeds. These undesirable oscillations are generally referred to as hunting. The hunting phenomenon can be explained adequately by the creep theory. A consequent application of this theory leads to the design of wheelset suspensions which result in wheel wear being minimized and distributed evently over the tread surface, thus reducing the tendency for the wheeltread conicity to change with wheel wear. Such suspensions require wheels having profiled wheeltreads of a relatively high effective conicity. In addition, the elastic yaw constraint between wheelset and truck frame must not exceed certain values.

ANALYTICAL AND EXPERIMENTAL DETERMINATION OF NONLINEAR WHEEL/RAIL GEOMETRIC CONSTRAINTS

The wheel/rail geometric constraint relationship for actual wheel and rail profiles are generally nonlinear functions of wheelset lateral displacement. Two of these relationships which strongly influence the lateral dynamics of railway vehicles are the effective conicity and gravitational stiffness. An algorithm for the digital computer is presented that calculates these nonlinear relationships for arbitrary wheel and rail head profiles. An experimental apparatus was developed to determine the location of the wheel/rail contact points as a function of wheelset lateral displacement for arbitrary profiles. Experimental data obtained with this apparatus are presented for various cases which validate the results of the analytical procedure.

TRACK-TRAIN DYNAMICS

The purpose of this paper is to outline one of the serious dynamic problems involving railroad cars and to propose an orderly approach to the definition of a dynamic model through analysis and testing that can be used to investigate various fixes. The problem in question is the hunting phenomenon involving lateral instability of the car suspension (trucks). This phenomenon has been recognized as a major contributing factor in a significant number of derailments causing millions of dollars in losses. This paper expounds on the mechanics and characteristics of hunting. The planned solution is outlined as a building block approach directed at formulating a test verified dynamic model of an open hopper freight car-truck assembly. Results obtained to date are presented together with conclusions related to the program.

DETERMINATION OF LOADS ON TRACK
In the past decade, advances in the technology of instrumentation and of computers have made possible the determination of wheel/rail loads so that proper design and maintenance procedures may be developed for vehicles and track so that the industry can live with today's axle loadings. Methods of determining such loads by measurements on the vehicle and the track are discussed. Mathematical modeling procedures may also be utilized to calculate such loads. Computer simulation which includes both vehicle and track in a dynamic interacting system permits specification of outputs in the form of vertical and lateral forces between wheel and rail. Some of the research programs in load determination are then described.

TRACK STRUCTURES FOR HEAVY WHEEL LOADS
The load bearing capability of track depends on the combined characteristics of foundation, superstructure and loads to be carried. Evidence is that loads imposed by 100-ton cars exceed the load-bearing capacity of much of the track over which they operate. Track deterioration under heavy loads appears in the form of loss of surface and line; in conversion of subgrade and ballast sections into plastic masses that pump mud and water, in wide gauge, plate cutting, tie splitting and spike-killed ties; in rapid wear, battered rail ends and in formation of corrugated and shelly rail. After discussing facets of track design and track deflection, the problems of ballast and subgrade are examined and the effects of wheel loads are detailed. Ten recommendations for combatting effects of high wheel loads and two other lines of action for limiting or accounting in advance for track deterioration are suggested.

EFFECT OF HEAVY AXLE LOADS ON RAIL AND TIES
The Quebec North Shore and Labrador Railway was built in 1953 to handle iron ore from mines 350 miles north of the St. Lawrence River. Trains of up to 280 cars with five locomotive units are operated. This presentation reports the maintenance experience on track which carries up to 50 million net tons annually, and has handled almost 700 million gross tons since opening. Among the findings: line, surface and gauge must be maintained even on tangent track; corrugated rail develops quickly on grades and curves and must be countered promptly; joint bars must be kept tight and rail ends restored; oilers are all-important on curves.

PROGRESS REPORT ON THE TRUCK DESIGN OPTIMIZATION PROJECT
The Federally funded Truck Design Optimization Project (TDOP) is being conducted by Southern Pacific Transportation Company to furnish new technical and economic insights into the procurement and use of freight car trucks. A variety of outputs are emerging, including digital data tapes that may prove useful to future investigators of freight car truck dynamics. TDOP will furnish railroads with technical and economic information on freight car truck performance. Performance data is required to correct existing problems and establish future truck system needs. Phase I effort is anticipated to include technical performance specifications and an economic methodology for use in evaluating trucks.

IMPROVED SUSPENSION FOR 100-TON CARS ON ROUGH TRACK

American Steel Foundries set out to develop a freight car suspension defined as a highly refined, state-of-the-art, three-piece truck designed as a system rather than a collection of components. This article discusses suspension reserve work capacity, optimum damping, design process, ride quality findings in the vertical, lateral and rocking modes, and the determination of the wheel-rail forces as evidenced by factors such as flange wear and truck component wear.

MODIFIED THREE-PIECE TRUCK REDUCES HUNTING AND IMPROVES CURVING-STATUS REPORT

The often-condemned three-piece cast steel freight truck has two advantages: It is inexpensive to manufacture and it has excellent load equalization that allows it to negotiate large changes in crosselevation. This paper describes Standard Car Truck's work with the Anchor Truck design of the South African Railways which improves the basic three-piece truck's curving ability and yet gives it high-speed stability. Utilizing the creep theory in which a wheel is displaced from its position of pure rolling, various conclusions are drawn about wheelset and truck stability. The role of the SAR-developed diagonal anchors and the service experience on SAR's ore car and with a US installation on a 100-ton hopper are described.

ORE ORGANIZATION AND ITS STUDIES IN TRACK, SUSPENSION AND TRACK/TRAIN INTERFACE

The procedures and facilities utilized by the office for Research and Experiments of the International Union of Railways are described. The studies on conventional and on concrete slab track are described. The investigations of train/track interraction and of derailments are then discussed, as well as axle loading as a function of speed and wheel diameter. It is concluded that in Europe the ballasted conventional track is nearly optimized and much study is being made of concrete slab track. Studies of car suspension systems have only involved two-axle cars. Recommendations on improving the riding stability and quidance of locomotives have been formulated and of maximum loadings for axles and bridges are being progressed.

RAIL WEAR AND CORRUGATION PROBLEMS RELATED TO UNIT TRAIN OPERATIONS: CAUSES AND REMEDIAL ACTION

This paper is a case study of rail wear problems on Canadian National's main line through the Rocky Mountains as a result of unit train operation. The problems are gauge-face wear on the high rail on curves, rail head flow on the low rail and corrugations having a wavelength varying from 8 to 30 inches on the low rail. Prior to introduction of unit trains there were almost no such problems. A study of the lateral forces is described. Remedial action requires a concentrated effort by Engineering, Equipment and Transportation groups with no quick "fix" available. Absence of any action will only cause track deterioration and if it is desired to more bulk commodities in unit trains, the problem must be attacked in an organized manner.

HEAVY AXLE LOADS IN NATIONAL RAILWAYS OF MEXICO AND NEED FOR STRENGTHENING OF BRIDGES

National Railways of Mexico has been confronted with many low-capacity bridges on lines where heavy cars are being, or will be handled. While the new bridge standard is Cooper E72 rating, those built prior to 1970 range downward from E60 to E35 on some former narrow-gauge routes. NdeM has raised the ratings on some bridges since diesel locomotives have replaced steam with resultant reduced impact loadings. Slow orders are imposed on certain structures to handle concentrated program of strengthening bridges where it is reduce impact on bridges and use of neoprene pads under the rail base for the same reason have been widely applied. A concentrated program of strenthening bridges where it is economical has been undertaken. Bridges of low capacity or in bad condition are replaced.

COMPARISON OF LIGHT INTENSITIES OF VARIOUS LOCOMOTIVE HEADLAMPS AND VISUAL RANGE BY HEADLAMP ILLUMINATION
With the increasing train speed more powerful headlamps are demanded to prevent accidents especially at highway crossings. The light intensity distributions of the various headlamps installed in the actual locomotives were measured at the neighborhood of the Shinmachi Station of the Takasaki Line. The photometric property of the sealed beam headlamps is superior to that of the ordinary type. To secure good illumination, two or more headlamps are to be installed in a locomotive.

SAFETY ON THE RAILWAYS
The article comments on the improvement of railway safety on the German Federal Railways over the past 15 years. Between 1954-1960 a relatively short period, passenger deaths dropped from 115 to 72 and the number of passenger injuries decreased from 830 to 531. The improvement in railway safety is attributed to a general improvement in technical standards. Many improvements have been or are proposed to meet the demand for higher maximum speeds and to cope with the higher bending stresses and slightly higher axle-loads produced by diesel and electric locomotives as compared with the heaviest steam locomotives. An important measure is the introduction of the S54 rail which may supercede the S49 standard profile. Also, improvements in bridge and tunnel construction, the redefinement of clearance gauges and signalling techniques have enhanced safety operation.

WHEEL TREAD FAILURE-CHICAGO AND NORTHWESTERN RAILROAD
Two 36" locomotive wheels were tested after their removal from service because of shelling. These wheels had approximately 10,000 service miles under an E-8 locomotive after they had been turned down once. The wheels had previously seen 77,700 service miles under a locomotive before being turned down. The tests run included visual examination with magnafluxing, chemical analysis, hardness evaluation, and microstructure. The tests showed that the wheels were classified incorrectly at the factory as Class B wheels. They were actually Class A type, which were not capable of withstanding the severe service to which they were subjected.

SD-45 LOCOMOTIVE DYNAMIC BRAKE TRAIN HANDLING TESTS ON PENNSYLVANIA RAILROAD
Because of a major derailment near Johnstown, Pa., a series of dynamics brake handling tests were conducted between Harrisburgh and Pittsburgh, on severe grades and curves. The trains in which the test unit and the adjacent long overhang boxcar operated were varied in nature, ranging from tonnage trains while operating in a two-unit consist to trailer trains and PR trains in four-and eight-unit consists. In general, with the loaded long overhang boxcar leading the train, the records indicate that at no time did the danger of derailing due to drawbar forces exist. No instances in the entire test program exhibited lateral force levels which would be of concern with respect to derailment. The boxcar was loaded with freight during all of the tests.

THE USE MADE OF SPECTROGRAPHIC ANALYSIS OF DIESEL ENGINE SUMP OIL BY THE ENGINEER
The inspection program of the London Midland Region of the British Railways is described. Important metals whose concentration in the oil are measured include: iron, lead, silicon, sodium, aluminum and copper. Bearing wear is predicted by abnormal concentrations of lead from the flushing followed by copper, since the bearing surface contains 90 percent lead and the underly contains 70 percent copper. Piston seizure is predicted by abnormal concentrations of iron and aluminum, since the pistons are of aluminum alloy and the rings are of iron alloy. The oil samples are taken every 200/250 hours or about every 2-3 weeks. A summary of examinations is given for a two year period.

SAFE OPERATION OF HIGH-SPEED LOCOMOTIVES
In this paper are presented the basic theories, test information, and the chief conclusions of an investigation of factors entering into the mechanical design of locomotives for high-speed operation. The author points out that (1) recent trends in railroad operation have been toward higher speeds over longer distances and (2) the development of electric and oil-electric power, and lightweight equipment have changed many of the conditions under which these higher speeds are attained. In view of the radically new types

of equipment available, the increased severity of requirements both as to performance and cost of equipment, and the necessity for preserving the railroad's record for safety, it has been necessary to make an extended theoretical and experimental analysis of high-speed locomotive operation. Such an analysis is given in this paper.

This paper appeared in Anthology of Rail Vehicle Dynamics, Volume 2: Effects of Train Action and Rail Car Vibration. The anthology was sponsored by the Rail Transportation Division, ASME. Presented at the Annual Meeting, New York, N.Y., Dec. 2-6, 1935.

DEVELOPMENT OF SCRATCH-AND SPALL-RESISTANT WINDSHIELDS
Studies were performed to evaluate possible ways of improving the primary weaknesses in existing Army helicopter windshields, namely, scratching and spalling. Three experimental windshield material configurations offering a potential solution were fabricated for test and evaluation. The spall problem was approached by using plycarbonate as a backup material and was incorporated into each design. The scratch problem was approached by employing either (1) a hard surface coating, (2) an acrylic cladding, or (3) a thin glass cladding to the polycarbonate backup material. Commercially available materials and abrasion-resistant coatings were evaluated utilizing a windshield wiper apparatus, while spall performance was studied by ballistic testing and high-speed photography of each of three test configurations. /NTIS/

HIGH SPEED TRAIN PROTOTYPE PROVES ITS WORTH
Unhappy experience with small batches of diesel locomotives ordered off the drawing board in the 1950s ensured that extensive prototype testing would precede series production of British Rail's next generation of 200 km/h intercity trains. The prototype High Speed Train completed in 1972 has already proved its value, but further modifications are continually being introduced so as to prove their acceptability before they are incorporated in the next batch of production trains.

THE IMPACT OF STONES HITTING AGAINST THE LOCOMOTIVE WINDSCREENS [Steine gegen Lokomotivscheiben]
The windscreens on motive power units must be strong to protect drivers from the impact of solid objects, especially since train speeds are increasing. The author describes an experimental measuring device to help in choosing windscreens which are acceptable both from the technical and and the economic point of view and which provide satisfactory protection for locomotive drivers. A solid propellant is used to project a stone weighing one kg at 400 km/h in a tube measuring one metre long and with an inside diameter of 100 mm. A photoelectric method is used to measure the speed of the stone before it hits the the windscreen. [German]

DIESEL RECORDS SYSTEM
The file name is DIESEL RECORDS MASTER FILE. The objectives of this computer program are: 1. To aid in scheduling and verifying completion of locomotive maintenance items. 2. To aid in isolating problems with specific locomotives by providing a history of pertinent information for each unit. Output consists of a semi-monthly printout showing the following information for each unti due maintenance during the next fifteen days: 1. Maintenance items due to be performed including repetitive maintenance items which are done at fixed intervals and special upgrading or correction projects. 2. A history of traction motor failures on each unit by pedestal number. 3. An indication if the traction motor model is not one of the models which is recommended for use on the specific locomotive model. (Recommendation is based on reliability considerations). Other outputs include a current "cab card" and various inventory listings of main components (traction motors, main generators, turbochargers, etc.). Feedback is provided when maintenance items are completed by having the person who did the work sign the computer report and then keytyping data from the report. A maintenance item will continue to appear on the report each month until it is reported completed. Input consists of: 1. Oil control lab data, in-service failures, and defects from the Locomotive In-service Failure/Defect Analysis Program. 2. Feedback data from the shops on each maintenance item or project completed. 3. Traction motor applications and removals from the diesel shops. 4. Tables of frequency of repetitive maintenance items. 5. Tables identifying which units are due for special projects.

TRACTION MOTOR RELIABILITY
Computer program: MAIN DIESEL COMPONENT INVENTORY, CAR MOVEMENT HISTORY FILE. Program produces a family of reports giving traction motor reliability data by model. Reports provide basis for decision rules for vendor selection, and preferred combinations of traction motor model--locomotive model. Input consists of traction motor application (to locomotive units) and removal records, traction motor disassembly and reassembly records. Mileage is obtained from the car movement history file. Output consists of the following reports: 1. Traction motor overhaul data by motor serial number. 2. Traction motor overhaul data by armature serial number. 3. Traction motor armature overhaul rates by armature manufacturer for each 100,000 mile increment since manufacture or rewinding. 4. Traction motor model-locomotive model failure rates by combination showing number of motors in class, mileage last 3 months; reason for overhaul and number of overhauls.

LOCOMOTIVE IN-SERVICE FAILURES/DEFECT ANALYSIS
File name is LOCOMOTIVE FAILURE/DEFECT FILE, CAR MOVEMENT HISTORY FILE. Major objective of computer program is to isolate major causes of locomotive in-service failures. Input consists of: 1. Data on the results of a monthly spectrographic analysis of samples of the cooling water, crank case oil, and air compressor oil from each locomotive. 2. Data on in-service failures (motive power failures which result in either reducing the tonnage of a train or in a train delay.) 3. Diesel shop report on in-service failure giving cause, type to defect, data repaired, etc. 4. Reports of locomotive defects (conditions not causing failure). Monthly output reports include: 1. A raw data tabulation of each failure listing all pertinents data and sorted by locomotive model and within model by cause of failure. 2. A summary of locomotive in-service failures by maintenance points, locomotive model, and failing component for both one month and three-month periods giving number of failures and failures per million miles. 3. Summary of locomotive defects by defective component and by the reporting Road Foremen of Engines. 4. A summary of in-service failures by operating division and by type of service (passenger, freight, or switching). 5. Identification of units which have had repetitive duplicate oil lab findings.

INTERNAL COMBUSTION ENGINE FAILURES: A STATISTICAL ANALYSIS
The company's primary interest is in the safe operation of all insurable equipment and in the prevention of failure of that equipment, wherever possible, by means involving manufacturing, operation and maintenance, and inspection techniques. The equipment involved includes diesel and dual-fuel engines, spark-ignited gas and gasoline engines and internal combustion engines driving reciprocating compressors. The accident analysis coding system provides three basic categories under which each reported failure is coded for future analysis. These are: Type of Accident. Initial Part to Fail. Primary Cause of Failure. For convenience the items are handled in that order with a brief discussion following each.

CONSUMPTION OF THE WIRE IN CONTACT LINES IN RELATION TO INCREASES IN SPEED AND CURRENT [Il consumo del filo nelle linee di conttato in rapporto agli aumenti di velocita e di corrente]
An enquiry is made into the effects which the speed of trains and the current absorbed by them has on the consumption of the conductors. Speed and current are considered as independent parameters and their effects are considered through friction, insofar as speed is concerned, and through the joule effect with regard to the current. One reaches the definition of two coefficients, K sub V and K sub I, which quantitize the phenomena referring K sub V to an average speed V sub O, whilst the coefficient K sub I is used to identify levels of wear, choosing as reference the value I of the coefficient K sub I calculated on the wear of the entire network. To the product K sub V-K sub I, calculated line by line, is attributed the significance of the coefficient of wear of the line. The question is handled with a theoretical formulation and thus an experimental control is suggested. [Italian]

TEST OF FIRE FIGHTING FOR LIVE LINE ELECTRIC EQUIPMENT
Fighting of fires in cars on electrified lines normally requires the cutting of power. Damage can be increased substantially while waiting for confirmation that power has been disconnected. This study was concerned with the possibility of fighting fires with the power system energized. Various equipment was sprinkled with differing nozzle patterns and using water and other extinguishing materials. The results are expected to be reflected in the fire fighting equipment to be provided in long tunnels and the extinguishers to be carried on electric cars and locomotives.

LOCOMOTIVE TO AUTOMOBILE BASELINE CRASH TESTS
Four Locomotive to Automobile Crash tests were performed by the Dynamic Science Division of Ultrasystems at DOT's High Speed Ground Test Center under contract to the Transportation Systems Center, which is conducting the work for the Federal Railroad Administration. This report documents these four tests, which will provide baseline data for evaluation of future locomotive front structure modifications designed to attenuate the severity of the grade crossing accident. The automobiles were all 1973 standard size sedans of the same model with similar options. For each test, a 130-ton Alco locomotive impacted a stationary automobile at a nominal 50 mph. The first two tests contained no instrumentation on either the locomotive or automobile except for high-speed cameras. The last two tests were instrumented repeats of the first two tests which also involved a direct side impact and a side impact centered on the automobile front fender. The last two tests had an anthropomorphic dummy in the automobile and over 50 accelerometers installed in it. Each test had extensive high frame rate photographic coverage.
Sponsorship was from Federal Railroad Administration, DOT.

WHEEL-RAIL ADHESION
The subject of adhesion between locomotive wheels and rails has been an area of vital interest to locomotive manufactures and to the railroads. Horsepower of internally powered locomotives has continued to increase significantly, thereby providing more power for traction. The trend of increasing horsepower has been the product of progress in technology and engineering development. Wheel-to-rail adhesion within the lower speed range has been a limiting factor in tonnage ratings for locomotives in drag service on U.S. railroads. Factors Affecting Adhesion are: (1) Vehicle Factors, (2) Track Factors, and (3) Contact-Area Common Factors. Additional discussion of the conclusions follows.

MUTUALLY PERMISSIBLE WEAR PROFILES OF WHEEL TYRES AND OF POINTS AND CROSSINGS. ASSESSMENT CRITERIA FOR THE PERMISSIBLE WEAR PROFILES OF WHEEL FLANGES AND SWITCH COMPONENTS.
Studies include the investigation of the wear forms of a great number of worn wheel flanges used on various types of vehicles (passenger coaches, wagons, railcars, electric and diesel bogie locomotives) and of worn rails in areas containing points and crossings so as to obtain an adequate basis, adapted to practical demands, for arriving at a judgment. Starting from a characteristic wear profile of a flange a track guage was developed, permitting the verification of the compatibility of the wear profiles of the ironwork of switches with such a flange.

Measurements conducted using the gauge enable development of wear forms of rails endangering the traffic to be detected (particularly in sections containing switches and stock rails) and they indicate, at the same time, how this risk can be eliminated and how their use can be prolonged by reprofiling operations. The results of the studies are that it will be possible to deduce, from an analysis of the geometry of the contact between flange wear shapes and track, the compatibility criteria adapted to practical conditions and only requiring simple measures to be taken on the wheel and the switch work items (checking by means of the gauge). This procedure will lead to a decisive improvement of the riding safety of vehicles.

Restrictions on the use of this document are contained in the explanatory material.

A NEW TRANSIT PROPULSION UNIT SUSPENSION-PROVED ON NORTHEAST CORRIDOR HIGH SPEED TEST CARS
The old generation propulsion units for lightweight, inboard journal trucks had the motor and gear unit bolted solidly together, driving the axle through, and supported on, rubber around the axle. By correcting deficiencies in this design, yet retaining the principle of floating the motor in rubber to isolate it from rail shocks, this new propulsion unit arrangement for lightweight, inboard journal trucks has successfully permitted the car operating speeds to double, from 75 to 150 mph in one jump. Paper has been written to emphasize the growing importance of dynamic vibration analysis in the design of rail vehicle trucks and truck and axle-mounted propulsion equipment. Detailed analytical studies of the wheel and axle, truck, and propulsion equipment suspension dynamics has generally been deferred in the past. The car body dynamics have been studied closely to ensure that the passengers receive a smooth ride, but the ride of the trucks and their equipment has been of little concern to most. We will point out why the suspension dynamics of the truck must be studied, how they can be analyzed, and the consequences of failure to do so.

TRAIN RESISTANCE, POWER AND ENERGY REQUIREMENT OF M-U CARS
Equations to be used in determination of multiple-unit train resistance,

power and energy requirement are developed. Curves are presented for air resistance in tunnels. For open air the effect of wind speed and direction is also analyzed. Methods are presented for energy requirement optimization. Considerable energy savings can be realized by using these methods as guide lines for operational criteria. This study extends the work of W.J. Davis, Jr., for all kinds of M-U cars. The Davis equations were prepared and still are successfully used for conventional rapid transit train speeds and shapes, but not for high speeds and streamlining.

TESTS OF PENNSYLVANIA RAILROAD ELECTRIC LOCOMOTIVES AT CLAYMONT, DELAWARE

In 1934 studies were made by the Pennsylvania of larger size electric motive power in anticipation of the heavier trains to come. A class R-1 locomotive was designed and built in 1934 with a 4-8-4 wheel arrangement. It was considerably heavier on the axles than the consulting firm which electrified the Pennsylvania deemed desirable, and they persuaded the Pennsylvania Railroad to borrow one of the new New Haven locomotives, which had a wheel arrangement of 4-6-6-4 and had a comparable axle load to the earlier class of Pennsylvania locomotives. The R-1 could not match the tracking flexibility of the GG-1, wheel arrangement of which was articulated. The GG-1 was safer and smoother riding at high speed with less destructive forces being exerted on the rail than the R-1.

TRACK-TRAIN DYNAMICS STUDY PROJECT TR-14 RAIL-VEHICLE INTERACTION STUDY REPORT NO. 1 (PRELIMINARY ANALYSIS OF SAMPLE DATA)

As a result of various derailments, a task force was formed to investigate the dynamic forces exerted by locomotive and freight car wheels against the rail. Critical study was directed at the 3 and 2 axle trucks of high horsepower locomotives, 85 feet TFC cars, and 50 feet box cars. The objective of this investigation was to determine if dynamic forces of sufficient magnitude to cause derailment were being generated by equipment, track structure and operating practice, and to recommend whatever corrective action might be indicated. Extensive field tests of wheel-rail interaction were conducted in various territories between Los Angeles and Pine Bluff, Arkansas. An analysis of these test results led to the following general conclusions: 1. Dynamic forces of sufficient magnitude to cause derailments are being generated in every day operation of revenue trains. 2. The forces are also sufficient to cause greatly accelerated wheel and rail wear. 3. Forces of sufficient magnitude to exceed the ability of the track structure to resist permanent deformation in alignment are also being generated.

PROTECTION OF RAIL JOINTS FROM CORROSION TO PREVENT RAIL END BREAKS

Many parts of the railway track including the rails are made of carbon steel. Carbon steel excels in strength but is prone to be corroded. Rail end breaks are considered as fatigue destruction caused by corrosion. Since stress and corrosion act at the same time, cracking is developed easily. It is because the fatigue strength of a rail decreases sharply in acid environments, that end breaks are more liable to occur in non-electrified sections than in electrified sections. Since corrosion has much to do with end breaks of rails in tunnels, the application of a proper protective method prevents end breaks of rails.

JACKKNIFING OF DIESEL ELECTRIC LOCOMOTIVES REPORT OF THE JOINT COMMITTEE ON RELATION BETWEEN TRACK AND EQUIPMENT

A number of railroad companies had been reporting difficulties with diesel electric locomotives under buffing or pusher operation. This action was evidenced by lateral instability between the several units, especially those under the largest buffing forces and resulted in lateral displacements and lateral forces of such magnitude that the rails were turned over and derailments caused in some cases. To obtain as complete an understanding of the jackknifing action as possible it was decided to make measurements on both the locomotive and the track. A test location was picked on a right curve of 8 deg. 6'. The grade was 1.72 percent at the curve but within a mile became 2.20 and 2.40 percent so that part of the train on the steeper grade when the recordings were made. The rail was 131 lb. RE Section laid in 1946 and rather badly curve worn. The test locomotives were GP-7 Electro Motive general purpose road switchers. The following conclusions were drawn: Jackknifing is the result of lateral instability of the several units and its severity is dependent on the magnitude of the buffing force and the eccentricity of the force. It is evident the eccentricity of the force will depend on the amount of overhang and the clearance available for lateral movement. Reduction of the bolster clearance to a small amount improves the conditions sufficiently that operation is not excessively difficult. Lateral forces are reduced about 50 percent. Operation of the general purpose units with full bolster clearance and standard couplers under buffing forces is not practicable with four units and probably undesirable with three units. Forces of almost 25,000 lb were measured at 10 mph and 140,000 to 175,000 lb

tractive force and higher forces can be developed at lower speeds or under impact conditions. These laterals applied continuously will be very detrimental to rail and wheels, cause journals to run hot, and may cause derailment. The use of the alinement control coupler attachments reduced the forces to a normal amount for the curvature of the test location. The lateral forces under full regenerative braking with alinement control couplers for an undetermined reason were a little higher in the few tests made than in the pusher operation which had twice the tractive force. However, they are still quite moderate. The jacknife position, once assumed, remains until the train is stretched out.

PLASMA TORCH PROVED FOR LOW SPEED APPLICATIONS
The article discusses research results of the British Railways attempts to improve adhesion of rail vehicles by using a plasma torch to remove materials from rail surfaces. Laboratory tests confirmed the feasibility of using such a device, in two areas: low speed operation for freight trains and high speed operation for passenger trains. A test vehicle was made up to field test the plasma rail vehicle. Results of the testing show that mechanical condition of the rail head is important; old rail with large areas of contact required higher output than new rail. The tests show conclusively that starting and low speed operation of freight vehicles with low adhesion can be resolved by the application of the plasma torch.

METHODS OF TESTING AND EVALUATING LOCOMOTIVE RUNNING QUALITIES
The German Railways initiated a thorough research into the question whether the new developments in locomotive and car construction assured safety in relation to the new developments in rail and track structures. Present day techniques are described in the ongoing studies and tests of the vehicle dynamics and wheel to rail interaction of locomotives. Among the data cited were measurements of an electric locomotive that indicated that the trailing axle wheel set of the two wheel truck imposed about double the lateral load against the rail as the leading axle wheel set on straight track. The discussion concluded that more research and testing would be continued, using more sophisticated measuring means that are available.

LATERAL RAIL FORCES DUE TO VARIOUS LOCOMOTIVE AND TRAIN CONSISTS
A series of tests was performed to determine the lateral forces developed by various types of locomotives and train consists. Analysis of the data indicates that no excessive lateral forces were developed by any of the test consists. The maximum average force, 7,400 pounds was developed by the T.P.F.C. freight. The effect of roadway irregularities on lateral forces generated by normal consists remains largely unknown. Based on the results of this test series, it is concluded that light locomotive, passenger and freght consists generate relatively low lateral force on good roadway. There is a slight reduction in maximum lateral forces as training tonnage is increased. A study of the available research literature on the forces required to overturn rail shows that the maximum pressures measured were about 30% of the forces theoretically needed.

SWITCH LOCOMOTIVE V 90 OF THE GERMAN FEDERATED RAILWAYS
Only a portion of the article describes this locomotive. One portion deals with the latest design of cardan shafts having ball joints made of plastic that eliminate the need for periodic lubrication servicing. The other describes the truck design, which includes springs made of rubber "sandwiched" with steel plates that are used at the journal boxes and over the coil springs between the truck and the locomotive frame. The truck is simple, with cast members welded together, and with the traction transfer points below the axle center line. The composite design has effectively reduced lateral and vertical accelerations.

TESTS WITH THE E 10 CLASS LOCOMOTIVES FOR THE DEVELOPMENT OF THE HIGH SPEED LOCOMOTIVES CLASS E 03
The author describes a research program on the testing of the locomotive design and components for the development of the high speed (200 km/h) electric locomotive, Class E 03 on the German Railways. One of the test locomotives was equipped with trucks having leaf springs over the journal boxes in addition to coil springs between the truck frames and the body; the other was equipped with trucks having coil springs throughout. The former gave a very hard ride at the lower speeds, with much body vibration up to 100 km/h, and over 140 km/h there was excessive fore and aft vibration longitudinally. The locomotive with coil spring suspension gave a very satisfactory ride up to the desired 200 km/h. Since, at the speed of 200 km/h, 1 km is traversed in 18 seconds, the enginemen's controls were designed semiautomatic, an electronic system of controls was built in to take over the control of the acceleration of speed from 30 km/h to 200 km/h. Conversely, reduction in speed is also automatically controlled. Thyristors are used with the high voltage transformer, which eliminate the troublesome high voltage switch gear with contacts.

LATERAL FORCES BETWEEN WHEELS AND RAILS, AN EXPERIMENTAL INVESTIGATION
The paper deals with a new method of measuring continuously the lateral forces between the wheels and the rails over long distances. Fundamental knowledge concerning these forces has been obtained both from studies of the results from short test runs and from statistical assessments of the results from long sections of the Swedish railway network. Since the tests are concerned only with a single locomotive, the results should not be generalized. It is clear, however by means of the individual diagrams of curve

forces as well as the statistical evaluation of about 40 curve runs, that the lateral forces between the rails and the wheels of the leading axle are on the whole substantially greater than the resulting force on the permanent way. This factor should be all the more noticed, since the utilized friction coefficient can assume such unexpectedly high values, as is shown from the measurements.

THOUGHTS OF A CURVE DERAILMENT
The derailment of the New York Central New York to Chicago express on April 19, 1940, at Little Falls curve is described. The train was about half-way around the curve travelling 14 mph in excess of the stipulated limit when derailment occurred. Speed alone was not responsible for the accident. A locomotive inspector had instructed the driver to brake. It is believed that the driver either became confused and closed the throttle or applied the brakes which slowed the locomotive much slower than the remaining train and caused the jack-knife action between the engine and tender.

BENDING STRESSES IN A MOTORED AXLE ON ELECTRIC ROLLING STOCK--1
This article gives results of strain gauge tests on a motored axle both empty and loaded. Deductions from the results lead to an emphasis on the transverse friction between wheel and rail. This factor, neglected in axle stress formulae, is shown to be of major importance in the bending moment on the wheel seat of an axle, amounting to about 40 percent of the total on a curve with equilibrium cant. Support for the deduced theory is given by the correspondence between calculated and measured stresses, and also by the results of direct comparative tests. Additional stresses from cant deficiency, track irregularities, and acceleration or braking are discussed. The apparatus used in the test and the procedure of testing are fully described.

BENDING STRESSES IN A MOTORED AXLE ON ELECTRIC ROLLING STOCK--2
A further check of the theory that transverse friction is a major item in the stressing of axles was made by a series of comparative tests. While vertical differences in track level apparently affect the stress in the axle very little, it has been found that the test axle assembly is very sensitive to the condition of the running edge of the high rail on a curve. Contrary to expectation, passage over the toes of switches and the noses of crossings did not produce high stresses in the axle. Passage through the lead of turn-outs caused high values to appear, though no higher than those which occurred on some curves.

ADHESION RESEARCH
The use of an arc plasma generator (apg) to improve wheel to rail adhesion is examined in a letter to the editor. It is pointed out that rail contaminants affecting adhesion adversely fall into two groups: oil and water films and emulsions not bonded to the rail, and metallic soaps produced by chemical reaction between fatty acids and steel which are integral with the rail surface. Both contaminants must be treated. The gross films can be removed mechanically, but the chemical structure of the soaps must be broken down by heating to about 30 deg C. The second task is most demanding and forms a basis for performance predictions. The maximum power requirement occurs at high speed, say 240 km/h, when both traction and "steering" rely upon enhanced adhesion. A graph shows the variation of power with the penetration depth of the 300 deg C isotherm in a steel rail. Power decreases with plasma length, but the power intensity increase outside the attainable range. The variation of power with length (and consequently with speed) is strongley non-linear. The authors of this letter believe that each fast train must carry an a.p.g. module.

BR CLASS 40 LOCOMOTIVE SUSPENSIONS MODIFIED
The article discusses the suspension design of the British Railways class 40 locomotive, which was modified to minimize the maintenance and repair of the laminated springs. The suspension system also subjected the truck frame to high vertical and lateral stresses. The modification replaced the laminated springs by helical springs. Result was improvement in the vertical riding qualities especially over 50 mph. A reduction of dynamic forces was also achieved, which will result in longer suspensions and track frame life.

ADHESION RESEARCH ON B.R.
The British Railways has conducted research into means to increase rail adhesion. The means used fall into 4 categories: mechanical; chemical; thermal; and quantal. The mechanical methods include scrubbing, abrading and sanding rails which tend to foul points and to be detrimental to the rail surface. Chemicals to remove contaminants in the rail surface have also been evaluated, but results are difficult to evaluate. Thermal and quantal methods include the use of an electric ore between the vehicle and rail head and the plasma jet. This device produces thermal, quantal and chemical effects, as well as increasing adhesion coefficient from 0.1 to 0.5 in laboratory tests.

CHEMICALS TO IMPROVE RAIL ADHESION
The chemical spraying method developed by British Railways offers a promising solution to the wheel slip problem, and it is significant that there is now a proprietary spraying device known as the P and M Maxi-mu. An important and essential feature in the application of the chemical spray method is the making of adhesion surveys, using the tribometer, of portions of the track where wheel slip is serious prior to the installation of distributors. This enables the most effective positions for distributors to be determined. Spreading of the chemical fluid is actually performed by the train wheels. During 1964-65 extensive tests of ethyl caprillate were made, and it is now established that this is the most generally satisfactory of all the chemicals which have been so far tried.

UNIVERSAL BOGIE DESIGNS FOR HUNGARIAN BUILT LOCOMOTIVES
Multi-gauge twin-axle truck designs are described for locomotive power from 600 to 2,000 hp and axleloads up to 20 tons. An important aspect was to design with three principal objects: to keep down the unsprung weight; increase the wheelbase, and provide suitable spring characteristics and adequate damping. Riding properties of locomotives equipped with this basic type of bogie have been found to be very good. Effectiveness of the non-linear primary suspension has fulfilled expectations and even without damping at this stage, no tendency to resonance conditions has been encountered.

HYDRODYNAMIC BRAKING FOR LOCOMOTIVES
Dynamic braking has one feature in common with the normal air or vacuum brakes. The limit of its force is dependent on the adhesion between a steel wheel and a steel rail. However, with dynamic braking there is no possibility of slide; over-braking dynamically produces a reverse slip, which is much less damaging to wheels, rails and braking elements. A very detailed description of this type of brake is provided, covering such topics as cooling factors, braking efforts and ranges, decelerating characteristics, driving technique and air control.

EVALUATION OF THE PLASMA TORCH. STUDY OF OPERATIONAL TESTING AND EVALUATION OF AN ARC PLASMA GENERATOR AS A MEANS TO IMPROVE WHEEL-RAIL ADHESION
Effectiveness of the d.c. are plasma generator as a tool for improving

wheelrail adhesion was measured. Two torches per rail were found very effective in eliminating low adhesion areas. Generally, adhesion values of 0.1 to 0.2 were increased to nearly 0.3. More specifically, adhesion corresponding to the 2% slip risk level, averaged over all tests in the speed range up to 30 mph, was increased from 0.19 to 0.29. Significant improvement of adhesion was found up to six hours after treatment with the plasma torch even though climatic changes had brought about changes in the adhesion of both control and test sections. Over longer periods, large numbers of freight and passenger trains distribute fresh contamination over the test and control sections thereby changing the identity of the sites. The power used was increased with the square root of speed up to 15 mph when it totalled 60 kw for both rails. Above 15 mph the power was held approximately constant at 66 kw. Constant power operation results in adhesion increases which are significant but less than would have been obtained if power had been increased. The power level used in all the trials was such that no damage could occur to the rails. Experiments in the laboratory have shown that even with much greater plasma powers the mechanical properties of rail steel were unaffected; this provides a high level of operational safety should the power control system malfunction. With this equipment the problem of wheel slip on starting, for heavily laden freight and passenger trains, can be confidently said to be overcome.

REDUCING FLANGE-WEAR ON BOGIE LOCOMOTIVES
The phenomenon of relatively rapid flange-wear on sharp curves with the bogies of Bo-Bo and Co-Co locomotives must be accepted pending the results of further research into the reduction of bogie weight and unsprung weight, the height of the bogie centre of gravity, different relative speeds of the axles and motors, weight transfer, etc. Flange or rail lubrication using a lubricant matched in viscosity to suit the ambient temperature lengthens the flange life from six to nine times, this factor varying according to the tire steel used. A change from tires of "D" steel to those of 70-ton tensile steel alone can increase flange life by as much as three times. A combination of lubrication, hard tires, and the fitting of a centralizer linking the movement of the two bogies and which is capable of drastically reducing flange forces on curves, will improve flange life by 12-15 times.

WHEEL AND RAIL LUBRICATION
Remarkable increases in life of rails and wheel flanges through lubrication, by as much as 700 percent, are quoted by Dr. Fritz Birmann, in his paper "Lubrication of Rails and Wheels." The requirements of a lubricating system to reduce wear of rails and tires, are that the lubricant must be prevented from spreading to the running surface of the rail, thereby reducing traction; that the efficiency of the system must not be spoiled by dust, dirt or weather influences; that the lubricating devices and spray nozzles must be profile free on the rail and vehicle; and that lubrication must not start too late on the curve, so that it is preferable, where possible, to lubricate tires before entering the curve.

BENDING STRESSES IN A MOTORED AXLE ON ELECTRIC ROLLING STOCK--3
This article presents formulae used in the determination of bending moment of axles of powered tracks. Also comments concerning track irregularities upon wheels are also discussed. Mention is made of the differences between calculated stresses and recorded stresses, which are usually small except in stress increase by press fitting of wheel brakes. Conclusions are that vertical track irregularities are unimportant in stress of axles and that the use of check rails can reduce axle stresses. Finally, a prediction of axle life and axles stress is close between calculated and test results.

MECHANICS OF WHEEL AND RAIL
Tire-profiling tests undertaken in New South Wales to reduce oscillation resulted in an increase in the severity of the oscillations, which was directly traceable, not to the contact of the flange root with the edge of the rail, but of the steeply inclined portion of the tread adjoining the flange root. This is a well-known characteristic of all worn or hollow tire profiles. The objective of the tests was to defer the formation of the objectionable tread ramp near the flange in a worn tire. The design specifically allowed that there should always be a portion of the root radius still available to contact the edge radius of the rail. Diagrams representative of each of the tire contours and conditions of service are reproduced. In these diagrams, there will be noted a step developed after service at the junction of the flange root and the recess due to flange wear.

B4 039475
ADHESION AND FRICTION IN RAIL TRACTION
For dry rails, a coefficient of adhesion of 0.25 may be assumed for speeds up to 40-50 m.p.h. At higher speeds, however, there is less information to draw on. Above the 40-50 m.p.h. range, the dependence of adhesion on speed introduces a bend into the curve connecting speed and power output. For wet rails, the coefficient of adhesion is reduced to about 0.6 of the value determined for dry rails. Of the many variables encountered in brake-block friction, there is abundant evidence of the dependence of coefficient of friction on speed and brake-block pressure. Substances should be saught for blocks for which the coefficient of friction is less affected by speed than in the case of cast iron; the effect would be to allow acceptable braking distances without having to use high braking ratios, so that a reduction in the weight of brake gear could be contemplated.

THE FRENCH RAILWAY SPEED RECORD
As part of a study of the technical and economic aspects of high-speed operation, the SNCF conducted four days of trial runs at progressively higher speeds. The purpose of the tests was to investigate the margin of safety allowed by the speeds now regularly scheduled with normal types of locomotives and rolling stock. They were also regarded as a contribution to research into methods of improving the productivity of transport and reducing its cost, by showing how the building of vehicles able to run at ever-increasing maximum speeds can reduce maintenance expenditure on locomotives and track when operating at the speeds now normally scheduled. The test train consisted of three coaches of a recent design. Continuous records were made on all the runs by means of piezo-electric apparatus of the lateral forces exerted on the track by the first and third axles of the locomotive bogies. It was found that these did not exceed 4.2 tons.

GP-7 LOCOMOTIVE WHEEL TO RAIL LATERAL LOADING TEST ON ILLINOIS CENTRAL RAILROAD
The report is based upon testing conducted by EMD to determine causes of derailments which involved GP-9 locomotives. The EMD Test Car was used to determine wheel loading levels for the GP-9 locomotive to determine wheel loading at the derailment sites. The test train from which data for this report was obtained represented a typical freight train operating in normal service through the areas where previous derailments occurred. The loads measured between wheel and rail during the testing were substantially below levels which are normally considered necessary to cause derailment by wheel climbing rail, rail turn-over, or shift of entire track structure. The maximum steady state net lateral load measured on the guiding wheel was 13,200 lbs. which represents 41.2% of the nominal wheel vertical load. Accompanying this load was a 5,400 lb. axle lateral load which represented 8.5% of the nominal axle vertical load. The above loads were measured in a 6-1/2 inch curve. Threshold tendency of wheel climbing rail is generally expected when net lateral force on guiding wheel is 90 to 100% wheel vertical load. Rail turnover demands that total lateral load compared to total vertical load on an entire rail length unsupported, or practically unsupported, by adjacent lengths gives a ratio great enough to cause the load resultant to fall outside of the base of the rail. Dynamic instanteous peak loads which are of very short duration resulting from sudden rail irregularities (joints) are not believed to affect wheel climbing rail or rail turn-over. Train speed did not significantly change steady state forces in a particular curve. However, increased speed did significantly change the level of dynamic loading as much as 200%.

ANALYSIS OF WHEEL-RAIL LOADING OF FP-45 LOCOMOTIVE ON A 3 DEGREES 3' TRACK CURVE SANTA FE RAILROAD
This report is an investigation of lateral loading of an EMD FP-45 locomotive to determine the relationship to derailments. Included is a comparison between the FP-45 and other six, four and two axled locomotives. Finally, with a discussion of lateral load data and dynamic lateral forces, the report concludes that the derailments caused by rail turnover were the result of poor rail joints which were present in the section.

THE APPLICATION OF BEARING SPRINGS TO LOCOMOTIVES AND OTHER RAIL UNITS
The design, maintenance and characteristics of suspension systems for locomotives and railcars are discussed. The design of a locomotive places restrictions upon suspension systems, which differ from railway cars. The characteristics of steam locomotives require different suspension systems than electrics. Stresses and dimensions for laminated springs for railway vehicle use are tabulated.

LATERAL FORCES ON TRACK AND EQUIPMENT DUE TO DYNAMIC BRAKING ON THE SOUTHERN PACIFIC LINES

This report embraces a description and analysis of data secured during the operation of regular scheduled freight trains on the Southern Pacific Company between Roseville, California and Sparks, Nevada. The purpose of the investigation was to determine the coupler forces and resulting lateral forces exerted on the rails by the passage of an 85 ft. car coupled to a short car in a train with the locomotive using dynamic braking while operating on steep grades and curves up to 10 deg. During the investigation, data were secured on coupler and car angles, lateral and vertical truck forces and longitudinal acceleration of the 85 ft. car with the train operating at various speeds. The analysis of data contained in this report may be summarized as follows: 1. The steady or longitudinal coupler forces for both pull and push conditions, as expected, are in proportion to the weight of that portion of the train behind the point of measurement. The compressive coupler forces were reduced considerably when the train air line pressure was reduced with the locomotive under dynamic braking on the descending grades. 2. The coupler angles are in direct proportion to the track curvature with the values obtained under the pulling condition slightly greater than those under the pushing condition. 3. The data indicate there is a linear relationship between the track curvature or coupler angle and the lateral truck forces acting on the rail. 4. The occurrence of slack action was rather infrequent due to the long and almost continuous grades for but some coupler forces as large as 90,000 lb were obtained by an application of the dynamic brakes which permitted the slack to run-in. 5. The sprung weight of the 85 ft. car was subjected to longitudinal accelerations as large as 2.2 g but there does not appear to be any direct relationship between the direction and magnitude of this acceleration with respect to the direction and magnitude of the slack action coupler force.

THE RAIL MOTOR-BRAKE

Achieving train speeds of 300 to 400 KMH are discussed. Over 200 km/h no conventional technical solution is suitable as to the fundamental aspects of traction, and mainly the braking. The rail would become an integral part of the electric motor, propulsion and braking systems regenerating linearly, rapidly and indefinitely under the field part of the motor, of which it becomes, electrically, the armature. The motor or braking effort, the system being reversible, hence are produced between the rail head, wherein flows induced currents producing the effort. A magnetic core, provided with windings, constitutes this part of the motor which provides the inductor field necessary for propulsion, asynchronous sliding field, by its feed with variable frequency, polyphase, alternating current. This motive power unit would employ classical railway, yet would be independent of traction adhesion and braking limits.

THE BEHAVIOUR OF THE MOTIVE POWER AXLES (WHEELS) ON THE S.N.C.F.

Wheel-set stresses are modified by the action of the strains inherent in service which may be categorized as follows: those affecting the shrinking-on; those which correspond either to vertical effort exerted by the wheel on the rail, essentially cylical, or to the lateral reactions of the rail on the wheel both cyclical and erratic (abnormal shocks); and those set up by a temperature rise, due to braking. The SNCF has tested, both in the laboratory and in service, the diverse stresses as they are linked up with strains. Common damages to wheelsets are described and are shown. Wheel manufacturers are using the test results to enhance wheel design criteria.

APPLICATION OF GRINDING STONE BLOCK TO PREVENTION OF WHEEL-SKIDDING OF HIGH SPEED VEHICLES

Resin-bonded grinding stone block was applied to the shoe of a special tire cleaning device mounted on the vehicle for the New Tokaido Line in order to improve the adhesion and prevent the wheel-skidding. The grinding stone shoe which was apt to be abraded and to grind the wheel-tread more or less had the tendency to remove undesirable adhesive material and produce a more active surface with improvement of adhesion. The abrasion of grinding stone block increased in the order of emery, single crystal aluminium oxide, regular aluminium oxide and silicon carbide as abrasive grain material and with grain percent and inversely with grain size. A running test with the vehicles has shown the tendency of the frequency of wheel-slips being reduced under use of the grinding stone shoe.

WHEEL AND RAIL LOADING FROM DIESEL LOCOMOTIVES

This review is divided into the following areas: sample derailment data; basic curve negotiation mechanics; experimentally determined wheel-to-rail forces; rail profile data; the effect of dynamic brake levels; and mechanical considerations. Sample derailment data was taken from all six areas and well illustrated with examples. A summary of results is shown. There are a number of mechanical areas involved in the locomoitve which can and do affect the wheel-rail loading. Among these, although there are many others, are the alignment control draft gear, matching wheel sizes, and maintenance of truck bolster stops.

SUITABILITY OF SIX-AXLE LOCOMOTIVES FOR C&O--B&O SERVICE--THE INTERACTION WITH TRACK STRUCTURE

A series of tests was conducted with 6-axle locomotives in heavy, coal drag service on Cranberry Grade to investigate the interaction of locomotive tractive power and track conditions. Particularly, the performance of 6-axle locomotives in this service was investigated to determine the relative merits of that design versus the 4-axle units previously used. Five major areas were found to be significant and completely interdependent: I. Locomotive wheel life with 6-axle units. II. Rail cleanliness affects locomotive adhesion. III. The condition of the track and the rail govern overall acceptability of 6-axle locomotives. IV. Operating practices covering the use of sand are related to increased wheel wear and increased track maintenance. V. Instrumented wheel tests: A. To determine to what extent and under what circumstances the wheel and rail wear attributable to 6-axle locomotives exceeds that of 4-axle units. B. To determine effect of track surface on locomotive riding qualities. C. To determine suitability of 6-axle locomotives.

FLEXICOIL SECONDARY SUSPENSIONS IMPROVE HIGH SPEED RIDING
Following successful experiments with flexicoil secondary suspension fitted to a Class 86 electric locomotive, British Railways intends to make further use of this type of springing. Faulty hydraulic dampers caused pitching oscillations of 2.42 c/s resonant at 100 mile/hr with 60 ft. rail joints and body nosing oscillations of 1.25 c/s on straight track. Design installation and evaluation of a flexicoil suspension system resulted in significant improvement in the riding characteristics at high speed.

THE TRACTIVE RESISTANCE OF DIESEL LOCOMOTIVES
This report of tractive resistance data from a British Transport Commission bulletin in terms of lb. per ton yielded a dimensionless drag of 0.6 to 0.9 and rolling resistance values of 3.5 to 4 lb. per ton for various diesel locomotives. At speeds above 10 mph and particularly in the speed range of 20 to 80 mph the values of r or R are influenced by the component proportional to (V/10) and not by C(sub d) and the (V/10(super 2)) factor. This suggests that the effect of transmission and coupled axles action is of considerable influence.

SPARKING TO IMPROVE ADHESION
Development of the use of arc plasma as a means of improving adhesion between wheel and rail is discussed. For ordinary thin oil films energies of 50 J/cm2 or more are needed. The main factor involved in adhesion increase by sparking is the removal of the pollution from the rail surface, including moisture, and any effect on the actual surface itself. An example of the improvement in spark tests that can be achieved is shown in several slip risk probability graphs for a severely polluted rail. On unsparked rail the use of a tractive effect requiring 17 1/2 per cent adhesion would result in a 10 percent slip risk, but after the successive amounts of sparking used the same slip risk occurs at 26 1/2, 33 and 45 1/2 per cent respectively. The mobile test bed is an experimental device to measure the changes in adhesion; it is not a tool for the practical application of sparking in service.

ANALYSIS FO DD-35 LOCOMOTIVE & TRUCK IN OPERATION ON NEW YORK CENTRAL R.R. TRIBES HILL 2 DEGREE 58' CURVE
This report is a study of the conditions associated with operating the DD-35 locomotive over the 2 degree, 58 minute curve involved in the derailment at Tribes Hill on February 21, 1964. The expected lateral loading considered likely to occur on the Tribes Hill curve under the most extreme conditions would give net lateral wheel load of 15,900 pounds with instantaneous peaks to approximately 25,000 pounds. This extreme value of 15,900 pounds represents only 37 per cent of the associated vertical wheel load. Analysis and test results accumulated from numerous tests, including curve negotiation of many different locomotive models and measurements of wheel stresses, axle stresses, and lateral loads, indicate: the instantaneous peak values acting over and above the base loads are not significant in rail turnover, and, lateral loadings representing 90-100 per cent of vertical load can be applied to the rail at a single wheel location without any indication of rail turnover or wheel climbing.

SD-45 LOCOMOTIVE DYNAMIC BRAKE TRAIN HANDLING TESTS ON PENNSYLVANIA RAILROAD

Because of a major derailment near Johnstown, Pa., a series of dynamics brake handling tests were conducted between Harrisburgh and Pittsburgh, on severe grades and curves. The trains in which the test unit and the adjacent long overhang boxcar operated were varied in nature, ranging from tonnage trains while operating in a two-unit consist to trailer trains and PR trains in four-and eight-unit consists. In general, with the loaded long overhang boxcar leading the train, the records indicate that at no time did the danger of derailing due to drawbar forces exist. No instances in the entire test program exhibited lateral force levels which would be of concern with respect to derailment. The boxcar was loaded with freight during all of the tests.

BOGIE LOCOMOTIVE RIDING PROBLEMS

The performance of vehicle suspension can be adversely affected by lateral plane design, which appears to be of minor importance. The low order restoring forces due to swinglinks, which are about one ton per inch per bolster, are discussed as to their relationship to ride quality. A Bo-Bo electric locomotive with 20 inch vertical swinglinks is used as an example. The link ends were mounted on rubber and rubber snubbers were required to prevent impact between the bolster and the track frame. Lateral pull tests are described on this system, which were conducted to determine source of the poor ride quality. It is shown that the effective length of the 20 inch swinglinks is only 6.8 inches.

LATERAL LOADING BETWEEN LOCOMOTIVE TRUCK WHEELS AND RAIL DUE TO CURVE NEGOTIATION

Curve-negotiation mechanics and forces resulting when locomotive trucks negotiate curves are well recognized. However, meaningful and reasonable prediction of forces resulting in service conditions has been limited. An instrumented wheel-axle assembly was developed and used on 2,3, and 4-axle trucks to study the effect of creep and the transverse load reactions resulting between wheel and rail. Instrumentation was used to measure these forces and the reactions between axles and truck frame under operating conditions. Test results confirm predicted phenomena and indicate the effect of creep on resulting loads. This paper includes a brief and general review of curve-negotiation mechanics and presents the test results and their relation to the theoretical analysis.

COMMENTS ON PENNSYLVANIA RAILROAD ELECTRIC LOCOMOTIVE TRACK TESTS CONDUCTED BETWEEN 1930 AND 1938

These are the first tests in which a section of track was equipped with special ties with means of measuring the maximum lateral force exerted outwardly on the rail by an electric locomotive on a test run. The tests were quite extensive with respect to instrumentation and also the number of run made with various types of locomotives. The section of test track consisted of steel ties spaced on 43 inch centers. The applied loads would be considerably different than on wood ties placed on 20 inch centers. A loaded profile of the right rail and left rail on the tangent track test section 440 ft. long including 128 test ties was intentionally made with variations in cross level in order to develop the performance of locomotives under unusually large variations in track cross level for very high speed running. The second phase of the tests included the use of weight bars equipped with magnetic strain gages to measure the lateral force exerted by the axle against the locomotive frame. These tests are of limited value to diesel locomotives and freight car equipment now in service.

MEASUREMENTS OF VERTICAL AND LATERAL FORCES ON BOTH RAILS OF A SIX-DEGREE REVERSE CURVE UNDER DIFFERENT TYPES OF SIX-AXLE AND FOUR-AXLE DIESEL LOCOMOTIVES

An investigation was conducted on a 6 deg. reversed curve with 150 ft. spirals and practically no tangent between them. The track was instrumented at two locations, one on each of the spirals near the juncture with the 6 deg. curve. Vertical and lateral wheel loads were measured for each passing wheel of the locomotives on both rails. Four classes of locomotive were included in the tests having six wheel trucks as well as locomotives having four wheel trucks. The lateral force exerted against the high rail increases with speed; is relatively low for the freight diesel locomotives with four axles and the passenger diesel locomotives with six axles; and is appreciably higher for the two types of freight locomotives with the trimount trucks.

DYNAMIC MEASUREMENT OF RAIL PROFILE AND RELATED LOCOMOTIVE TRUCK MOTIONS
The profile of the railroad track on which a railway vehicle operates represents an input into the vehicle. This input is due to vertical and lateral rail irregularities and can cause dynamic loads that result in excessive damage or wear and tear on vehicle components and on the track itself. In order to study the dynamic operation of rail vehicles, it is necessary to know the profile of the track on which they operate. Since the unloaded profile of the rail can vary significantly from the loaded condition, it is the loaded-rail profile that must be known. This paper presents a method developed by the authors' company for the rapid measurement of the loaded-rail profile and includes some typical rail profiles and related truck motions resulting from these profiles. The instrumentation resulting from this work appears to have immediate application in day-to-day railroad operation and in high-speed rail transportation studies.

UNDERSTANDING WHEEL-RAIL ADHESION
The terms of wheel-rail adhesion are defined. An extensive review of the problems associated with adhesion and the attempts to solve these problems is presented. The results of experiments conducted by the author on scale equipment show that creep is present as long as there is adhesion demand. As the adhesion demand increases, the percentage creep increases until creep becomes slip and eventually slide. It is shown that true adhesion varies with velocity. Suggestions are given for means of approaching true adhesion values on the railroad. The danger of wheel damage caused by high adhesion could offset the advantages.

COMPOSITION BRAKE-BLOCKS-EFFECTS ON ADHESION
The effects of composition brake blocks on adhesion were investigated by the DB. The measurements were analyzed statistically and the results plotted in the form of curves. Generally, lower adhesion values were ascertained when braking with K blocks than when using cast-iron blocks. As such an effect is only acceptable if it is small, severe testing is, in this respect, considered to be necessary when submitting K blocks to acceptance tests.

DERAILMENT OF A PASSENGER TRAIN CONSISTING OF A DIESEL LOCOMOTIVE WITH SIX-WHEEL TRUCKS, A BAGGAGE CAR, AND A COACH
Three letters discuss the derailment of June 7, 1968. A sketch of the derailment area and photographs of sections of the track involved are included. This derailment is characteristic of a number of derailments that have occurred on curves at or near permissible speed of passenger trains having locomotives with six-wheel trucks, derailment apparently occurring first of the rear truck of the locomotive unit or the lead truck of the baggage car following. In each case the high rail of the curve was overturned. A high ratio of L/V is required to overtrun a rail and it is unlikely that this high a L/V ratio would be developed in track unless there is some unusual condition such as a jack-knifing of couplers between cars, an unloading of the lead wheel of the truck on the high rail, or some severe wedging action of the truck between rails due to a malfunction of the truck components.

TEST TO DETERMINE VERTICAL AND LATERAL FORCES IMPARTED TO THE RAIL BY A TYPE U28CG GENERAL ELECTRIC LOCOMOTIVE, SANTA FE CLASS 350
The test runs were made using a train consisting of two lightweight chair cars and three baggage cars and a locomotive of two units, one having the instrumented truck. Tests were run at speeds up to 90 mph on dry rail and

moderate temperature. The test results show lateral forces of substantial magnitude being exerted on the rails, an occasional one having a finite duration of ten feet. They also show vertical wheel loads of low value in some locations. The test results indicate it is possible for these two conditions to occur simultaneously on two or three adjacent wheels of a truck and produce an effective L/V ratio of sufficient magnitude to overturn the rail.

MEMORANDA ON CONFERENCES HELD TO DISCUSS THE DERAILMENT PROBLEM WITH 6-AXLE TRUCK LOCOMOTIVES

Two memoranda discuss derailments involving 6-wheel truck locomotives in which the high rail of a curve has been rolled over. An itemization is made of 20 derailments involving six railroads during the time period 1964 to 1970. The memoranda discuss the deliberations of a meeting between representatives of each of the railroads involved and the AAR.

SOME DESIGN PROBLEMS OF DIESEL LOCOMOTIVES

This paper focuses on the problems of diesel-hydraulic vibration systems, the power transmission to axles via a geared system, and the ride problems of the D.800 and D.1000 locomotive classes. Illustrations reveal shaft failures, comparisons of original and tuned vibration systems, crankshaft torsional vibrations, vertical movements of locomotive bogies, and tire profiles of new and worn wheels.

COMPOSITION BRAKE BLOCKS AND TYRES

This paper describes some of the problem which have arisen from the use of composition brake blocks in the past. For at least two of these, wet stopping performance and thermal cracking, there is now an understanding of the problem and possible solutions. Present-day production has also resulted in blocks free from the other difficulties. Other methods of avoiding the dangers associated with thermal cracking have been indicated: these involve moving away from the classic wheel and tire arrangement and the materials which have persisted for many years.

A METHOD FOR ESTIMATING BRAKING DISTANCES

This method allows for a time delay in the development of full brake power after a brake application has been initiated at the driver's cab, by taking note of the actual pattern of this development during this period. Thereafter, the distance traversed with full brake power before coming to a stop can be computed. Allowance has also been made of the brake power development characteristics of the motive power units. The method is suitable for application to all brake systems, compressed air standard AVB, and AVB with Quick Application valves--in fact, for any system where the brake power development curves can be established.

THE SULZER 12LDA29 DIESEL ENGINE AS APPLIED TO RAIL TRACTION

It is very difficult to make a fabricated structure which has no 'stress raisers' due to either bad geometry or lack of welding quality. Any fabricated structure which carries a high general stress is likely to develop fatigue fractures in certain areas. In order to avoid this situation and provide an engine structure which will reliably last the life of the engine, it is necessary to design the engine to a standard which will avoid a generally high stress and avoid areas which will concentrate stress. It will also be necessary to ensure a very high standard of welding quality. The additional expense and weight penalty of raising the standard of the structure in this way will tend to narrow the economic gap between the fabricated structure and the cast structure and may indeed close it completely.

MODERN DEVELOPMENTS IN WHEELSLIP CONTROL ON ELECTRIC LOCOMOTIVES

The reasons for wheelslip are discussed indicating what happens when it does occur on different types of locomotive and under different circumstances, and what action can be taken to correct it. The coefficient of friction is shown versus slip speed and the probably maximum useful adhesion is shown for various speeds on wet and dry rail. The natural and slipping characteristics of a number of motors shows why some locomotives are less steady on their feet than others. Wheelslip results in loss of tractive effort and at a standstill or at low speeds can cause wheel burns. Ways of avoiding wheelslip by correcting weight transfer problems, by controlling the acceleration cycle with small notches in the contactors and by limiting the tractive effect. When slip is detected, one of the following actions is recommended: reduction of tractive effort, applications of sand, light application of air brakes, and armature shunting.

HYDRAULIC DAMPERS AND DAMPING
After brief review of the influence of viscous damping on free and forced oscillations of mass-spring systems, and its effect on response to impulses, suitable damping factors are quoted for control of body and truck oscillations on the suspension. This is followed by discussion of the most suitable forms of force-velocity characteristics for railway applications, and a section dealing with damping calculations. The influence of damper flexible mountings is then examined, with particular reference to impulsive suspension response and response to sinusoidal in deal with excitation. Experimental work relating to vehicle damping requirements and the recently issued B.R. specification with stipulates the requirements for dampers for use on British Railways' vehicles is discussed. Difficulties in the manufacture of dampers with linear symmetrical force-velocity characteristics are then pointed out with special reference to the tendency for current damper designs to result in S-shaped characteristics.

RECENT RESEARCH ON ADHESION
The various studies and contributions are drawn into a coherent statement of how wheel/rail friction varies. Surveys of a number of track sites have identified the contaminants present in the wheel/rail interface, and measurements have been made of the adhesion which is experienced by railway traffic. A principal contaminant is a surface active oily fluid spread by the passage of wheels which forms a bonded surface layer on the wear band. A simple relationship has been found between the amount present on the surface and the resulting friction.

DYNAMIC ANALYSIS OF LONG-TRAVEL, HIGH-EFFICIENCY SHOCK ABSORBERS IN FREIGHT CARS
A dynamic analysis is presented relating the principle design parameters of a constant force type, dissipative shock absorber to the forces experienced by a resilient lading. The analysis, which correlates the effects of coupler force, lading force, cushion travel, closure time, impact speed, and friction, represents an application of classical mechanics to a dynamical system with sliding friction (Coulomb damping). Although a lumped-parameter analysis forms the basis of the derivation, a procedure is described which takes into account the mass-and compliance distribution within the lading.

WHEEL AND RAIL LOADINGS FROM DIESEL LOCOMOTIVES
A review of wheel and rail loadings from diesel locomotives is presented in six areas: 1) sample derailment data, 2) basic curve negotiation mechanics, 3) experimentally determined wheel-to-rail forces, 4) rail profile data, 5) the effect of dynamic brake levels, and 6) mechanical considerations. In summarizing all of these factors the following areas deserve the most attention: 1) locomotive braking practice with regard to delay in power to brake transfer, gradual buildup of braking level and control of braking level over crossovers, turnouts, and curves; 2) track in relation to gage widening, level of rail irregularities, and possible thermal strain investigations; and 3) mechanical factors including proper alignment control in draft gears, and proper bolster stops on units without alignment control.

CURVE WEAR WITH DIESEL LOCOMOTIVES ON THE BESSEMER AND LAKE ERIE RAILROAD
A series of test runs were made to obtain definite information on the amount of rail curve wear produced by diesel locomotives relative to that produced by the remainder of the train. A second series of tests was made for the purpose of relating the effectiveness of flange oilers on the locomotive and rail lubricators in the track in controlling the amount of curve wear. Instrumentation consisted of a box to catch metal abraided by diesel units from the track and a motion picture camera to photograph the passing wheel flange on the high rail. The tests show that although the rate of rail and wheel wear with a diesel unit is greater than for a heavily loaded freight car, the greater amount of rail wear is due to the train rather than the diesel units. Rail and wheel flange wear on curved track can be practically eliminated by lubrication with either flange oilers on the diesel units or rail lubricators in track, or a combination of the two.

CONSTRUCTIONAL ARRANGEMENTS FOR IMPROVING THE RIDING STABILITY AND THE GUIDING QUALITY OF ELECTRIC AND DIESEL LOCOMOTIVES AND VEHICLES. MEASUREMENT OF THE FORCES ACTING BETWEEN WHEEL AND RAIL
The knowledge of the forces acting between wheel and rail is important when studying the riding stability of a vehicle. Several procedures are available to measure these forces using measuring wheelsets. Several Administrations have developed, for this purpose, wheelset calibration rigs, whose design is described in a special chapter. Another chapter concerns the costs of these measurements. Some application examples should give an idea of the possibilities offered by the methods described.

B4 052682
CONSTRUCTIONAL ARRANGEMENTS FOR IMPROVING THE RIDING STABILITY AND THE GUIDING QUALITY OF ELECTRIC AND DIESEL LOCOMOTIVES AND VEHICLES. COMPARISON OF THREE MEASURING METHODS FOR DETERMINING THE FORCES EXERTED BY THE WHEELS OF A MOTIVE POWER UNIT ON THE RAILS IN A CURVE OF 300M RADIUS (GIORNICO 1957)

In order to make a comparison between the measuring methods developed by the NS and the SJ for determining the forces occurring between wheel and rail, comparative tests were carried out on a curve of 300 m radius on the Gothardline in October 1957. For these tests the following measuring apparatuses were used: one measuring rail of the CFF; six measuring base plates of the NS; six measuring base plates of the SJ. For an initial series of tests, the measuring rail was laid on six adjacent sleepers fitted with the measuring base plates of the NS and, for a second series of tests, on six adjacent sleepers fitted with the measuring base plates of the SJ. The measuring rail was secured to the other sleepers by means of the usual CFF fastenings. The forces indicated by the CFF measuring rail on the one hand and by the NS measuring baseplates and the SJ measuring baseplates on the other hand, were determined at various speeds and compared with each other. Considerable differences were shown by the lateral forces determined in this way, by means of the measuring rail and the measuring baseplates of the NS and the measuring rail and the measuring baseplates of the Sj, respectively. Better agreement was displayed by the vertical forces, though, in this case, comparison was only possible between the measuring rail and the measuring baseplates of the NS (the measuring baseplates of the SJ not being designed for the measurement of the vertical forces). The considerable differences between the measured values were considered to have been caused chiefly by the mutual influence of the measuring rail and the measuring baseplates of the NS and the measuring rail and the measuring baseplate s of the SJ respectively, on each other. Since the test arrangement used at Giornico-measuring rail laid on measuring baseplates-did not prove satisfactory, it is suggested, when making comparative tests in the future, to have the three methods of rail measuring equipment arranged at adjacent sites on a curve. The relationship between the values supplied by the three measuring methods should be established with the aid of a fourth measuring method, e.g. by means of directly measuring on the wheel of the vehicle under test the forces exerted on the rails (as already developed by the SJ to a certain degree of perfection).

Restrictions on the use of this document are contained in the explanatory material.

B4 052683
CONSTRUCTIONAL ARRANGEMENTS FOR IMPROVING THE RIDING STABILITY AND THE GUIDING QUALITY OF ELECTRIC AND DIESEL LOCOMOTIVES AND VEHICLES. MEASUREMENTS OF THE FORCES EXERTED ON THE RAILS BY VARIOUS TYPES OF MOTIVE POWER UINTS (MEASURED IN A CURVE OF 300M RADIUS AT GIORNICO)

In 1955 the CFF decided to intitiate investigations in order to determine by means of experiments the extent of the wear to which the track would be subjected in a curve of 300 m radius by the then newly developed locomtive types of the series Ac 4/4 (BoBo) and Ae 6/6 (CoCo). The measuring rail working according to the Schlumpf system was used as measuring apparatus. The results of these measurements have shown that the modern bogie locomotives subject the track to less wear at the same speed (BoBo) or to hardly any heavier wear (CoCo) than the rigid frame locomotives of not so recent date. Following the tests which had been made at the suggestion of the Working Group "Measurements on the track" of the B 10 Specialists Committee, for the comparison between three different measuring methods (see B 10 RP 4), arose the possibility of repeating the tests made in 1955. The measuring rail was again used as measuring apparatus, as it had been done for the tests made in 1957, but the tests included a larger number of locomotive types and a considerable versine error was intentionally arranged in the test track. The tests made in 1957 have confirmed the fundamental results of 1955, moreover they have shown that 1) a transverse coupling between the bogies and 2) the lateral movement of the rubber cushioned leading axles of the CoCo locomotives considerably reduce the forces exerted on the track.

Restrictions on the use of this document are contained in the explanatory material.

B4 056839
ON THE EFFECT OF TRACK IRREGULARITIES ON THE DYNAMIC RESPONSE OF RAILWAY VEHICLES

The steady state response for models of a six-axle locomotive running on a sinusoidally irregular track has been investigated. Two mathematical models have been set up, a full model for the stationary vehicle in which creep between wheels and rails was neglected, and a full model for the moving vehicle in which creep forces gravity stiffness effects and wheel tread profiles were considered. The use of the generalized method of complex algebra to obtain the steady state response of the railway vehicle components to varying input frequencies was used. The results given in this paper are for the case of sinusoidal lateral track irregularities only, but the method is general enough to allow also for vertical track irregularities. The analysis may be used to check the response of any proposed design for a railway vehicle to economically attractive track irregularities. It may also be used to adjust geometry, spring rates and damping characteristics in order to maximize operating speeds while providing optimum damping for the trucks and body motions.

B4 084732
ON THE EFFECT OF TRACK IRREGULARITIES ON THE DYNAMIC RESPONSE OF RAILWAY VEHICLES

The steady state response for models of a six-axle locomotive running on a sinusoidally irregular track has been investigated. Two mathematical models have been set up, a full model for the "stationary" vehicle in which creep between wheels and rails was neglected, and a full model for the "moving" vehicle in which creep forces, gravity stiffness effects and wheel tread profiles were considered. The use of the generalized method of complex algebra to obtain the steady state response of the railway vehicule components to varying input frequencies was used. The results given in this paper are for the case of sinusoidal lateral track irregularities only, but the method is general enough to allow also for vertical track irregularities. For the "stationary" vehicle the input frequency is increased from zero to 3 cycles per second. For the "moving" vehicle the input frequency is a function of the track wave length and the vehicle forward speed and is given in terms of the vehicle speed. The frequency response curves are computer plotted in each case. For the "moving" vehicle, responses for the cases of both new and worn wheels are obtained. The natural frequencies for the full model are also calculated. The results obtained show the effect of the creep forces and the condition of the wheels on the steady state response. It is recommended that slip and corresponding creep forces, wheel tread and rail profiles, and the gravity stiffness effect be included in the steady state response analysis of railway vehicles to track irregularities.

THE "CREEP" OF LOCOMOTIVE DRIVING WHEELS (PART 1)

Creep, or the additional rotation of a wheel transmitting tractive force due to the elasticity of the tire and rail, is important in solving many riding and other problems and there appears to be some difficulty in its calculation because estimated values often do not agree with actual measurements. The author presents the problem in a simpler manner and a revised expression is obtained from which creep can be easily calculated.

AXLE-DRIVE DYNAMICS FOR HIGH RUNNING SPEEDS OF A DIESEL LOCOMOTIVE [La dynamique d'entrainement de l'essieu pour vitesses de marche elevees d'une locomotive Diesel]

A study of the vibratory movement of the drive system using seven coordinates to define vertical displacement, angular direction and inertia moments in relation to their balancing position. From an analysis of the specific example of a locomotive driven independently by an electric transmission it has been possible to reach the following conclusions: a tangentially flexible wheel reduces dynamic stresses by 40 percent over rigid transmission; the flexible suspension of the engine reduces the torque whilst improving the rate of adherence; for speeds between 10 and 200 km/h, the maximum axle discharge value is virtually constant. [French]

THE "CREEP" OF LOCOMOTIVE DRIVING WHEELS (PART 2)

The first part of this article showed that there has been some misunderstanding about the value of creep obtained in a driving wheel exerting a tractive effort and a revised expression for this was obtained. In this second part, values so calculated are compared with values measured both in the laboratory and in service. While the estimated values of creep are confirmed, it is shown that there are certain other factors occuring in service which must also be taken into account.

WHEEL/RAIL ADHESION. THE INFLUENCE OF RAILHEAD DEBRIS

Evidence that rust is a major source of railhead debris, is presented. Particles are observed to spread on the wear band in wet weather and to be worn off in the dry. Laboratory experiments show that debris has little effect on friction except when mixed with an oil. Friction is then reduced depending on the quantity of oil and the surface area of the particles. A considerable proportion of oil is needed to reduce friction to its lowest value. Water can also substantially reduce friction on debris covered surfaces. A correlation is demonstrated between friction and humidity in which the friction coefficient is shown to be a simple function of the amount of water absorbed.

150TH ANNIVERSARY ISSUE

The Institutions of Mechanical, Civil, Electrical and Railway Signal Engineers conducted an International Engineering Conference in September 1975 to commemorate the 150th anniversary of passenger railway. This issue has editorical comment designed to complement the papers presented at the Conference. The contents of this issue are as follows: Modern track fastenings; Developments in Welding techniques for rolling stock; Modern dc traction motor design practice; Non-ferrous brake materials; Bridge reconstruction for overhead electrification; Ferrous fittings for overhead equipment; Roller bearings for railway rolling stock; Thyristor control of traction motors; Appraisal of tank car valves and their application; Australia's railways invest in passengers; Electric cables for signalling and track to train communications; Brake blending and wheelslide protection; High speed track recording coach; Ultrasonic rail flaw detection; Flexicoil suspensions; Prestressed concrete beams for bridges; Recent developments in plain bearings; Asynchronous motor drive for locomotives; Gangway connections between long carriages; Point heaters--progress in design; Batteries for railway applications; TOPS equipment; electrical carbon and the challenge of railways; Design and cost of containers; Railway roller bearings; Computer aided design in railway signalling; Adoption of AWAC catenery on BR, Powered doors for rail vehicles; Signal control desks.

DEVELOPMENT OF A FLANGE LUBRICATING DEVICE AND BRAKE-SHOE INSERTE GUIDED BY THE FLANGE FOR THE DIESEL LOCOMOTIVE BR120 [Die Entwicklung einer Spurkranzschmiereinrichtung sowie spurkranzgefuehrter bremssohlen fuer die Diesellok BR120]
Wear on the flanges of motive units running on winding lines can be reduced by using flange lubricating devices. However, instead of brake-shoe inserts to exert a braking force on the flange, inserts guided by the flange must be used. The authors describe the flange lubricating device and guided brake-shoe inserts for the diesel locomotive BR 120. These brake-shoe inserts guided by the flange do not affect the flange lubrication in any way.

PROBLEMS OF THE ADHESION COEFFIEIENT OF ELECTRIC LOCOMOTIVES [Problemy Koefficienta sceplenija elektrovozov]
The article examines:-the various adhesion coefficient concepts to be applied to these locomotives,-a method for determining the adhesion coefficient,-the tasks involved in making an objective evaluation of this coefficient, taking into account the running conditions of an electric locomotive when adhesion is at a maximum. In addition, details of the extent and methods for preparing a new method of determining the adhesion coefficient are given. A statistical study of wheel slipping must be made in order to establish a technically and economically optimal theoretical adhesion coefficient for electric locomotives in operation at present and for those which will be improved upon later, especially using electrical means for obtaining greater adhesion. This study is necessary because it takes into account all of the various aspects of adhesion. The study of wheel slip and the operation of the motor equipment of electric locomotives must be the basis for the creation of a method of controlling these locomotives by means of a constant command of adhesion. COMPARATIVE STUDY OF LOCOMOTIVE LATERAL STABILITY MODELS
In this paper a comparative study is made between present investigation of the 39 degree-of-freedom mathematical model and other simplified models. The results of the study of a typical six-axle locomotive obtained from the 39 DOF model are presented. The lateral stability is appraised, and the model includes the coupling between vertical and lateral motions. The merits and demerits of various models are discussed. A bibliography is included.

FUNDAMENTAL STUDY ON IMPROVEMENT OF ADHESION
An increase or stabilization of adhesion under car or locomotive wheels by means of plasma or ionized gas jets has been studied. With any condition of the rail surface, the coefficient of adhesion does increase, but then decreases with the passage of time after the treatment. The increase of the adhesion coefficient is attributed to the cleaning action and to conversion of rust into ferric oxide particles which increases the adhesion just as sanding would. The metallurgy of the rail itself is unaffected.

WHEEL/RAIL ADHESION-THE OVERRIDING INFLUENCE OF WATER
Laboratory experiments are described which show how water reduces friction between rail and tire steel surfaces. Depending on the amount of oily containation, the friction coefficient is reduced to a value between 0.3 (no oil present) and the friction which is characteristic of an excess of the oil. Lower friction on oil-free surfaces is observed using laboratory machines which involve continuous rolling; water mixes with wear debris or surface rust to form a lubricating past, and friction coefficients as low as 0.05 result. The lowest friction occurs when the ratio of water to debris is small,and a viscous (non-Newtonian) paste is formed which is observed on the laboratory rigs for a few seconds wherever wetted surfaces are on the point of drying completely. Trains similarly encounter low adhesion in slightly wet conditions, most noticeably on little used lines where a substantial coverage of debris particles is present on the wear band.

ADHESION AND DYNAMIC PHENOMENA DURING SLIPPAGE OF ELECTRICAL ROLLING STOCK-3. SELF-EXCITED VIBRATION DURING SLIPPAGE OF ELECTRIC LOCOMOTIVE TRUCKS
When the driving axles of an electric locomotive slip, self-excited vibration will occasionally occur in its trucks. To suppress such self-excited vibration, detailed theoretical calculations of the vibrations during slippage of typical trucks were made and stability criteria were sought by simplifying the system. Theoretical expressions were derived for the vibrations during slippage of typical trucks, that is, individual quill spring drive type trucks, and individual axle-hung motor type trucks, and numerical calculations regarding actual examples were made. The calculated and observed results generally agree with each other, revealing that the behavior of trucks can be predicted through theoretical calculations. Stability criteria were sought for several problematical modes of vibration, that is, the torsional vibration of both individual and monomotor driving systems and the pitching of an axle-hung motor about the axle. The validity of the stability criteria was proved by comparing them with actual examples, and some instances of success in suppressing self-excited vibration were disclosed.

RECOMMENDED DESIGN LIQUID TEMPERATURES WITH SUMMER AND WINTER FILLING DENSITIES FOR TANK CARS IN ANHYDROUS AMMONIA AND LP-GAS SERVICE
Phillips Petroleum Company issued a report recommending new filling densities for tank cars in anhydrous ammonia and LP-Gas service. Two conclusions drawn from the test data and study were: Light liquids with low specific heats would reach higher temperatures in insulated tank cars than in uninsulated tank cars; heavy liquids with high specific heats would reach higher temperatures in uninsulated tank cars than in insulated tank cars. In comparing data, it was learned that the apparent phenomenon was caused by reflected radiation on the ambient temperature thermocouple at the test site. This radiation was enough to cause the test site ambient temperatures to occasionally read higher than they otherwise would have. Amended recommendations for summer operations are contained in this report.

PROCEEDINGS OF SEMINAR ON RAIL CAR UTILIZATION
It was the purpose of this seminar to explore the newest techniques in rail car and systems design along with railroad programs which provide the greatest degree of rapid recovery of use of rail cars. The effective adaptation of almost instantaneous data retrieval is one method explored as a means of more fully utilizing available rail car capacities. Other means included more efficient use of railcars while in the hands of shippers, reduced warehousing use of existing cars and better designed cars and systems. All of these methods were discussed in this seminar with the hope that it would provide all interested in reduced distribution costs with a greater knowledge of the latest tools available to move the goods of commerce faster and more efficiently. Specific presentations included: Planning for Improved Rail Fleet Utilization; Designing for Improved Car Utilization; Inventory Control of Rail Equipment; and use of a Computer Based Information System to Reduce Total Distribution Costs.

RAILROAD ACCIDENT REPORT. DERAILMENT OF TOLEDO, PEORIA AND WESTERN RAILROAD COMPANY'S TRAIN NO. 20 WITH RESULTANT FIRE AND TANK CAR RUPTURES, CRESCENT CITY, ILLINOIS, JUNE 21, 1970
Train No. 20, an eastbound freight train of the Toledo, Peoria and Western Railroad Company, consisting of a four-unit diesel-electric locomotive and 109 cars derailed the 20th to the 34th cars, inclusive, at the west switch of the siding in Crescent City, Illinois, at about 6:30 a.m. on June 21, 1970. Included in the 15 derailed cars were nine tank cars loaded with liquefied petroleum gas. During the derailment one of the tank cars was punctured, and the leaking propane was immediately ignited, engulfing the other tank cars in the fire. A series of explosions of the remaining tank cars occurred, beginning about 1 hour following the derailment, resulting in the injury of 66 persons and the destruction of a number of buildings within the town of Crescent City. The National Transportation Safety Board determines that the probable cause of this accident was the breaking of the L-4 journal of CB and O 182544, the 20th car, due to excessive overheating, which permitted the truck side to drop to the track and derail the leading wheels of the car. The cause of the overheating could not be determined. (Author)

DERAILMENT AND COLLISION AT HENWICK HALL
This accident report describes the derailment of a freight train and consequent collision with a passenger train on October 28, 1964, near Henwich Hall, England. It was concluded that the basic cause of the accident was the condition of some of the privately-owned tank cars in the train, the events leading up to the derailment being initiated by the failure of a rear coupling at a fault in the weld. Both crowns of this link had been severely reduced by wear, and the quality of the iron was inferior to that specified. The derailment itself occurred due to excessive difference in face

camber in four bearing springs and excessive wear on the locating lugs in all four brass bearings in the axleboxes on one wagon.

TANK WAGON FIRE AT CRICH JUNCTION
The train consisted of ten 100-ton Class A tank wagons loaded with light distillate feed stock with an empty coal wagon as a barrier at each end, drawn by a Class 48 diesel locomotive. The cause of the fire was brake block sparks during braking that ignited vaporized oil spilt from unsecured hatches. The subsequent heavy braking by the driver after he first saw the wagons on fire caused more oil to spill and so increased the extent of the fire. Out-of-place hatch lids may have been the prime cause of spillage rather than oversight in fastening. It is now the rule that hatches shall be secured after loading before the wagons are moved forward, as well as an independent inspection after securing before despatch.

TANK WAGONS THAT SURVIVE DERAILMENT
The conclusion of a U.S. Department of Transportation study to reduce the hazards of tank car transportation is cited. A primary hazard of tank cars undamaged during derailment is explosion caused by extreme heat from burning cars in the accident. The pressure relief valves now in service are incapable of discharging the contents sufficiently fast to prevent explosion. A secondary pressure-relief device of substantial capacity such as a rupture disc is recommended for all but highly toxic materials.

DERAILMENT AT ROTHWELL HAIGH
Derailment of a train comprising three empty six-wheel milk tank wagons marshalled next to the 2,500 hp Type 4 diesel-electric locomotive, and eight passenger coaches two of which were sleeping cars is described. It was travelling at about 60 mile/h. The rolling of the leading tank wagon as it approached Rothwell Haigh may have synchronized with the natural slight impact of the first common crossing, and its pattern could have matched the reversals in cant through the obtuse crossings, thus accentuating the roll. The tendency under the influence of the roll would be to lift and the falling cant gradient of the crossing was 1 in 93 for about 3 feet, it did so lift coming down on its next roll on the head of the rail at the point of derailment.

HAZARDOUS MATERIAL TANK CARS-TANK HEAD PROTECTIVE 'SHIELD' OR 'BUMPER' DESIGN
The objective of the study program is to design a railroad tank car head protective device which will reduce the frequency of head punctures in accidents. Accident data were reviewed in detail for the years 1965 through 1970 to correlate head damage frequency and severity with various types of tank cars, to determine distribution patterns of damage over tank car head surfaces, and to assess the costs to the railroad shipping industry of head punctures. Full scale head impact tests, previously run were also reviewed. From these two reviews, design criteria were established and used to reduce an initial compilation of 74 concepts to a group of 15, which when applied to various classes of cars, comprised a semi-final total of 42 combinations, or schemes, as referred to in this report. Designs for these 42 schemes were then detailed and cost estimated. Next, a comprehensive cost/benefit analysis was applied. Three schemes appear attractive for the non-insulated pressure cars of the DOT 112A or 114A type. A recommended test program is outlined, and a preliminary estimate of its cost is given. (Author)

A STUDY TO REDUCE THE HAZARDS OF TANK CAR TRANSPORTATION
The report details the findings of a 4-month study contract directed at reducing the hazards of tank car transportation. A number of shortcomings with existing safety-relief specifications were indicated. A key finding was that the controlling condition in sizing for propane relief should be the liquid feed, or 'upset' car condition, and not vapor feed per the current criterion. The net result is a significant undersizing of relief area considering the existing heat flux criterion to be accurate. Analytical studies and review of test data indicate the existing heat flux criterion to be significantly low--further increasing the possibilities of overpressure. A staged safety relief system was recommended for cars with liquefied compressed gas ladings. The primary relief element would be a pressure-maintaining system sized for handling abnormal operating conditions other than severe fire exposure. The secondary relief system would be a 'dump' type to drop system pressures to levels preventing catastrophic rupture and 'rocketing' under severe fire exposure conditions. Both model and full scale test programs are recommended. (Author)

DERAILMENT AT CHIPPING SODBURY
On September 20, 1966, the train consisting of 46 empty six-wheel milk tank wagons and two bogie brake vans, and travelling along the down main line at a speed well above the maximum of 50 mile/h allowed for empty milk tanks derailed when the trailing wheels under the 30th tank wagon became derailed. The train ran on for 1-1/2 miles to Chipping Sodbury Station where the derailed wheels struck the connection just short of the platform, causing the rear section of the train to become detached and derailed. Calculations suggested that the train speed was 60 to 65 mile/h when the brakes were applied. The cause of this derailment was excess of speed. The milk tank left the rails because of its inherent instability at speeds above its limit rather than any specific fault in the milk tank itself or any serious imperfection in the track.

A STUDY OF HAZARDOUS MATERIALS INFORMATION NEEDS AND IDENTIFICATION SYSTEMS FOR TRANSPORTATION PURPOSES
Information needs and methods to transmit that information are analyzed to determine the basic requirements of a hazard identification system for packages containing, and vehicles carrying, hazardous materials. Persons who come in contact with hazardous materials shipments are identified and a typology is developed. Information needs by type, amount, and timing are listed by category, and sixteen existing labeling systems are evaluated according to these and human factors criteria. Another dimension of users considered is transportation mode and job function of personnel. Conclusions and recommendations based on this analysis are discussed.

CAR USER INPUT
The presentation is concerned with the approach by DuPont as a shipper. The consideration by the shipper in the selection and design of freight cars is discussed and may be summarized by considering: the lowest physical distribution cost combined with safety; low designs must take into account restrictions in car movement which would result in higher costs; and the

designs must consider the future not restricted by old conditions and practices. The mix of railway cars in the DuPont fleet is described.

ALUMINUM IN ROLLING STOCK: THE VALUE OF RESEARCH AND DEVELOPMENT
In Canada, aluminum is considered standard for box cars roofs, the inside lining of refrigerator cars, brine tanks, hopper cars for bauxite and alumina, hopper car hatch covers, piggy-back trailers and passenger car furnishings. The properties of aluminum which make it ideal for use in rolling stock are good strength and impact resistance, light weight, excellent corrosion resistance and good fabricating characteristics. Service experience and impact tests, which were more rigorous than conditions encountered normally, have shown that all-welded aluminum hopper cars are strong and rugged enough to withstand such severe treatment. Impact and fatigue test results are reported for several types of aluminum cars. The lightness of aluminum cars mean that fewer of these cars are required to transport a given cargo. The excellent resistance of aluminum to the weather and corrosive cargoes means that annual maintenance costs can be lowered appreciably. The life of the aluminum cars will be governed by failure due to mechanical causes rather than corrosion and even after their normal service life they will have a high scrap value.

STRENGTH OF A HORIZONTAL RESERVOIR SUPPORTED PARTIALLY BY EQUIDISTANT SADDLES
This theory could be considered in the designs of railway tank cars, especially those of the "jumbo" size. In a horizontal reservoir, partially supported by saddles, great stresses arise near the supports, and the magnitude of these stresses is closely related with the form of the saddle supports. The strength is discussed of such a reservoir and its relationship to the form of the saddle supports, utilizing the fundamental differential equation of cylindrical shells, and the importance of the form of the saddle supports is pointed out. To decrease the magnitude of the stresses arising near the supports, research on the optimum form of the saddle supports was made. The deformation of such a reservoir was very large.

THE TORSIONALLY STIFF BOGIE WAGON
Torsional stiffness is an important factor bearing on the ability of vehicles to run over twisted track. Results of British Railways tests of tank cars with tare of 26 to 28 tons and 41.75 ft. truck centers are described. Track twist varied from 1 in 400 to 1 in 150. The design limitations for wheel load is calculated. Suspension changes to eliminated derailment tendencies are discussed.

B5 040357
ANALYSIS OF HOT BOX DATA SUBMITTED BY FOURTEEN MEMBER ROADS
The result of this study of 2,161 hot boxes' data indicates that hot boxes occur less frequency on spring plankless trucks. However the cars with spring plankless trucks are newer cars, a fact which should be given weight in any conclusions reached. The ratio of ownership of spring plank trucks to spring plankless trucks is 2,48 to 1.0 but the ratio of hot boxes on spring plank trucks to spring plankless trucks is 3.45 to 1.0. It was concluded that the major causes of hot boxes (71.16%) are derived from the conventional waste pack. Elimination of this waste pack by substituting an improved method or material to provide the lubrication would eliminate many hot boxes. Periodic repacking, and the associated attention to the box assembly at that time does not reduce the frequency of hot boxes during the immediately following months, as might be expected. The higher capacity cars run hot less frequently than the lower capacity cars, but the higher capacity cars are generally more modern. The number of hot boxes caused by bearing defects indicates need for improvement of bearing design and box assembly. Tank and refreigerator car performance is less satisfactory than the average of all other types.

REPORT ON A STUDY OF METAL SPECIMENS REMOVED FROM TANK CAR TANKS INVOLVED IN A DERAILMENT AND EXPLOSIONS AT LAUREL, MISSISSIPPI
On January 25, 1969, Southern Railway freight train 154, derailed at Laurel, Mississippi as a result of a broken wheel on the leading truck of the 62nd car a non-insulated, non-continuous centersill tank car transporting liquified petroleum gas. Fifteen tank cars of similar design and containing LPG were involved in an ensuing general derailment. Thirteen of the cars ruptured at various time intervals following the derailment resulting in ignition of contents and a general fire. General elements of this study were as follows: specimens were selected to determine if the tank steels met the minimum requirements; tests to determine the brittle and ductile characteristics of the steels involved; studies of the tensile properties of tank steels at elevated temperatures; studies of welds and weld quality; and, metallographic analyses. All data is tabulated. Temperature-impact energy transition curves for the Charpy tests are shown. It appears that tank steel toughness requirements at low temperatures should be incorporated in appropriate steel specifications for the cars involved. Research should be immediately progressed to determine performance characteristics of current designs of pressurized tanks exposed to high thermal inputs, both general and localized and to temperature gradients produced in the tank shell when exposed to high localized temperatures.

REPORT ON A STUDY OF TANK CARS INVOLVED IN A COLLISION AT CRETE, NEBRASKA
On February 18, 1969, a Chicago, Burlington & Quincy eastbound freight train derailed cars and freight cars standing on an adjacent double-end siding. The group of standing cars included three tank cars loaded with anhydrous ammonia. The center car of this standing group of tank cars was a stub-sill, non-insulated tank with a nominal capacity of 33,500 gal. In the collision, the tank ruptured, permitting contents to escape. Temperature-impact energy transition curves from the Charpy tests are shown. The fracture of the Crete tank car was almost entirely of a brittle nature. The metallurgical processing of the tank led to a microstructure conducive to low toughness and a high NDTT.

FIRE PROTECTION OF RAILROAD TANK CARS CARRYING HAZARDOUS MATERIALS-ANALYTICAL CALCULATIONS AND LABORATORY SCREENING OF THERMAL INSULATION CANDIDATES
In recent years there have been a number of incidents in which railroad tank cars carrying liquefied petroleum gas (LPG) have been engulfed in fires. The LPG cars have ruptured from the fires, causing extensive property damage and loss of life. This report describes a laboratory screening program to select two thermal insulation candidates for use in future fire tests of fifth-scale and full scale LPG tank cars. Also included are analytical calculations to predict pressures and liquid levels in LPG tank cars being heated by fires. (Author)

1972 SPECIFICATIONS FOR TANK CARS
Numerous additions and revisions keeping this publication current with AAR and DOT requirements has necessitated a complete reprinting. There are revisions in safety relief flow rating requirements and approvals, a new list of certified facilities for tank fabrication and repair, an index of special commodity requirements, and a new section giving tank car definitions. Many of the appendixes have been completely rewritten.

Notice of this publication was given in Volume 146, No. 11 of "Railway Locomotives and Cars", dated December 1972.

STUDY TO REDUCE HAZARDS OF TANK CAR TRANSPORTATION
This 172-page report of a four-month study undertaken for the Federal Railroad Administration by Cornell Aeronautical Laboratory defines the rate of generation of vapors of hazardous materials in tank cars and then attempts to develop the performance of safety devices which might prevent catastrophic explosions. It was found that safety devices should function to release liquids, as well as vapors, from upset tank cars. Staged safety relief devices were recommended with a secondary arrangement to dump ladings when primary devices were no longer adequate.

This report was announced in Railway Locomotives and Cars, V145, N9, September 1971.

TRANSPORTATION OF LIQUEFIED NATURAL GAS BY RAIL AND BY HIGHWAY [TRANSPORT DE GAZNATURAL LIQUEFIE PAR RAIL ET PAR ROUTE]
The design and fabrication of two transport vehicles for liquefied natural gas is described. One is a railroad tank car and the other is a highway tractor-trailer. In addition to an introductory history and some administrative detail, the design limitations, safety regulations, material specifications, and similar design considerations are discussed. Both carriers utilize an inner tank of 5% nickel austenitic stainless steel which is designed for 95% liquid content and 5% ullage. The outer tank is common boiler plate. The annular space (220-250-mm thick) contains insulation, perlite for the trailer and hostaflon for the railroad car. The inner tank is attached to the outer longitudinally by tension-compression tie-rods with ball-and-socket joints at both ends. It is supported transversely by a bottom rail and lateral elastic pads. This complex support system is designed to minimize thermal stresses in and loading thermal shock to the internal tank. [French]

CHICAGO, BURLINGTON, AND QUINCY RAILROAD COMPANY TRAIN 64 AND TRAIN 824 DERAILMENT AND COLLISION WITH TANK CAR EXPLOSION, CRETE, NEBRASKA, FEBRUARY 18, 1969
A train accident is reported in which one consequence was the complete fracture of a tank car and release of its load of 29,200 gallons of anhydrous ammonia into the atmosphere. A gas cloud was formed which blanketed the surrounding area for a considerable time because of prevailing weather conditions. All persons directly exposed to the cloud of ammonia gas received either fatal (six people) or serious (53 people) chemical injury to the respiratory tract; people within the area of the gas concentration who remained in their homes or who had adequate protection escaped with little or no injury. The cases of the complete failure of the tank car following derailment were heavy impact with another car and the brittleness of the tank car steel at the ambient temperature of four F. More than 11,000 tank cars of this type are in service, most carrying liquefied petroleum gas. In low-temperature conditions, the consequences of accidents involving some large LPG cars are most likely to be catastrophic than in warm weather. The failure to thoroughly test tank cars for such hazards as flammability and brittleness before they are put in service is both false economy and an injustice to persons living along the tracks. Thorough study of tank car materials and of methods for rapid dispersion or absorption of clouds of toxic vapors is recommended.

RECLASSIFICATION OF MATERIALS LISTED AS TRANSPORTATION HEALTH HAZARDS
The study consisted of three phases. Phase I--An extensive literature search was conducted for pertinent human and acute animal toxicity data for about 200 materials, classed as Poison A, B, or C in the Commodity List, Section 172.5, Title 49 CFR, and/or as Toxic (Class 6.1) in the Subsidiary Risk Category in the United Nations publication, Volume I, Transportation of Dangerous Good, 1966. Materials were classified according to the proposed classification criteria. Phase II--Inhalation (LC50) toxicity tests were run on mice and rats for five materials and oral toxicity (LD50) tests were run on mice and rats for 40 other materials. The phosphine evolution rate for aluminum phosphide in air (55% relative humidity) and in water were determined. The results were summarized and the materials classified. Phase III--Verification inhalation toxicity (LC50) tests were run on mice and rats exposed to chlorine, anhydrous ammonia and hydrogen sulfide. Results were included and reflected in the classification of these materials.

TANK CAR SAFETY PROJECT...MILEPOST IN RAILROAD RESEARCH
The tank car is a special type of freight car and has a unique character of its own. This unique character relates to what happens when a tank car is damaged or derailed and releases its lading. Much has been learned about tank cars as a result of the Tank Car Safety Research and Test Project. Four results have been achieved: (1) a better understanding of tank car performance, of how to improve tank car safety, (2) a better understanding of the design character of certain components of any freight car that can reduce the severity of damage when a wreck or derailment occurs, (3) various forces in the railroad industry joined ranks and proved that they could get far more done by working in unison than separately, and (4) there is an emerging methodology of railroad research that has been applied more extensively and more intensively to the tank car project than any other heretofore. Significant is the conclusion that "while head punctures can be reduced significantly by a head shield, the E top and bottom shelf coupler is not only more effective, but is significantly more cost-effective." To evaluate the shelf coupler in normal service, 200 car sets are currently being installed by railroads and tank car companies.

COUPLER IS SUBJECT OF TWO SAFETY PROJECTS
The freight car coupler's sphere of operation is one of almost constant violence. Couplers must take the brunt of crushing forces. But when something goes wrong, the strong coupler can damage other components. A key safety recommendation is that car couplers should be modified to prevent uncouplings in derailments. Both the Type F coupler, with a top shelf, and the Type E coupler, with top and bottom shelves, have the ability to reduce the probability of vertical separation. For better than two years, the Type F coupler has been required on new tank cars. It is felt the Type E coupler would not only do a better job of preventing punctures of tank cars, but would be more cost effective. Service testing of 200 car sets of the Type E coupler is now in progress. Plans call for an instrumented boxcar to be operated over 25,000 miles by more than eight railroads to produce a fair sampling of the railroad environment.

WHAT HAPPENS WHEN LNG SPILLS?
The worldwide shortage of natural gas, largely methane, has led to widespread activity in setting up projects to transport liquefied natural gas (LNG) from producing countries to gas-hungry population centers. There is some concern that transportation of LNG may lead to accidents that will release the liquefied product and endanger lives and property. This paper reviews the development of LNG technology, cites a number of misconceptions regarding LNG, and reviews information on the behavior of LNG during and after spills.

RAILROAD ACCIDENT REPORT: DERAILMENT OF MISSOURI PACIFIC RAILROAD COMPANY'S TRAIN 94 AT HOUSTON, TEXAS, OCTOBER 19, 1971
The Missouri Pacific Railroad's freight train 94 was traveling north on track which belongs to the Atchison, Topeka and Santa Fe Railway when 20 of its cars derailed in Houston, Texas, on October 19, 1971, at 1:44 p.m. There were four diesel-electric locomotive units and 82 cars in the train. Derailed cars included six tank cars containing vinyl chloride monomer and two cars containing other hazardous materials. Two tank cars were punctured in the derailment. The vinyl chloride monomer escaped and ignited. The Houston Fire Department attempted to control the fire. Approximately 45 minutes after the initial derailment, one tank car ruptured violently and another tank car 'rocketed' approximately 300 feet from its initial resting place. This sequence of events caused the death of a fireman. Fifty people were injured and there was considerable property damage. Most of the injured were firemen. The Safety Board determines that the probable cause of this accident was an unexplained emergency brake application which induced lateral forces exceeding the holding capacity of the track fasteners.

CHEMICAL TRANSPORTATION SAFETY INDEX
All chemicals can be safely transported and handled if necessary precautions and control measures are observed. However, in the event of an accident, hazardous chemicals present a particularly dangerous situation, often requiring rapid, critical handling by personnel not aware of the specific hazards and methods of handling the chemicals involved. Although there is extensive literature on the hazards of chemicals, it is widely scattered and generally not on hand at an accident. Deepening the severity of this information and communication problem is the fact that actions taken in the first few minutes of an emergency can spell the difference between disaster and orderly return to normal operations. Faced with this problem and the desire to provide a quick, concise and accurate guide to the handling of over 200 commonly transported hazardous chemical substances, the RSMA has developed the Chemical Transportation Safety Index as the "first-aid" step in its comprehensive Commodity Safety System.

EVALUATION OF THE HAZARD OF BULK WATER TRANSPORTATION OF INDUSTRIAL CHEMICALS. A TENTATIVE GUIDE
This study rates 337 industrial chemicals that are bulk shipped by water transportation. The rating system used to determine their hazardousness is in keeping with their objective to provide the Coast Guard with technical information that can be used as a guide for establishing safety regulations. The ratings are designed only toward water transportation of these chemicals and are not valid when used in any other manner. The rating system is designed for reclassification when new information becomes available. Thus the report originally printed in 1966 was updated in 1969, 1970 and this 1972 edition.

A report prepared by the Evaluation Panel of the Committee on Hazardous Materials, Division of Chemistry and Chemical Technology, NRC, for the Coast Guard under Task Order 13.

IMPACT VULNERABILITY OF TANK CAR HEADS
An Impact Vulnerability study of tank car heads was undertaken by means of semi-analytical evaluation of head failures through careful observation of indentations and punctures produced in a series of full scale tests. Vulnerability influencing parameters were identified. Simple formulas to determine the permanent indentation and the impact force were developed in conjunction with a theoretical analysis of influential dimensionless parameters and an application of Hertz' force-indentation law to collision problems. Finally, the tank car head failure criteria were established.

HAZARDOUS MATERIALS: CAN THEY BE TRANSPORTED SAFELY AND PROFITABLY

A recent series of incidents has caused concern that the enviable safety record of the rail industry in transporting hazardous materials may be changing. Therefore the AAR has created a committee to study the problem of transporting hazardous materials both safely and profitably. The committee found that there are many forces of an economic nature from outside the rail industry working against the safe movement of these commodities. These include competitive factors associated with product manufacturing and distribution, larger-volume and lower-unit-cost concepts, service requirements and investments in jumbo equipment. The committee does not believe that hazardous materials can be transported safely and profitably under present circumstances. It cannot condone the sacrifice of safety responsibilities to serve a short term economic gain at the expense of potential consequences which at the very least can wipe out any economic gain for the future. The committee therefore recommends: greater efforts to minimize train accidents, better coordination as an industry by means of a specialized technical organization with authority such as the Bureau of Explosives, stronger control of the practice of issuance of special permits for movements which have not been thoroughly evaluated as to potential hazards.

SAFETY SYSTEM DESIGN CONSIDERATIONS FOR THE TRANSPORTATION OF HAZARDOUS MATERIALS AND CHEMICALS

A computer-aided specification system for handling transportation of hazardous materials by rail is proposed which would classify the risk potential of the shipment, provide safety controls such as fire-extinguishing agents and provide data to all personnel involved on freight handling.

SAFETY, RISK AND REGULATION--BASIC CONCEPTS FOR "SAFETY" RISK ANALYSIS

This paper discusses the applicability of risk-based concepts to "safety" problems generally. "Safety" programs exist to fulfill future expectations of people to live out their useful days free of accidental interruption. Utilizing a proposed generalized accident theory, the author describes the probabilistic nature of the existence of the ingredients necessary for an accident to occur, and the effects of man's capability to change such probabilities. An "accident risk" approach to "safety," in terms of the probable accidental reduction in useful life span associated with an activity, is presented. Establishment of an acceptable accident risk level as a "safety" objective, and the effects of risk creation and risk bearing on the establishment of that objective are discussed. "Safety" regulation is described as a risk-setting function, and the implications of that view in terms of "safety" responsibility, authority, and accountability are explained. Effects of a risk-based approach on safety data generation and collection are suggested. Additional research needed to permit implementation of the proposed approach is described.

RISK EVALUATION--MARINE TRANSPORT OF LIQUEFIED NATURAL GAS (LNG)

Due to the energy shortage in the United States, new energy sources are being developed; one such source is the importation of liquefied natural gas (LNG). In the coming decade LNG terminals to handle ships carrying large quantities of this material (of the order of 750,000 barrels) will proliferate. Our firm was retained to make a risk evaluation associated with moving a large tanker full of LNG up a busy river on the East Coast of the United States. The basic purpose of this evaluation was to provide a systematic framework for deciding which factors are important and to determine the impact upon these factors of alternative actions and/or design parameters in the system. The systematic framework or model adopted was that provided by the National Transportation Safety Board (NTSB) with some modification to suit the case at hand. In this paper, we shall provide a cursory discussion of the models, its results, and the data gaps which we found in constructing the model and attempting to obtain reliable values.

THE ANALYSIS OF TRANSPORTATION RISKS FROM A SHIPPER'S VIEWPOINT

Du Pont as a manufacturer and shipper of hazardous commodities is concerned not only with safety during the manufacturing process but also with the safe transportation of such commodities. It relies to a substantial degree on experience derived from manufacturing and plant handling for achieving safety during transportation of its hazardous products. Du Pont supports new procedures or refinement of existing methods which will

enhance safety in the transportation of hazardous commodities, but believes it will be necessary to rely on the present regulatory system while new approaches are being tested and evaluated.

A RAILROAD HAZARD ANALYSIS

Why should Southern Railway be interested in hazard analysis? It goes beyond Laurel, Miss. Southern's revenue from traffic classed as hazardous by the current classification methods is about $40,000,000 per year. Some segments of this traffic are growing at a rate faster than the average of all commodities handled by Southern. There is a substantial stake in this area now and it could be even greater in the future. At the same time there is the extraordinary exposure faced with handling some of these commodities. It was logical to try to assess what this traffic is worth, including the exposure to extraordinary costs from accidents.

B5 047947
RISK ANALYSIS FOR TRANSPORTATION SAFETY THE REGULATOR'S VIEWPOINT

It is clear that the consumer is a very important person in the regulatory process. In this brave new world of cost benefit analysis user acceptance or nonacceptance of a standard is a strong consideration in the tradeoff of competing requirements. The concept of risk management and its application to the transportation regulatory process is an orderly and reasonable course to follow. There is a world of difference in doing something in a systematic way and doing it because it seems a good idea. The gain may be difficult to measure but the increased knowledge will help the decision-maker. It is possible that a mathematical prediction model would be most useful to the decisionmaker in evaluating the effectiveness of various programs and standards. When coupled with cost information the maximum benefit could be obtained by proper allocation of resources. Finally, I believe that risk technology is a great and coming field. One can no longer wait for damaging events to warn of hazards to people, to products or to the environment.

DETONATION OF A FLAMMABLE CLOUD FOLLOWING A PROPANE PIPELINE BREAK: THE DECEMBER 9, 1970, EXPLOSION IN PORT HUDSON

This report summarizes the incidents that preceded the December 9, 1970, propane-air explosion in Port Hudson, Mo., and then attempts to establish the nature of the explosion from the ensuing events. Special emphasis is given to possible ignition sources, the distribution of flammable vapors, and the analysis of blast damage. Both near-and far-field damage indicated that this explosion may be attributed to the detonation of propane in air with an energy release equivalent to that from about 50 tons of detonating TNT.

EVALUATION OF THE HAZARD OF BULK WATER TRANSPORTATION OF INDUSTRY CHEMICALS--A TENTATIVE GUIDE

The ratings put forth in this report represent the considered opinion of the Committee regarding the over-all potential hazard connected with the bulk water shipment of specified industrial chemicals. The ratings were prepared specifically to reflect to the Coast Guard the hazards or absence of hazards in shipping chemicals in their present industrial grades in bulk by water. They are not intended to be used for any other purpose and they are not considered valid to estimate the degree of hazard of handling these chemicals in any other manner.

EQUIVALENT SAFETY AND HAZARDOUS MATERIALS TRANSPORTATION

This paper proposes a methodology to assess hazards, safety, and safety requirements in the marine transportation of hazardous materials. The basic approach is to quantify on a relative basis rather than on some absolute

scale. The authors suggest that each hazardous commodity can be graded on a numerical scale indicating the relative hazard while the vessels can be graded on a numerical scale for relative safety provided by the design, operation, etc. By combining the commodity relative hazard rating with the vessel relative safety rating an overall transportation safety rating may be obtained. Different commodities carried in vessels of differing designs could have the same transportation safety rating if equivalent safety had been obtained. The paper also suggests a method to quantify, on a relative basis, the safety requirements for waterways (including ports and terminals). By relating the transportation safety rating to the port safety requirement, one can determine what vessel design features are required to transport a specific hazardous commodity to a specific terminal over a specific water route.

CRITICAL VELOCITY FOR COLLAPSE OF A SHELLING CIRCULAR CROSS SECTION WITHOUT BUCKLING

Many practical devices involve high-speed collapse of shells of circular cross section. In all of the devices the stability of the collapse motion is of interest and in some it is essential for successful operation. In this paper, the buckling motion of shells of circular cross section during high-speed collapse is analyzed and critical collapse velocities are determined for which the growth of initial nonuniformities by buckling during collapse is 10 and 100.

EVACUATION AREAS FOR TRANSPORTATION ACCIDENTS INVOLVING PROPELLANT TANK PRESSURE BURSTS

Evacuation areas are defined for those transportation accidents where volatile chemical propellant tanks are exposed to fire in the wreckage and eventually explode with consequent risks from fragments in surrounding populated areas. An evacuation area with a minimum radius of 600 m (2000 ft) is recommended to limit the statistical probability of fatality to one in 100 such accidents. The result was made possible by the derivation of a distribution function of distances reached by fragments from bursting chemical car tanks. Data concerning fragments was obtained from reports or tank car pressure bursts between 1958 and 1971. (Author)

THE TRANSPORTATION OF HAZARDOUS MATERIALS: TRANSPORT OF BENZENE BY TANK CAR

The research is an investigation of the problems involved in the transportation of hazardous materials with emphasis placed on the transport of benzene by railroad. Specific recommendations on the identification and labeling of the hazards associated with benzene are discussed and a risk rating model is suggested for general use in the transportation of hazardous materials. Through use of a gross hazard analysis and a fault free analysis, the basic parameters involved in the transport of benzene are determined. (Author)

RECLASSIFICATION OF MATERIALS LISTED AS TRANSPORTATION HEALTH HAZARDS. SUPPLEMENT

In a previous report the toxicity of several compounds of interest to the Department of Transportation was discussed. This was done in the light of a reexamination of existing data or the determination of acute toxicity data on those compounds where no previous data existed. The information so gathered was used to help reclassify these compounds into categories which may help to define shipping and handling requirements concomitant with the hazard associated with each compound. The classifications assigned are not official regulatory classifications and are presented for technical information only. Seven new compounds were examined in this same light to provide additional information to the Department of Transportation. These compounds are as follows: mixed cresols, allyl isothiocyanate, methyl isothiocynate, methyl isocyanate, ortho-nitroaniline, ethyl chloroacetate and phenyl isocyanate. HAZARDOUS MATERIAL TANK CARS--TANK HEAD PROTECTIVE "SHIELD" OR "BUMPER" DESIGN

The objective of this study program is to design a railroad tank car head protective device which will reduce the frequency of head punctures in accidents. Accident data were reviewed in detail for the years 1965 through 1970 to correlate head damage frequency and severity with various types of tank cars, to determine distribution patterns of damage over tank car head surfaces, and to assess the costs to the railroad shipping industry of head punctures. Full scale head impact tests, previously run were also reviewed. From these two reviews, design criteria were established and used to reduce an initial compilation of 74 concepts to a group of 15, which when applied to various classes of cars, comprised a semi-final total of 42 combinations, or schemes, as referred to in this report.

ASSEMBLY AND ANALYSIS OF FRAGMENTATION DATA FOR LIQUID PROPELLANT VESSELS
The objective of this work was to assemble and analyze fragmentation data for exploding liquid propellant vessels. These data were to be retrieved from reports of tests and accidents, including measurements or estimates of blast effects, fragment velocities, masses, shapes, and ranges. Correlations were to be made, if possible, of fragmentation effects with type of accident, type and quantity of propellant, blast yield, etc. A significant amount of data was retrieved from a series of tests conducted for measurement of blast and fireball effects of liquid propellant explosions (Project PYRO), a few well-documented accident reports, and a series of tests to determine autoignition properties of mixing liquid propellants. The data were reduced and fitted to various statistical functions. Comparisons were made with methods of prediction for blast yield, initial fragment velocities, and fragment range. Reasonably good correlation was achieved. Methods presented in the report allow prediction of fragment patterns, given type and quantity of propellant, type of accident, and time of propellant mixing. However, more work must be done before the results of this study can be easily applied to estimation of damaging effects of fragments from exploding liquid propellant vessels.

THE INCIDENCE OF HAZARDOUS MATERIAL ACCIDENTS DURING TRANSPORTATION AND STORAGE
This report is one of a series describing background research concerning the incidence of abnormal loading. The report is organized in terms of modes of hazardous material transportation and storage. These modes--pipeline, water, motor vehicle, and railroad transportation systems--are addressed in four sections with Storage Systems discussed in a fifth. The sections depend on the amount of available data, rather than the risk involved in an accident. A summary of the results is presented in the last section. On the whole, there is little empirical evidence to substantiate a threat to buildings from hazardous materials transport. However, trends in volumes shipped in proximity to structures of interest raises the prospect of future incidents.

MILLION GALLON "TANK CAR"
General American Transportation, applying the benefits of volume transportation through the unit train, has come up with an integral train concept that it calls a "million gallon tank car." Since it involves handling techniques of storage tanks, it holds potential of improving the distribution of bulk liquid commodities. The new system has a unique combination of interconnects of flexible hoses and special valves. With them a million gallon 40 car tank train can be filled or emptied from a single connection. The train thus brings that capability to the terminal.

RISK ANALYSIS IN HAZARDOUS MATERIALS TRANSPORTATION, VOLUME I
A contracted research project was undertaken by the University of Southern California for the Office of Hazardous Materials, Department of Transportation, on the subject topic. The results are as follows: (1) A risk analysis model is developed which is provided with input from existing data bases with some minor extensions and revisions and is logically consistent and satisfying. In fact, several agencies are already employing like models in analysis and operations; (2) Twenty examples are shown which demonstrate the procedure, its flexibility in accepting different levels of detail of data, and the type of results which are obtainable. In this phase several specific recommendations for data input needs and procedural development are made; and (3) The petition evaluation shows a clear dominance of one alternative over the other in terms of risk, bodily injury, deaths (equal), normal and total cost.

PREDICTION OF HAZARDS OF SPILLS OF ANHYDROUS AMMONIA ON WATER
Maritime transport of liquid anhydrous ammonia (LNH3) poses a potential hazard to the public, to aquatic life, and to other shipping should there be an accidental surface or underwater release of ammonia. This report contains the results of an experimental and analytical program aimed at evaluating the hazards presented by a 3,000 ton release of liquid anhydrous ammonia on water. Test spills were conducted in the laboratory (up to 1/2 gallons), in a swimming pool (5 gallons) and in a lake (50 gallon size) and the fraction of released ammonia dissolving in water and the amount vaporizing were determined. The dispersion of vapor in air was measured and a theory was developed to predict the movement. Analytical models to predict water dispersion are also presented. (Modified author abstract)

SYSTEM FOR EVALUATION OF THE HAZARDS OF BULK WATER TRANSPORTATION OF INDUSTRIAL CHEMICALS
This is a report of results, to date, of the efforts of the Committee on Hazardous Materials to develop and evolve a scheme of hazard evaluation. The Hazard Evaluation System described in this report employs four main classes of hazards: fire, health, water pollution, and reactivity; and further subdivides the health, water pollution, and reactivity into subclasses. Under each class or subclass, a numerical rating is given to indicate the relative degree of potential hazard. General guidelines were developed to describe five levels of severity for each. The Committee, using those general guidelines, has rated 367 industrial chemicals suggested by the Coast Guard. It should be borne in mind that these ratings relate to hazardous situations that may arise in the marine transportation of the materials under consideration, and are not necessarily applicable to other situations.
This is a report to the Department of Transportation, United States Coast Guard.

B5 057878
RAILROAD ACCIDENT REPORT: HAZARDOUS MATERIALS RAILROAD ACCIDENT IN THE ALTON AND SOUTHERN GATEWAY YARD IN EAST ST. LOUIS, ILLINOIS, JANUARY 22. 1972
At about 6:20 a.m., on January 22, 1972, an overspeed tank car loaded with liquid petroleum gas collided with a standing hopper car in the Alton & Southern Railroad Company's Gateway Yard in East St. Louis, Ill. In the overspeed impact, an overriding coupler on the empty freight car punctured the tank head. The pressurized propylene gas in the tank car leaked to the ground and vaporized. A large vapor cloud was formed, which ignited and exploded. More than 230 people were injured as a result of the explosion, and property damage was estimated at more than $7-1/2 million. The National Transportation Safety Board determines that the probable cause of the overspeed impact was the failure of the retarding system in the hump classification yard to decelerate effectively heavy cars with oil or grease on their wheel rims; the absence of a backup system to halt cars passing through retarders at overspeeds; and the routine acceptance at the Gateway Yard of uncontrolled overspeeds. Propylene leaked from the tank car because the tank head was too weak to resist the impact of the overriding coupler of the hopper car. Lack of specifications that define permissible impact and adequate crash resistance was a contributing factor.
Railroad Accident Report. This report contains Railroad Safety Recommendations R-73-1 through R-73-4.

A MODAL ECONOMIC AND SAFETY ANALYSIS OF THE TRANSPORTATION OF HAZARDOUS SUBSTANCES IN BULK. EXECUTIVE SUMMARY (REVISED)
This summary presents the results of the six-month study begun in October 1973 and is an abbreviated version of the final report (COM-74-11271). The objective in the study was to analyze quantitatively the economics and safety of transporting selected bulk hazardous substances, other than oil, by inland waterway and overland (rail, truck, and possibly pipeline) modes, so that the costs and risks associated with the different modes could be compared. There were three major components to this process: (1) choosing the substances, origin-designation combinations, and shipment characteristics to be studied; (2) determining all costs involved in transporting each substance between the designated points by barge and relevant overland modes; and (3) determining the frequency and quantity of spills likely with each mode and the resultant risk to people, property, and the environment.

A MODAL ECONOMIC AND SAFETY ANALYSIS OF THE TRANSPORTATION OF HAZARDOUS SUBSTANCES IN BULK
The movement of hazardous materials through transportation channels creates risks which are not fully understood. Consequently, the question of which was the best mode of transportation for the movement of hazardous substances had to be examined quantitatively. The objective of this study was to quantitatively analyze the economic and safety aspects of transporting hazardous substances by inland waterway and overland (pipeline, rail and highway) modes so that the comparative costs and risks of the different modes could be assessed. The chemicals studied as examples are acrylonitrile, anhydrous ammonia, benzene, caustic soda, chlorine, ethylene glycol, methanol, styrene, sugar, and sulfuric acid.

RAILROAD ACCIDENT REPORT: CHICAGO, BURLINGTON AND QUINCY RAILROAD COMPANY TRAIN 64 AND TRAIN 824 DERAILMENT AND COLLISION WITH TANK CAR EXPLOSION CRETE, NEBRASKA, FEBRUARY 18, 1969
At about 6:30 a.m., on February 18, 1969, Chicago, Burlington, and Quincy Train No. 64 derailed the 72nd to the 90th cars, inclusive, at a turnout located on the spiral of a 2 degree curve as the train was entering Crete, Nebraska, at a speed of about 52 miles per hour. The derailed cars struck standing cars on a siding south of the main track and the cars of train 824 standing on a track north of the main track. A tank car in train 824 was completely fractured on impact with the derailed cars which released the lading of 29,200 gallons of anhydrous ammonia into the atmosphere. A gas cloud was formed which blanketed the surrounding area for a considerable time due to the weather conditions. Three trespassers riding on train 64 were killed as a result of the derailment and six people were killed and 53 were injured as a result of exposure to the cloud of ammonia. The Safety Board determined that the derailment was caused by the movement of a rail of the turnout due to lateral forces produced by the locomotive as it moved over track alignment and surface deficiencies of the track. The complete fracture of the tank car on impact was contributed to by the brittleness of the steel of the car caused by the low ambient temperature.

RAILROAD/HIGHWAY ACCIDENT REPORT: BOSTON AND MAINE CORPORATION SINGLE DIESEL-POWERED PASSENGER CAR 563 COLLISION WITH OXBOW TRANSPORT COMPANY TANK TRUCK AT SECOND STREET RAILROAD-HIGHWAY GRADE CROSSING EVERETT, MASSACHUSETTS, DECEMBER 28, 1966
At 12:10 AM, on December 28, 1966, eastbound firstclass passenger train No. 563, consisting of a single car diesel-powered passenger unit operated by the Boston and Maine Corporation collided with a northbound motor tank truck owned and operated by the Oxbow Transport Corporation stopped across the Second Street grade crossing at Everett, Mass. The collision resulted in the death of 11 of a total of 28 passengers and 2 of the 3 train crew members and other injuries and damage to property. The semi-trailer of the tank truck containing 8,200 gallons of fuel oil ruptured on impact, covering the forward end of the passenger car with the oil. A spread of flames immediately covered the forward section of the car. The fatalities were due to thermal burns and smoke inhalation. There was a lack of emergency exits in the car, in addition to an inward opening rear door which became jammed in a closed position while people were attempting to escape. The truck driver had left the vehicle prior to impact and was not injured. The probable cause of the accident was the loss of air pressure in the brake systems of the tractor-trailer which resulted in an automatic application of the brakes that could not be released from the cab of the tractor and therefore held the tractor-trailer directly across the Boston and Maine track at the collision point.

RAILROAD ACCIDENT REPORT: PENN CENTRAL TRANSPORTATION COMPANY FREIGHT TRAIN DERAILMENT PASSENGER TRAIN COLLISION WITH HAZARDOUS MATERIAL CAR, SOUND VIEW, CONNECTICUT, OCTOBER 8, 1970
At 8:50 p.m., October 8, 1970, Penn Central Transportation Company's freight train derailed near Sound View, Connecticut. Freight cars obstructed track in the path of Penn Central passenger train. The passenger train struck the freight cars, puncturing an LPG tank car designated as "empty." The derailed units of the passenger train passed through ignited gases from the punctured tank car and crossed a railroad bridge. Train crewmembers and passengers were injured. The Safety Board has determined that the probable cause of the derailment of the freight train was the breakage of a truck side of a car on the freight train which followed a progressive fatigue crack failure. The breakage of the truck side resulted in damage to a turnout, which caused derailment of the following cars. The cause of the collision to the passenger train was the obstruction of track No. 2 by cars of the freight train. The Board concluded industry controls to prevent application of improper car components are inadequate, empty tank cars may be hazardous, and suggested that the industry should incorporate crashworthy concepts, improve communication and equipment design, and controls over maintenance, retirement, and testing of equipment components. The Board requested that bridge standards and joint corridor usage be reviewed.

RAILROAD ACCIDENT REPORT: ILLINOIS CENTRAL RAILROAD COMPANY TRAIN SECOND 76 DERAILMENT AT GLENDORA, MISSISSIPPI, SEPTEMBER 11, 1969
About 2:35 p.m., September 11, 1969, an Illinois Central freight train struck a pedestrian near the Glendora, Mississippi, station. When the engineer applied the brakes in full emergency in an attempt to avoid striking the pedestrian, the 149-car train buckled at the 108th car. The resulting derailment involved 15 cars, including eight tank cars loaded with vinyl chloride. The cars separated in the derailment and the coupler of one of the cars punctured one of the tank cars, spilling its contents on the ground. Initially, the breeze dispersed the vapor; however, about 8:30 p.m. the vapor accumulated in low places and was ignited by an unknown source. The ignition was followed by several explosions. Upon advice from a State chemist, an estimated 17,000 to 21,000 persons were evacuated because of an alleged danger from phosgene. The following morning a fire-impinged tank car of vinyl chloride exploded violently, seriously damaging the surrounding area. Four tenant houses, several auxiliary buildings, automobiles, and equipment were destroyed and damaged by fire. The pedestrian was seriously injured and a power company employee was burned. Both recovered. The Safety Board determines that the derailment was caused by the buckling of the underframe of the 108th car when the engineer made a full emergency brake application in an attempt to avoid striking a pedestrian who was walking in the track. The car buckled because of excessive and uncontrollable compression in the train which developed when the full emergency brake application created greater braking force on the head of the train than on the rear. The fire and explosions resulted from the rupture of a tank car of vinyl chloride by the coupler of one of the derailed cars. The absence of underlocking couplers and other means of preventing separation and jacknifing allowed the cars to jam up together. The pileup resulted in additional mechanical damage to the tanks and allowed the fire from the leaking tank to impinge on the others.

AT DERAILMENTS-DON'T BECOME A PROBLEM OR A CORPSE
With the chemical industry growing at 6% to 7% annually, and up to 60% of this new exotic products, the problems of tank car damage in derailments are increasing. While most attention has been given to cars containing highly volatile flammable liquids and liquefied compressed gases, there are other commodities which are more deadly, though not so spectacular. At derailments it is essential to determine what each car contains, and what it last contained. Needed immediately is information on the behavior of chemicals with and without fire, and on their possible reaction with each other. The AAR has recommended ten steps for safe transportation of compressed gases to the National Transportation Safety Board in response to its request.

RAILROAD ACCIDENT REPORT: PENNSYLVANIA RAILROAD TRAIN PR-11A, EXTRA 2210 WEST AND TRAIN SW-6, EXTRA 2217 EAST DERAILMENT AND COLLISION DUNREITH, INDIANA, JANUARY 1, 1968
About 9:30 p.m., January 1, 1968, Pennsylvania Westbound freight train PR-11A, consisting of 98 cars and five-unit diesel-electric locomotive, was passing Dunreith, Indiana, at 42 miles per hour when the trailing wheels of the 88th car, an empty tank car, AESX 850, derailed at a broken rail near the eastern edge of the town. At the same time, eastbound freight train SW-6 consisting of a five-unit diesel-electric locomotive and 106 cars, was moving eastward at 32 miles per hour on the adjacent track. The derailed car in train PR-11A continued westward until it became disengaged from its trailing truck when it struck the crossing board at a grade crossing about 723 feet west of the point of original derailment. One or more cars collided with cars of hazardous materials moving in the opposite direction in SW-6's train, causing a general derailment and puncturing several tank cars of flammable materials. A large-scale fire ensued, followed by a violent explosion of a tank car of ethylene oxide forty-five minutes later. Immediately after the derailment and outbreak of fire the population of Dunreith was evacuated without injury. A cannery and several residences and businesses were destroyed. Three firemen and two police- men were slightly injured in the fire and explosion. The probable cause of the initial derailment in train PR-11A was the broken rail within the compromise joint where two different sizes of rail were joined. A contributing causal factor was the inadequate track maintenance which left the joint unsupported and allowed the development of the break in the rail. This initial derailment and the design of the lift-off type of center-pin connection between the truck and body of AESX car 850 which allowed the truck to separate from the car under impacts of a simple derailment, led to the secondary collision and general derailment.

THE EFFECT OF THE STATE OF STRESS ON THE STRAIN AT FRACTURE
Tension tests on solid cylindrical specimens and internal pressure tests on one type of tubular specimen showed that a superimposed hydrostatic pressure increased the ductility. Internal pressure tests on a similar tubular specimen that was supported in a different manner showed that the hydrostatic pressure had almost no effect on the ductility.

RAILROAD ACCIDENT REPORT: DERAILMENT AND SUBSEQUENT BURNING OF DELAWARE AND HUDSON RAILWAY FREIGHT TRAIN AT ONEONTA, NEW YORK, FEBRUARY 12, 1974

This report describes and analyzes a derailment which occurred when a train separation resulted in unequal deceleration of the two parts of the train. Unusual lateral forces at the rear of the third locomotive unit canted the outside rail of a 3 degrees 30' curve outward enough to allow the wheels to drop inside. A tank car of propane was punctured and the ensuing fire impinged other tank cars and caused the violent rupture of three of them. Fifty-four person were injured by the fire and rocketing parts of tank cars. The National Transportation Safety Board determines that the probable cause of this accident was the inability of the track to resist the lateral forces which canted the outside rail outward and widened the gage of the track. These forces which were induced at the third locomotive unit resulted from the emergency application of the brakes when the train was separated between the third and fourth cars as it entered the 3 degrees 30' curve. The train separated as a result of the broken center sill on the fourth car.

This report contains Railroad Safety Recommendations R-74-31 through R-74-34.

TANK WAGONS FOR THE CONVEYANCE OF DANGEROUS GOODS ON BR LINES

Summarized are some of the important factors which warrant special attention in the design of tank cars for dangerous commodities. Quality of manufacture, coupled with rigorous inspection and testing procedures are cited. Ride and braking performance are essential elements in safe operation; the need for high maintenance standards during the car's service life must be recognized. British Rail and private owners strive to assure the containment of dangerous commodities in derailments, but the involvement of public agencies must also be encouraged.

RAILROAD ACCIDENT REPORT: SOUTHERN RAILWAY COMPANY TRAIN 154 DERAILMENT WITH FIRE AND EXPLOSION LAUREL, MISSISSIPPI JANUARY 25, 1969

Southern Railway train 154 was wrecked at Laurel, Mississippi on January 25, 1969 at about 4:15 a.m., when 15 tank cars of liquefied petroleum gas derailed. The train, with four diesel-electric locomotive units, 139 cars and caboose was moving northward at about 30 mph when the west wheel on the lead truck of the 62nd car in the train broke. The wheel which broke as it was passing over the crossing of the Gulf, Mobile, and Ohio Railroad, derailed about 256 feet north of the crossing, and the train continued northward for about 2,146 feet before the 62nd car and 14 loaded tank cars behind it were derailed. Most of the tanks were mechanically damaged by the derailment resulting in an immediate violent eruption of fire and explosion. Two fatalities resulted from injuries caused by the fires and explosions after the wreck, 33 persons were hospitalized. Property damage in the town was extensive and total damage to Southern Railway track, equipment and lading was estimated at about $3,000,000.

METALLOGRAPHIC EXAMINATION OF SPECIMENS REMOVED FROM A SECTION OF TANK CAR IN SOUTH BYRON, NEW YORK DERAILMENT

The analysis presented in this report was conducted on the two specimens removed from shell plates. There are variations in banding, ferrite volume, blocky and acicular ferrite, but these represent normal variations in ingot freezing practice and rolling mill practice. None of these variations should result in significant differences in tensile rupture characteristics.

COUPLER STEEL STUDY

FRA regulations stipulate that only approved couplers may be used on tank cars. Since some considerations was given a requirement for the use of Grade "E" steel in Type "F" couplers, the AAR Research and Test Department undertook a preliminary study of the properties of "C" and "E" steels in "F" couplers selected at random from stocks about to be utilized by railroads. The increase of strength between "C" steel and "E" steel does not contribute to an increase in a tendency toward brittle failure. In fact, the increase in strength is accompanied by a reduction in the transition temperature. Brittle service failures can be expected, especially in winter operating circumstances with heavy loads. The macroscopic examination reveals that the quality of the castings is lower than should be expected of material subjected to high service loading.

Contributing agencies are the Battelle Memorial Institute and the Southern Railway System.

OVERALL PROJECT SUMMARY REPORT
As a prerequisite to accomplishing the Project objective, over 4 man-years of effort were devoted to accumulating and analyzing accident data. Data on all accidents involving tanks cars were collected for the 6-year period 1965-1970, and for all major accidents back through 1958. The results of the accident review showed during the 1965-1970 period a loss of about $23.3 million was incurred due to product loss from tank cars that were punctured in accidents. About $15.4 million was caused by fire and about $7.9 million was attributable to non-fire causes. Careful attention was given to accidents involving tank cars that ruptured violently (vs. cars that were punctured) since these contributed primarily to the total losses. During the period from 1958 through 1970, a total of 113 cars ruptured violently, 41 during the single year of 1969. With this background the joint industry effort undertook numerous approaches to improving tank car safety with each appraised from a cost effectiveness standpoint. The various facets of the investigation are described with initial conclusions included. There are a series of detailed reports on the individual investigations available separately. A final report with added conclusions and recommendations is to be issued.

REPORT ON ANALYSIS OF TANK CAR TUB ROCKETING IN ACCIDENTS
The objective of Phase 12 of the RPI-AAR Tank Car Safety Project is to explain fundamentally the phenomena of tank car fracture behavior in accidents, particularly those fractures which led to violent ruptures. The Battelle Columbus Laboratories was engaged to conduct this research, and Battelle's final report on the study has been published under Report RA-12-2-20, "Phase 12 Report on Analysis of Fracture Behavior of Tank Cars in Accidents". The analysis explained the various fracture phenomena that have occurred and which have led to various tank rupture patterns. One type involves a fracture which runs longitudinally, then turns to a circumferential tearing shear fracture. This sometimes completely encircles the tank and creates a tank section open at the fractured end and closed at the other end by the tank head. The unreleased pressure acting on the closed end creates an unbalanced force on the "tub" and causes it to rocket. Battelle analyzed this rocketing phenomena and discusses the effectives on possible design changes which would offer the potential of reducing the distance travelled by the tubs, or eliminating the rocketing completely.

PRELIMINARY REPORT ON LABORATORY FIRE TEST APPARATUS FOR EVALUATING THERMAL SHIELD MATERIAL
RPI-AAR Report RA-01-2-7, "Summary of Ruptured Tank Cars Involved in Past Accidents," tabulated 84 cases of major ruptures and 14 cases of minor (local) ruptures of tank cars since 1958. Of these, the cause of rupture was known for 75 cases. Of these 75 cases, 66 were caused by fire impingement. As discussed in that report, there is strong evidence that most of these were a result of the unwetted (vapor space) steel being overheated and weakened. One method of reducing the probability of tank car ruptures due to fire exposure is to reduce the heat input to the steel with an intumescent paint, an ablative coating, a high temperature insulation, or some combination thereof. These are termed "Thermal shield materials" under the RPI-AAR Project, but, for brevity, will be called "coatings" in the remainder of this report. The original objective of the laboratory tests described in this report was to compare and screen such coatings in order to find attractive candidates early in the program for selection for subsequent 1/5 and full scale fire tests. The test apparatus was designed to simulate the behavior of the unwetted steel portion of a tank car when exposed to fire. Most of the thermal coatings tested were obtained from commercially available sources. This report is a synopsis of the test work completed to date.

REPORT ON ANALYSIS OF 1/5 SCALE FIRE TEST DATA
Under the RPI-AAR Phase II "Thermal Effects Study," a Series of 1/5 and full scale fire tests were conducted in cooperation with FRA. The tests were carried out at the White Sands Missile Range by personnel of the Naval Ordnance Laboratory. Under this cooperative arrangement, RPI-AAR is furnishing the 1/5 scale tanks and full scale tank cars, complete with lading, appropriate fittings and safety devices, and NOL is furnishing the instrumentation and providing the data reduction. Three tests were conducted on tanks constructed to a 1/5 linear scale of a nominal 33,500 gallon DOT 112A340W, tank car, except that full scale tank wall thickness was maintained, water was employed as lading in the first two tests, and propane was used in the third. All three tanks were bare (non insulated). Because of instrumentation difficulties in the water tests, all future 1/5 and full scale tests will be conducted with propane. This report covers an analysis of the results of the third (propane) test; analyses, results, conclusions and recommendations represent only the work and views of the RPI-AAR Project team and not those of DOT (FRA).

FINAL PHASE 09 REPORT ON TANKS, FITTINGS, AND ATTACHMENTS IN THE MECHANICAL ENVIRONMENT OF ACCIDENTS
Phase 09 of the RPI-AAR Tank Car Safety Research and Test Project concerns the behavior of tank car tanks and their appurtenances in the mechanical environment of railroad accidents. Thus, the items treated under this Phase 09 are: Tank shell-the portion of the tank between the heads, Tank fittings-the appurtenances attached to the tank shell and heads which are associated with openings through the vessel wall, and tank attachments-appurtenances attached to the tank shell and heads which are not associated with openings through the vessel wall. As an underlying principle, in the cost/benefit analyses under this study, the benefit values of design improvements, such as protective devices or "shields," are developed from accident data only from cases involving lading loss, the total dollar losses being the value of the lost lading plus that of subsequent losses caused by the lading loss. The cost of mechanical damage itself to shells or appurtenances is not considered reducible by a design change, it being assumed that the cost of repairing the "shield" is the same as that of

repairing the unshielded item. Following the statement of the objective, the report comprises four main sections: (1) review of typical current tank car shell and appurtenance designs, (2) review and analysis of accident data, (3) discussion and conclusions, and (4) recommendations.

B5 080291
EFFECTS OF FIRE ON LPG TANK CARS. PHASE II REPORT

The response of a DOT 112A340W tank car to a fire environment is investigated theoretically in this study, giving particular attention to propane lading. The possibility of tank rupture arising from variations in filling density, tank thickness, safety-relief valve setting and discharge rate is analyzed for fire conditions ranging from a unit heat input of 34,500 BTU/HR-FT over the entire tank surface to approximately one quarter of this value. The analysis and, hence, conclusions are based on several assumptions necessitated by the lack of data in certain areas; thermodynamic properties of commercial propane; valve discharge efficiencies with saturated fluids and slightly subcooled liquid; stratification effects; and of course, the statistical spectrum of the fire environment. Nevertheless, the results are published at this time as a foundation upon which further project work will be based.

REPORT ON SUMMARY OF RUPTURED TANK CARS INVOLVED IN PAST ACCIDENTS. PHASE 01 REPORT

This report constitutes an extension and refinement of previously issued Report RA-01-2-3, "Summary of Ruptured Tank Cars Involved in Accidents-12/4/70." Damage to a tank in an accident, leading to loss of lading, can be divided into two main categories: (1) Punctures, tears, dents with peripheral cracks, etc., caused by an external impact and involving little or no crack propagation away from the area of impact. (2) Ruptures, or outwardly moved metal, involving the propagation, and sometimes branching, or a crack (or cracks). A crack, once initiated, may or may not propagate. The propagation phenomenon--or tank rupture--is influenced by many variables, including the amount of energy which is available in the system and properties of the tank material at its existing temperature. As a result many modes of rupture occur. A comprehensive analysis of this entire subject is being performed by Phase 12 research contractor, Battelle Memorial Institute, and no attempt will be made in this report to develop explanations for the various rupture modes. This report is organized as follows: All ruptured cars (113 since 1958) are divided into two categories--those involving cracks which remained within a heat-weakened area (18 cars--listed in Appendix B), and those involving crack propagation beyond the heat-weakened area, or in tanks having no heat-weakened area (95 cars--listed in Appendix A). The ruptures in these two categories were generally "local" and "major", respectively; so, for brevity these terms will be used in this report. The data in Appendices A and B are summarized in Table 1 through 10, in Sections II, III, IV and V of this report. No conclusions or recommendations are made, since the only objective of this report is to publish information which we have been able to derive from a large collection of records and photographs on this important subject.

REPORT ON LITERATURE AND RELATED EXPERIENCE. PHASE 04 REPORT

Knowledge of the work done by others in technical areas related to the RPI-AAR Cooperative Research Program was largely unknown to project personnel. A review of the technical work already done was necessary to optimize project planning and avoid duplication of work while fulfilling project objectives. It was decided that the review would be most effectively accomplished by: 1. Engaging a research organization to review the literature pertaining to non-tank car pressure vessel destructive testing; puncture resistance; size and grouping vs. hazard; and material testing and selection. 2. Conducting a seminar attended by experts from industry, technical associations, consultants, research organizations and government. 3. Reviewing the files of trade associations. 4. Reviewing literature in areas of tank car accidents, properties of pressure vessel materials (including tank cars), safety valve technology, model theory, pressure vessel stress analysis, safety relief valve sizing, LPG and NH3 behavior under fire conditions, and intumescent, ablative and insulative coatings. 5. Collecting and assembling all pertinent literature in a library and cataloguing each article for ready reference.

REPORT ON DETERMINATION OF MOMENT CHARACTERISTICS IN A HORIZONTAL PLANE OF MATED COMBINATIONS OF TYPE "E" AND "F" COUPLERS. PHASE 10 REPORT
The objectives of this laboratory test were to determine the moment-angle relationship in a horizontal plane for each of three coupler combinations (E-E, F-F, and E-F) installed complete with draft gear, yoke, etc., in tank car stub sills and to study the elastic-plastic behavior of failure of the various components in the assemblies. The lateral moment resistance in all three coupler combinations is of the same magnitude. The moment-angle curves exhibit an identifiable elastic and plastic range. In the higher load region, the two "E" couplers exhibited greater ductile behavior--probably due to the elongation of the knuckles. In the case of the two "F" couplers, an earlier fracture occurred with less yielding of components. In the "E" combination, the higher load portion of the curve exhibited yielding somewhat between that of the other combinations. Failure in each test occurred in the coupler shank between the horn and that portion which contacted the striker side.

B5 080298
REPORT ON COMPUTER DERAILMENT STUDY. PHASE 08 REPORT
Train accidents involving cars carrying hazardous materials have been the cause of substantial losses in recent years. This is a source of great concern to carriers, owners, and government agencies. When a derailment takes place, little is known of the phenomenon of car behavior immediately thereafter. All that is known are the end results. Inasmuch as car derailments cannot be practically duplicated in the laboratory, an analytical approach is the obvious method to use in obtaining data on derailment behavior. The objective of this study is to set forth a mathematical model to find the motions, forces and accelerations experienced by the derailed cars at each instant of time in the train derailment. The information obtained can offer a promising path to evaluate car design and train makeup as related to derailment losses. In this theoretical analysis of the derailment, the equations of motion for each derailed car are derived in general in the horizontal plane. These are then coupled with a system of constraint equations and the equation of motion for the non-derailed cars. The equations are then solved numerically (by digital computer) in their non-linear forms with the first car derailed as the sole initially assumed conditions; the ground friction, mating coupler moment and brake retarding forces are in action accordingly. A total of twenty-six (26) simulations were run to show the influence of variables on derailment behavior over a range of feasible train design parameters.

DATA DISPLAY REPORT ON RESULTS OF TESTS ON MILL PLATE SAMPLES AND SAMPLES REMOVED FROM TANK CARS INVOLVED IN ACCIDENTS. PHASE 03 REPORT
One of the primary objectives of the Phase 03 "Material Study" was to assemble, through tests, the physical, chemical and metallurgical properties of: (1) Steels currently used in tank car fabrication (mill plate samples); (2) Steel samples removed from tank cars involved in accidents. To accomplish Item 1, steel samples were obtained from several of the tank car companies sponsoring the RPI-AAR Project. These samples included both shell and head plate steels and reflected various conditions of heat treatment. Steels rolled in both domestic and foreign mills were included in the program. The steel producers are identified by a code letter only since the program objective is to establish data ranges for similar steels and not to isolate particular producers. Steel samples under Item 2 above were collected by the AAR Research Center prior to the formation of the RPI-AAR Project (Glendora, Miss.; Troup, Texas; Lehigh, Kansas) and by the RPI-AAR Project team from accidents which occurred since that time (Crescent City, Ill.; South Byron, N.Y.; Callao, Mo.; Kamloops, B.C.; Houston, Texas). Metallurgical reports have been previously issued by the Project based on examination of samples from Crescent City and South Byron. The purpose of this report is to simply display all test data in tabular and graphical form in order to make it immediately available. Analysis of results, conclusions and possible recommendations will be made in the final Phase 03 report and in the Overall Project Report. This report is organized as follows: Tables 1 through 10 list all the steel samples tested and tabulate their properties and the primary results of the tests. Figures A through K shown the location of the steel samples removed from cars involved in accidents and show their relationship to the fracutre patterns in the tank plates. Finally, the results of all the Charpy V-Notch tests are given in Figures 1 through 43, the Dynamic Tear Tests in Figures 44 through 84, and the Drop Weight Tear Tests in Figures 85 through 93.

ANALYSIS OF FRACTURE BEHAVIOR OF TANK CARS, PHASE 12 REPORT
The objective of Phase 12 of the RPI-AAR Tank Car Safety Project is to explain fundamentally the phenomena of tank car fracture behavior in accidents, particularly those fractures which led to violent ruptures. The Battelle Columbus Laboratories was engaged to conduct this research and Battelle's final report on the study is included. Battelle's charge was to examine all accident data accumulated under the RPI-AAR Project and to supplement this with tests, accident site investigations, and other studies, as appropriate, to explain why the fractures behaved as observed. Based on the results, Battelle was asked how tank car modifications would alter the fracture behavior. This was done for all observed types of fracture patterns which were catalogued in scenario fashion. Conclusions are drawn on the effectiveness on reducing accident losses of various tank car modifications, particularly in the area of steel metallurgy and tank fabrication. These conclusions will be combined with the results of the RPI-AAR Phase 02 accident review to establish cost-effectiveness for each modification. From this recommendations will be made in the Overall Project Summary Report RA-00-1-22.

COUPLERS AND TRUCK SECUREMENT. PHASE 10 REPORT
Phase 10 of the RPI-AAR Tank Car Safety Project was established to study the influence on tank car behavior in accidents of all non-tank components of a tank car. Of these components, couplers and trucks were later selected as the only significant items for study. The influence of couplers on tank car accidents was evidenced by the accident data collected for the years 1965 through 1970. During this 6 year period, 173 tank cars incurred head punctures, and of these, 148 were known to have been caused by couplers on adjacent cars. The data also showed that truck components, particularly wheels, often punctured tank car shells. Finally, of interest was the influence on the severiry of derailments (i.e. number of cars derailed and degree of jackknifing) of various coupler deisgns and the concept of truck securement. The purpose of this report is to review and discuss the results of the studies and to draw conclusions regarding functional efficiencies of current and modified coupler and truck designs toward improving tank car safety in accidents.

ACCIDENT REVIEW. PHASE 02 REPORT
This report summarizes the activities under Phase 02 of the RPI-AAR Railroad Tank Car Safety Research and Test Project. Phase 02 was concerned with the analysis of tank car accidents to determine the probability of lading loss from tank cars involved in accidents and the potential value of various design concepts that would reduce the probability of lading loss. This report summarizes the incidents of lading loss from tank cars due to mechanical damage incurred in accidents in the period 1965 through 1970, the available information on tank car utilization during this same period, and the various statistics on risk levels and loss experience that were derived from this data. The values of various design concepts are presented, and an analysis is made of the effect of overlapping effects which would result from the implementation of more than one of the concepts.

TANK CAR HEAD STUDY. PHASE 05 REPORT
During initial planning of the RPI-AAR Tank Car Safety Project, it was known that tank car heads were punctured in accidents with sufficient frequency to warrant assigning a specific Project Phase (05) for its study. The sequence of analyses and tests that were conducted under this phase were: Analysis of scale model laws for establishing feasibility of reduced scale tests; Preliminary drop weight tests on 1/12 scale tank car heads; Head impact tests on full scale old rivited tank cars; Development of head protection schemes and related cost/benefit analyses under contract to DOT; Head impact tests on 1/5 scale pressure and non-pressure cars with and without sill-head reinforcements; Head impact tests on 1/5 scale 112A340W pressure cars; Head impact tests on full scale new pressure cars to evaluate final head shield design; Analysis of all tests to correlate data, evaluate sensitivity of parameters, and predict degree of protection offered by final head shield design under various accident conditions. The purpose of this final Phase 05 Report is to present all the results under one cover, discuss them, and draw conclusions.

REPORT ON ACCIDENT REVIEW. PHASE 01 REPORT
This report summarizes the activities under Phase 01 of the RPI-AAR Railroad Tank Car Safety Research and Test Project. Phase 01 was concerned with the collection and cataloging of tank cars in an accident environment. This report summarizes the procedures used to gather and catalogue the data, the sources from which data was collected, and the organization of the data in the Project files. Much of the data was coded and transferred to a magnetic tape for computer retrieval. The data codes, format of the data tape, copies of the computer programs used to maintain the tape and retrieve information, and examples of the summary information obtained from computer analysis of the data are also included in this report.

EXTENSION STUDY OF TANK CAR BOTTOM FITTINGS-EXECUTIVE SUMMARY. PHASE 09 REPORT
In its previous study of accident data over the 1965-1970 period, the RPI-AAR Tank Car Safety Project found that the most vulnerable tank car fitting was the bottom outlet on stub-sill non-insulated non-pressure class 111A cars. However, no cost-effective means were found to protect these outlets. In the final report RA-09-1-24, it was stated that with more current accident data and additional design ingenuity, this cost effectiveness picture may be altered. As a result, this Phase 09 extension effort was undertaken. Comprehensive studies were made of: 1) All accidents involving damage to bottom fittings during the 3 year period 1971-1973 2) Current designs of bottom fittings 3) Populations of tank cars with various bottom fitting designs 4) Numerous design solutions to reduce bottom fittings vulnerability (26 for new cars and 19 for existing cars) 5) Current tank car shipper/-receiver practices and philosophies regarding top and bottom loading and unloading of tank cars. With this background, cost-effectiveness calcualtions were made for solutions for all classes of cars. As found previously, the cars with the most vulnerable bottom fittings were the stub sill cars.

REPORT ON FEBRUARY 9, 1974, ACCIDENT INVOLVING TYPE E TOP AND BOTTOM SHELF COUPLERS (4/22/74). PHASE 10 REPORT
While it has not been within Project policy to issue reports on specific accidents, a second derailment has occurred which involved the Type E top and bottom shelf coupler (The previous derailment occurred on July 1, 1973 and is reported on in RA-10-3-25, dated 12/11/73) and is of sufficient interest to warrant departure from policy. The performance of these "shelf" couplers in accidents is of vital interest in view of the Project recommendation (ref. Section VI, Report RA-00-1-22) that all new tank cars and certain existing ones be equipped with these couplers to reduce the probability of head punctures, whereas the previous derailment involved a hopper car so

equipped (L&N 191421). The car is one of 225 cars which have been in trial service to determine if any problems exist with these couplers in normal railroad operational environment, satisfactory performance being a prerequisite to adoption of the Project recommendations. Conversely, it was not expected that sufficient derailments would occur with 225 cars to make the prime objective of this trial service one of evaluating the couplers' performance in the derailment environment; however, since a second accident has occurred, it is obviously worthy of careful review.

An RPI-AAR Cooperative Project. Direct requests to the Project Director's Office, Earl Phillips.

REPORT ON JULY 1, 1973 ACCIDENT INVOLVING TYPE E TOP AND BOTTOM SHELF COUPLERS (12/11/73). PHASE 10 REPORT

While it has not been within Project policy to issue reports on specific accidents, a derailment on July 1, 1973 near Romney, Ky. is of sufficient interest to warrant departure from policy. This derailment involved a tank car equipped with Type E top and bottom shelf couplers (hereinafter referred to as "Shelf couplers"). The performance of these couplers in accidents is of vital interest since the Project has recommended that all new tank cars and certain existing ones be equipped with these couplers to reduce the probability of head punctures. The involved car, UTLX 59641, is one of 225 cars which have been equipped with the shelf couplers under a trial service program. The objective of this program is to determine if any problems exist with these couplers in normal railroad operational environment, satisfactory performance being a prerequisite to adoption of the Project recommendations. Conversely, it was not an objective to determine the couplers' performance in the derailment environment; however, since the accident has now occurred, it is obviously worthy of careful review.

An RPI-AAR Cooperative Project. Direct requests to the Project Director's Office, Earl Phillips.

B5 080373
REPORT ON ANALYSIS OF 1/5 SCALE FIRE TESTS (12/12/73). PHASE 11 REPORT

Phase 11 of the RPI-AAR Project has addressed the question of tank car exposure to fire environments with the ultimate objective of developing cost-effective methods of reducing the probability of tank car ruptures in fires. By means of accident investigations, tests, and theoretical analyses, this study has sought to determine both the characteristics of the fire environment and the tank car response to fire exposure, including the assessment of thermal stresses. The study has emphasized the Class DOT 112A and 114A non-insulated cars since they have been involved in more significant accident loss cases. The several Phase 11 activities have included a series of laboratory fire tests conducted on plates simulating tank car steels and field fire tests conducted on 1/5 scale and full scale tank cars. The purpose of these tests has been to: 1. Study a single type of fire (i.e., the all-enveloping fire); 2. Characterize the response of 112A/114A type tank cars to the all enveloping fire; and 3. Evaluate representative state-of-the-art thermal protection systems (coatings) which might be applied to such cars. In addition to the above, the data from the 1/5 scale and full scale field tests will be used to improve a computer program which has been developed to predict the transient pressure/temperature histories of 112A/114A tank cars exposed to a variety of fires, including the all enveloping type. The data will also be used to improve the laboratory fire test apparatus. Both the computer program and laboratory test will be used in the development of performance requirements and specifications for candidate thermal shield materials. A specific purpose of the 1/5 scale tests has been to prepare for the full scale tests by gaining preliminary knowledge of the fires, instrumentation techniques, methods of data reduction and analysis, and the behavior of several thermal shield materials. The complete series of fire tests has consisted of seven (7) 1/5 scale and two (2) full scale tests, all conducted in cooperation with the DOT, FRA. These tests were performed at the White Sands Missile Range, initially by personnel of the Naval Ordnance Laboratory (NOL) and subsequently by the Ballistics Research Laboratory (BRL) under contract to the DOT (FRA). Under this cooperative arrangement the RPI-AAR furnished the 1/5 scale tanks and the full scale tank cars complete with lading, appropriate fittings and safety devices. The NOL (later BRL) provided the instrumentation, conducted the instrumentation, conducted the tests, and furnished reduced data. The report presented here analyzes the data obtained from the seven (7) 1/5 scale tests. The two (2) full scale tests will be treated in a subsequent report. All seven (7) tanks were constructed to a 1/5 linear scale of a nominal 33,500 gallon DOT 112340W tank car, except that the full scale shell thickness and safety valve were maintained. Figure A is a sketch of the 1/5 scale tank and the typical instrumentation and test setup. It is emphasized that the results, and particularly the conclusions, presented here apply only to the 1/5 scale tanks, and should not be extrapolated to the full scale case. Moreover, it is emphasized that this report represents only the analyses and views of the RPI-AAR Project, and does not necessarily reflect those of the DOT (FRA).

ANALYSIS OF NAD CRANE MAINTENANCE OF WAY

The report represents an in-depth comprehensive analysis of NAD Crane's railroad maintenance of way (M/W) program. Quantitative tools have been developed to provide a rational framework for decision making for M/W. This analysis was prompted by the occurrence of numerous derailments attributed to poor track conditions. The safety aspects of derailments of hazardous material including high explosives required a thorough analysis of causes related to operations of the Ordnance Department and the Public Works Transportation, Maintenance, and Maintenance Control Division. The report presents several recommendations for the establishment of annual levels of maintenance, recommendations on the equipment required, and recommendations on the priority use of maintenance resources. INVESTIGATION OF THE FEASIBILITY OF THE DELPHI TECHNIQUE FOR ESTIMATING RISK ANALYSIS PARAMETERS
An assessment was made of the feasibility of establishing by subjective estimates inputs for a previously developed risk analysis model. The model combines data on the likelihoods and costs of accidents that could arise in the transportation of hazardous materials. It thereby develops a measure of risk suitable for comparisons of possible alternate means of transportation. This can provide information of value to decision-making on transportation safety regulations and special permits.The present report covers the potential for this augmentation through organized surveys of experts following the procedures of the Delphi technique. The Delphi experiment that was conducted is described in detail and its results, concerned with alternate means of transporting hydrogen sulfide, are presented. A Bayes procedure for combining such results with any statistical accident data that may become available is also defined.

DEVELOPMENT OF PERFORMANCE ORIENTED SPECIFICATIONS FOR DRUMS AND PAILS USED FOR PACKAGING OF HAZARDOUS MATERIALS FOR TRANSPORTATION
A study was carried out to develop performance requirements and tests for drums and pails used to ship hazardous materials. The current requirements and tests were obtained by studying DOT regulations and other standards and specifications on drums and pails. Reports on the hazards of shipping and the tests used in the packaging industry were also studied. Hazard classifications, performance requirements and tests, and a container rating system were developed. The rationale behind the development is presented in the report. Test plans for Qualification and Periodic testing and detailed test procedures were prepared. Tests included were Leak, Distortion, Pressure-Proof, Repetitive Shock (Vibration), Wet Strength-Stacking, Drop, and Puncture Tests and a Temperature Cycle.

RAILROAD TANK CAR FIRE TEST: TEST NUMBER 7
A fire test was conducted on a one-fifth scale model pressurized railroad tank car on 7 February 1973. The tank car model had a thermal insulation of four inches (10.16 cm) of polyurethane encased in a 0.125 inch (0.318 cm) steel jacket. The model was loaded with propane and then engulfed in a JP-4 jet fuel fire.

HAZARDOUS MATERIALS TRANSPORTATION (A BIBLIOGRAPHY WITH ABSTRACTS)
The transportation of explosives, rocket propellants, chemical warfare agents, industrial chemicals, liquefied natural gas, chlorine, and other hazardous materials are covered in this bibliography which contains 126 abstracts. All means of transportation are described. Accidents, economics, and statistics are also included in these reports. See also Published Search, NTIS/PS-75/285, Hazardous Materials Waste Disposal. Radioactive wastes are excluded.

EVALUATION OF COMPUTERIZED TECHNIQUES FOR PREDICTING CHEMICAL REACTIVITY AND STABILITY
The purpose of this research project was to evaluate and optimize existing computer programs based on classical thermodynamics in regard to their ability to predict chemical reactivity, stability, and cargo compatibility in ship-board situations where unusual combinations might exist. Numerous calculated thermodynamic and experimental parameters were evaluated for their ability to predict the stability (self-reactivity) and reactivity (with other chemicals) of chemical substances. Also, thermodynamic prediction of toxic combustion products was accomplished for 20 bulk-transported chemicals under varying conditions. It was concluded that the relationship between the parameters considered and chemical stability and reactivity is too obtuse for conventional statistical analysis. Subsequently, pattern recognition techniques were employed and 11 of the more promising parameters were evaluated. It was concluded that thermodynamic prediction of toxic combustion products offered greater utility in assessing the hazard of burning chemicals than present consensus rating systems (USCG-(NAS-NRC) and NFPA), and a few experimental evaluations would be desirable to confirm the validity of the thermodynamic approach.

RAILROAD TANK CAR FIRE TEST: TEST NO. 6
The Department of Transportation is conducting an extensive research program designed to develop methods to minimize personal injury and damage to property caused by fire from ruptured railroad tank cars filled with hazardous materials. The Ballistic Research Laboratories were requested by the Department of Transportation to conduct a series of field tests with scaled model and standard size railroad tank cars. The test described is one of the scaled model series which had no thermal protective coating, and where the relief valve was turned ninety degrees from the vertical.

FRAGMENTATION AND METALLURGICAL ANALYSIS OF TANK CAR RAX 201
On 28 July 1973, the Ballistic Research Laboratories performed a full-scale fire test on a 33,000 gallon, DOT 112A340W non-insulated, pressure, rail rank car for the Federal Railroad Administration and Association of American Railroads. The car was filled with liquefied petroleum gas (LPG). After 24.5 minutes of exposure to the fire, the tank car ruptured. This report concerns the mapping of the fragments and metallurgical analysis of the ruptured car, along with an investigation of the cause and initial location of failure.

COST/BENEFIT ANALYSIS OF THERMAL SHIELD COATINGS APPLIED TO 112A/114A SERIES TANK CARS
A cost/benefit analysis of thermal shield coatings on 112A/114A tank cars was performed. Thermal shield coatings are coatings which are applied to the outside of a tank to act as an insulator in the event of a fire. The intent is that the coating prevent or delay overheating and overpressurization of the tank which could lead to tank rupture and large loss of life and property. The data for the analysis were taken from Railway Progress Institute (RPI)-Association of American Railroads (AAR) cooperative research program reports. The RPI/AAR determined accident data for the years 1965-1970 and based their cost/benefit analysis on this data. In this report, the data of RPI/AAR is updated to present dollars and a re-evaluation of the accident losses is made.

B5 091314
COST/BENEFIT ANALYSIS OF HEAD SHIELDS FOR 112A/114A SERIES TANK CARS
A cost/benefit analysis of head shields installed on new and existing 112A/114A series pressure tank cars was performed based on a redistribution of accident dollar losses. Head shields are designed to prevent puncture of a tank car head during an accident with resulting loss of lading and possibly extensive fire damage. The design of the head shields and data for the analysis were obtained from Railway Progress Institute (RPI)-Association of American Railroads (AAR) cooperative research program reports. The RPI/AAR considered accident data for the years 1965-1970 and assigned accident dollar losses during that period according to the tank element that failed. Supporting evidence is presented indicating that dollar losses are strongly related to puncture distribution for a more extensive set of data including all classes of tank cars.

THE EFFECTS OF A FIRE ENVIRONMENT ON A RAIL TANK CAR FILLED WITH LPG
A 127 kiloliter (33,600 gallon) railroad tank car was instrumented and filled with liquefied petroleum gas. A large JP-4 fuel pool fire then engulfed the tank car, and measurements of temperature, pressure, etc., were recorded as a function of time. After 24.5 minutes, the car failed catastrophically via stress-rupture. Mass flow rates and a discharge coefficient have been obtained for the relief valve. An analytical expression has been derived and then used to obtain the heat flux to the wetted surface of the tank car. The rupturing of the car is briefly discussed.

DEVELOPMENT OF A COMPUTER PROGRAM FOR MODELING THE HEAT EFFECTS ON A RAILROAD TANK CAR
A mathematical model has been programmed in FORTRAN IV that represents the response to a fire environment of a railroad tank car laden with a volatile, flammable fluid. Inputs to the program include total mass of lading per foot of tank length, tank length, number and flow area of relief valves, their opening and closing pressure, thickness and thermal conductivity of exterior insulation, and array of the thermodynamic properites of the lading, its initial condition, and heat transfer coefficient and fire temperature at various points on the tank. Output includes tank pressure, temperatures of the liquid and vapor, temperatures of the interior surface of the shell, mass of liquid remaining, and location of the liquid level. These are printed for the end of every computing interval, thus indicating the history of each.

COMPARISON OF THERMALLY COATED AND UNINSULATED RAIL TANK CARS FILLED WITH LPG SUBJECTED TO A FIRE ENVIRONMENT
Two fire tests were conducted on 128 kiloliter, high pressure rail tank cars filled with liquefied petroleum gas. Both tank cars were exposed to an intense hydrocarbon fire after being outfitted with appropriate instrumentation. The instrumentation was monitored and its output recorded throughout the fire tests. To test the feasibility of insulating railroad tank cars to protect them from fire exposure, one of the cars was coated with a 0.318 cm thermal shield. A comparison of data conclusively shows that a thermal shield significantly alters the thermal response of a rail tank car in a fire environment.

RAILROAD ACCIDENT REPORT: COLLISION OF ST. LOUIS-SAN FRANCISCO RAILWAY TRAINS 3210 AND 3211, MUSTANG, OKLAHOMA, SEPTEMBER 1, 1974
On September 1, 1974, at 1:44 to 1:46 p.m., the St. Louis-San Francisco Railway Company's eastbound freight train 3210 and westbound train 3211 collided head-on 1.7 miles west of Mustang, Oklahoma. The trains were scheduled to meet in Mustang. However, train 3211 passed Mustang ahead of schedule. As a result of the collision, 4 locomotive units were destroyed, 23 cars derailed, and hazardous materials caught fire in the wreckage. As a result of the fire, eight families were evacuated from their homes. A brakeman on train 3211 was killed, and the three other crewmembers of that train were injured seriously. The National Transportation Safety Board determines that the probable cause of this accident was the failure of the crew of train 3211 to take preventive action after the train passed Mustang ahead of schedule.

CHEMICAL HAZARDS RESPONSE INFORMATION SYSTEM FOR MULTIMODAL ACCIDENTS (CHRISMA). (A REEVALUATION OF CHRIS FOR ALL MODES OF TRANSPORTATION)
This report examines the need for improved technical and other information for meeting emergencies connected with the transportation of hazardous materials, particularly actual or potential chemical discharges regardless of mode. The Chemical Hazards Response Information System (CHRIS), under development by the United States Coast Guard to furnish in-depth guidance during emergencies involving waterborne transport, was seen as a likely prototype for other modes as well. Accordingly, a reevaluation of CHRIS has been conducted to determine the desirability of enlarging its scope to encompass all modes of transportation. It is concluded that the expanded system would indeed be beneficial in reducing losses to life, property, and the environment. Necessary modifications to CHRIS are conceptually quite modest in nature. The information system would be composed of a decentralized organization providing response guidance on request to local emergency services personnel, a computerized hazard assessment system operated at Headquarters, and three reference manuals furnished to all response organizations.

A REVIEW OF VIOLENT MONOMER POLYMERIZATION: A SELECTED LITERATURE SURVEY
In recent years, there have been a number of serious explosions involving violent monomer polymerizations. As a first step in the study of the causes and mechanisms of these violent polymerizations, a 20 years literature search was performed for twelve monomers. The monomers included in the search were: acrylic acid, acrylonitrile, butadiene, 1, 3, ethylene, ethylene oxide, methyl acrylate, methyl-methacrylate, B-propiolactone, styrene, vinyl acetate vinyl chloride, vinylidene chloride. This document presents the results of the literature search, annotation and data extraction work. To maximize the utility of the findings from this effort, they are organized into the four sections that follow this introduction. Section II provides basic descriptive data on each monomer, their properties, consumption and a discussion of handling hazards. Section III is a matrix presenting the properties of the monomers. These two sections will serve as inputs for the assessments by violent polymerization risk. Section IV is the annotated bibliography organized by key work for each monomer. For the

RAILROAD ACCIDENT REPORT-SOUTHERN PACIFIC TRANSPORTATION COMPANY FREIGHT TRAIN 2ND BSM MUNITIONS EXPLOSION, BENSON, ARIZONA, MAY 24, 1973
On May 24, 1973, Southern Pacific Transportation Company's freight train 2nd BSM 22, was approaching Benson, Arizona, when 1 of 12 munitions boxcars in the train's consist caught fire. The boxcars were loaded with 500-lb. MK 82 bombs. As the train stopped, the cargo exploded, and the explosions continued for several hours. The National Transportation Safety Board determines that the probable cause of the accident was the exposure of heat-sensitive bombs in Car 38 to a fire inside the car. The fire most likely originated from sparks off the brakeshoes which ignited the sodium nitrate impregnated floorboards.
This report contains Railroad Safety Recommendations R-75-8 through R-75-10.

THERMAL HAZARD FROM PROPANE FIREBALLS
Tank trucks and rail cars containing such hazardous materials as commercial propane are often involved in accidents wherein the tanks are ruptured and fires occur. In this study, a model for determining the thermal hazard associated with the resulting fireball is developed, and the results are compared with available test data. One way to minimize the fireball hazard is to distribute the propane in the proper size container for shipment and to space the containers so that ignition of one would not result in ignition of additional containers.

RAILROAD ACCIDENT REPORT: HAZARDOUS MATERIALS ACCIDENT IN THE RAILROAD YARD OF THE NORFOLK AND WESTERN RAILWAY AT DECATUR, ILLINOIS, JULY 19, 1974
GATX 41623 and four other tank cars loaded with isobutane gas were uncoupled at the west end of Decatur Yard by a switching crew and allowed to free roll eastward on yard track 11. The car impacted an empty boxcar, and its coupler overrode the tank car coupler and punctured the tank. Isobutane escaped and vaporized for 8 to 10 minutes before it exploded. The yard, surrounding residences, and commercial facilities were damaged extensively by fire and shock waves. Seven employees died from burns, and 33 employees were injured. Three hundred sixteen persons outside the rail yard were also injured as a result of the explosion. Property damage was estimated at $18 million. the National Transportation Safety Board determines that the probable cause of the accident was the overspeed impact between the heavy cut of tank cars and the uncoupled light boxcar, which resulted from the release of the tank cars at a higher-than-acceptable switching speed. The lack of written guidelines to assist the switchman in determining the proper switching speed contributed to the accident. The crew members' lack of understanding of the risks involved in switching hazardous materials also was a contributing factor. Recommendations were made regarding tank head shields and couplers, employee training, hazardous materials accident data reporting, and regulations to limit losses in hazardous materials accidents.

PHASE 05 REPORT ON JUNE 9, 1974 ACCIDENT INVOLVING HEAD SHIELDS
The head shield was recommended as a cost effective device for prevention of catastrophic punctures of tank car heads and 104 new cars for liquefied petrolium gas service were so equipped after 1972. One of these cars was involved in a derailment on the Norfolk & Western in Iowa. While the service trial was not to evaluate the shields' effectiveness in accidents, and statistically it was unlikely that a car would be so involved, this derailment did show the shield performing well. It was not possible to conclude it prevented a head puncture definitely, but it is probable it did so. Method of attachment appears good. No conclusion could be drawn about the effectiveness of mated F couplers because of the conditions of this specific accident.

This is an RPI-AAR Cooperative Program.

B5 099182
RAILROAD ACCIDENT REPORT: HAZARDOUS MATERIALS ACCIDENT AT THE SOUTHERN PACIFIC TRANSPORTATION COMPANY'S ENGLEWOOD YARD IN HOUSTON, TEXAS SEPTEMBER 21, 1974
About noon on September 21, 1974, 2 loaded "jumbo" tank cars, cars 17 and 18 of a 145-car complement, were uncoupled as a unit at the crest of the gravity hump in the Southern Pacific Transportation Company's (SP) Englewood Yard at Houston, Texas. The two cars passed through the hump master retarder and group retarder without being slowed and accelerated as they moved down the grade into bowl track 1. At a speed of 18 to 20 mph, the two tank cars impacted an empty tank car. Upon imppact, the coupler of the empty tank car rode over the coupler of car 17 and punctured the tank head. Butadiene spilled from the car and formed a vapor cloud, which dispersed over the area. AFter 2 to 3 minutes, the vapor exploded violently; as a result, 1 person died and 235 were injured. Total damages amounted to about $13 million, which included the destruction of 231 railroad cars and substantial damage to 282 others. The National Transportation Safety Board determines that the probable cause of the overspeed impact was the failure of the retarding system to slow the two coupled tank cars and the absence of a backup system to control cars which pass through the retarders at excessive speeds. The failure of the retarding system was caused by foreign substances on the wheels of the two cars that preceded the two tank cars through the retarders. Contributing to the accident was the failure of the Southern Pacific Transportation Company to enforce procedures to exclude cars with a foreign substance on their wheels from the humping system, and the Shell Oil Company's failure, after notification of the hazard, to eliminate spilled epoxy resin from the flangeways of their track.

RISK ANALYSIS OF SHIPMENTS IN THE NUCLEAR POWER INDUSTRY
A study is undertaken to determine risks from the transportation of radioactive materials generated in the production of electricity in the United States for the period 1970-2020. Radiation exposures under conditions of both routine transport and transport accidents are considered. Movements of spent fuel, recycled plutonium, and high level radioactive solidified waste are studied. The calculated gamma dose to the growing population from all routine shipments of these materials is found to not exceed 50 persons-rems-/yr by 2020.

A SCHEME FOR RECOGNIZING CHEMICALS AND THEIR HAZARDS IN AN EMERGENCY
In recent years a number of potential emergency situations have arisen following traffic accidents or fires involving chemicals. In an attempt to minimise the danger from such incidents in the U.K., an emergency advice scheme has been established by the Chemical Industries Association (CIA) in collaboration with Central Government. As part of the scheme, chemical companies are providing information to facilitate the identification of products and their hazards, and advice for their safe treatment in an emergency. The information is being organised so that it can easily be searched using a computer-based information retrieval system. The data being collected initially are related to the requirements of the public emergency services but they can be extended to meet the needs of other organisations. Indeed, the data bank is being augmented in this way under a contract from the E.E.C.

150TH ANNIVERSARY ISSUE
The Institutions of Mechanical, Civil, Electrical and Railway Signal Engineers conducted an International Engineering Conference in September 1975 to commemorate the 150th anniversary of passenger railway. This issue has editorical comment designed to complement the papers presented at the Conference. The contents of this issue are as follows: Modern track fastenings; Developments in Welding techniques for rolling stock; Modern dc traction motor design practice; Non-ferrous brake materials; Bridge reconstruction for overhead electrification; Ferrous fittings for overhead equipment; Roller bearings for railway rolling stock; Thyristor control of traction motors; Appraisal of tank car valves and their application; Australia's railways invest in passengers; Electric cables for signalling and track to train communications; Brake blending and wheelslide protection; High speed track recording coach; Ultrasonic rail flaw detection; Flexicoil suspensions; Prestressed concrete beams for bridges; Recent developments in plain bearings; Asynchronous motor drive for locomotives; Gangway connections between long carriages; Point heaters–progress in design; Batteries for railway applications; TOPS equipment; electrical carbon and the challenge of railways; Design and cost of containers; Railway roller bearings; Computer aided design in railway signalling; Adoption of AWAC catenery on BR, Powered doors for rail vehicles; Signal control desks.

VERTICAL MOTIONS DURING RAILCAR IMPACTS
In yard type impact situations, railcars strike other railcars producing car body pitching and vertical bounce. This vertical motion, if large enough, can cause vertical disengagement of couplers which could explain the penetration of tank car ends observed in accident situations. Preliminary investigation of vertical motions during impact, using a mathematical model, has successfully reproduced simulations of impacts in the elastic range. Examples confirm the possibility of coupler disengagement or center plate disengagement of railcars undergoing high speed impact. The computer program developed will solve for horizontal and vertical coupler force, vertical motion at the trucks and couplers, and slippage between adjacent car couplers. This work was sponsored by the RPI/AAR Tank Car Safety Research and Test Project Committee and represents one phase of the overall RPI/AAR study of means to improve tank car safety in accidents.
This paper was contributed the Rail Transportation Division of the ASME for presentation at the Winter Annual Meeting, Houston, Texas, November 30-December 4, 1975.

HAZARDOUS MATERIALS TANK CARS-EVALUATION OF TANK CAR SHELL CONSTRUCTION MATERIAL
A metallurgical analysis of a steel plate sample (the Bell sample) was requested by the Federal Railroad Administration. The steel sample was taken from a tank car (number 88300) which had been involved in an accident near Bell, West Virginia. An investigation was conducted at the National Bureau of Standards to characterize the steel from the failed tank car and to determine whether the steel meets the specification AAR Tc 128-69. Another purpose of the investigation is to determine the nature of the fracture of the head plate of the failed tank car.
Sponsorship was from the Federal Railroad Administration, DOT.

METALLURGICAL ANALYSIS OF A STEEL SHELL PLATE TAKEN FROM A TANK CAR ACCIDENT NEAR SOUTH BYRON, NEW YORK
A metallurgical analysis of a steel plate sample (the South Byron sample) was requested by the Federal Railroad Administration. The steel sample was taken from a tank car (number PPGX9990) which had been involved in an accident near South Byron, New York. This sample was reported to have been produced to specification AAR-M-128-65-DTD-1966-Flange Quality-Grade B, and it was reportedly taken from the second course of shell plate of car number PPGX9990. The fracture in this course circumscribed the tank car and resulted in the division of the car into two sections. An investigation was conducted at the National Bureau of Standards to

determine if the plate sample conformed with the above Association of American Railroads (AAR) Specifications for Tank Cars and to gather information pertinent to the question of the suitability of this type of steel for use as the shell plate of tank cars.

Sponsorship was from Federal Railroad Administration, DOT.

ANALYSIS OF FINDINGS OF FOUR TANK-CAR ACCIDENT REPORTS

A comprehensive overview of the findings and metallurgical analyses of tests conducted at the National Bureau of Standards on samples of tank-car materials submitted by the Federal Railroad Administration is presented. The submitted samples were taken from tank cars which had been involved in accidents during the period January 1970 to January 1971. The testing conducted during the metallurgical analyses included full chemical analyses, ambient temperature tensile tests on longitudinal and transverse specimens, quantitative metallography to determine ferrite grain size, peralite colony size, and inclusion content, size, and shape, hardness tests, bend tests on longitudinal and transverse specimens, and a very comprehensive program of impact testing, which is covered in a separate report on Impact Properties.

PHASE 05 REPORT ON HEAD SHIELD FATIGUE TESTS

In order to reduce the probability of DOT Class 112A and 114A railroad tank car head punctures, the Department of Transportation has required that one-half inch thick steel head shields be applied to these cars. They are to be spaced in front of the tank head and are to cover approximately the lower half of the head. Recognizing the need to assure that the method of attachment of these heavy plates is adequate, the RPI-AAR Tank Car Safety Project conducted an extensive series of instrumented impact and in-train tests of four different attachment designs. Using these test data and data on predicted in-service environment, fatigue life calculations were made for each design. This report describes the entire study and concludes with a proposed specification which is recommends be adopted by the AAR Tank Car Committee to qualify candidate attachment designs.

PHASE 03 REPORT ON FRACTURE PROPERTIES OF TANK CAR STEELS--CHARACTERIZATION AND ANALYSIS

Questions of fracture characteristics of tank car steels have been fully clarified by statistical examination of fracture properties based on rational fracture mechanics criteria. It is analytically proven that brittle fracture of tank cars is not a significant problem at any temperature of service. This independent finding is in agreement with general experience based on accident investigation and analysis. A clear relationship has been demonstrated between ASTM ferrite grain size and Dynamic Tear (DT) test rational criteria (true fracture mode for full section). It is possible to examine a metallographic sample and to predict within a narrow range of temperature the type of fracture to be expected for a tank car steel. The mechanical significance of deviations from unusual grain structures (such as mixed grain size, etc.) can be understood in terms of heat treatment or fire environments-based on the knowledge generated in this study. The relationship of plastic fracture properties to tearing type rupture of tank cars at elevated temperatures has been clarified.

This is a RPI-AAR Tank Car Safety Research and Test Project.

FINAL PHASE 03 REPORT. MATERIAL STUDY ON STEELS USED IN CURRENT AND FORMER TANK CAR CONSTRUCTION AND FROM CARS INVOLVED IN ACCIDENTS

A study has been made of the steels used in the construction of pressure tank car tanks as part of the RPI-AAR Tank Car Safety Research and Test Project. The number and type of tests made represent the most comprehensive ever performed on tank car tank steels. Fracture toughness properties are not a part of the material specifications for tank car tanks except for certain low temperature applications. None-the-less, the fracture toughness properties were determined using the Charpy V-notch Test, Drop Weight Tear Test, Dynamic Tear Test, and NDT Drop Weight Test for current, accident, and old materials. The fracture properties obtained represent the best properties that are technologically attainable for the current steels for the heat treatment employed. For TC128-B material, no significant transition temperature improvement can be achieved by changing to other pearlitic type steels. It was concluded that the TC128-B steel is an optimum product for the service and that changes are not justified on the basis of the fracture properties.

This is a RPI-AAR Tank Car Safety Research and Test Project.

THE TORSIONAL STRENGTH OF BOGIE WAGONS [Der Verwindungswiderstand von Drehgestell-Guterwagon]
The number of wagons with torsional rigidity and widely spaced bogie king pins is increasing. The greatest attention should be given to the constructional rigidity of wagons. The author gives comments on calculations for a tank-wagon design in which torsional strength does not endanger safety against derailment. He adopts as a basis the test results of the ORE B 55 Specialists Committee on "Prevention of derailment of goods wagons on distorted track", and on the estimated derailment of an empty 102-tonne tank wagon. PHASE II REPORT ON FULL SCALE FIRE TESTS
This report presents an analysis of the results obtained in two tests of propane-laden DOT class 112/114A340 tank cars completely immersed in all-enveloping fires generated using JP-4 fuel. In the first test, an uninsulated car (RAX 201) ruptured at a pressure of about 335 PSIG after 24.6 minutes exposure to the fire. The safety valve incorporated on this car limited the maximum tank pressure to less than 350 PSIG, even in the all-enveloping fire. However, a rise in the temperature of the unwetted upper section of the steel shell to about 1200 degrees F precipitated rupture when the tank was about half full of liquid propane. In the second test, car RAX 202, insulated with a spray-on thermal protective coating, ruptured after about 93.7 minutes exposure to fire. With a heating rate averaging about 12,100 btu/hr/sq ft (43% of the 27,650 btu/hr-sq ft average from the first test), the longer time to rupture in this test is not solely due to insulation, as lower fire temperatures and other variables played an important part. As in the first test, rupture was precipitated by a rise in unwetted shell temperature to levels at which the shell strength could not withstand even the reduced tank pressures. As well as can be determined, it appears that the shell failure was initiated in an area which contained flaws or non-uniformities in the insulative coating.

B5 130842
PHASE II REPORT ON SPECIFICATIONS FOR THERMAL SHIELD SYSTEMS ON DOT 112A (114A) TANK CARS
This study was prompted by the need to find a thermal shield system which will reduce the probability of rupture of DOT 112A(114A) tank cars in accident fires. Importantly, this will reduce the severity of the "chain reaction" type accident wherein a fire initiates from one car in the derailment and causes a sequence of thermally induced rupture of other cars. This study is directed toward insulation-steel jacket type systems; however, the proposed thermal qualification criteria apply equally well to any type system, including sprayed-on coatings. Over a hundred fire tests of various materials were conducted on a specially constructed laboratory apparatus at the AAR Technical Center using both "pool" fires (1550-1650 degrees F flame) and "torch" fires (2100-2200 degrees F flame). Data from two full scale fire tests and many accidents were used in developing this apparatus. Several of the attractive materials were also tested in full scale torch fires at the FRA Pueblo Test Center. With available clearance on many existing cars limited to one inch, most tests were conducted on materials near this thickness. The report concludes with a recommendation that the laboratory apparatus be adopted as a qualification device with acceptance criteria being that the candidate system not allow the back side plate (representing the tank car shell) to rise above 800 degrees F. The time criteria will be later developed from further correlation tests between the laboratory and Pueblo facilities; however, 35 minutes appears a probable time for the torch test.

A METALLURGICAL ANALYSIS OF FIVE STEEL PLATES TAKEN FROM A TANK CAR ACCIDENT NEAR CRESCENT CITY, ILLINOIS
A metallurgical analysis of five steel samples (numbered FRA-1 through FRA-5) was requested by the Bureau of Railroad Safety, Federal Railroad Administration, Department of Transportation. These steel samples were taken from two tank cars (numbered SOEX 3037 and SOEX 3219) which had been involved in an accident near Crescent City, Illinois. Sample FRA-1, FRA-4, and FRA-5 were reported to be shell plates and sample FRA-3, a head plate. Sample FRA-2 was a welded sample of head plate and shell plate and it was used for most of the mechanical properties determinations in this report. An investigation was conducted at the National Bureau of Standards to determine if the samples conformed with the appropriate specifications for tank car materials and to gather information pertinent to the question of the suitability of these steels for use as plate materials of tank cars. Samples FRA-1,-2, and-5 were reportedly produced to the specification for ASTM A 212-65 Grade B, flange quality steel (A 212-B); and FRA-3 and-4 were reportedly produced to specification AAR M128 Grade B, flange quality steel (M128-B).

RAILROAD ACCIDENT REPORT: BURLINGTON NORTHERN, INC., MONOMETHYLAMINE NITRATE EXPLOSION, WENATCHEE, WASHINGTON, AUGUST 6, 1974
At 12i32 p.m. on August 6, 1974, a shipment of monomethylamine nitrate solution (PRM) detonated during routine switching operations in the Burlington Northern Inc. Apple Yard in Wenatchee, Washington. The explosion killed 2 persons, injured 113, and destroyed equipment and buildings. Estimated losses exceeded $7,500,000. The National Transportation Safety Board was unable to determine the probable cause of the accident. A partial list of the possibilities that could not be ruled out completely includes a reaction of dried crystals, a reaction of spilled or leaking crystals in the insulation space, a reaction in one of the tank components, cavitation and recompression of the solution, compression of an air bubble entrained in the solution, a reaction of solution or crystals sensitized by contamination, or the ignition of escaped product by friction. The Safety Board concludes that the classification of monomethylamine nitrate as a "flammable solid" permitted shipment of the chemical without proper safeguards against predictable hazardous conditions. The National Transportation Safety Board made five recommedations to the Department of Transportation.

MECHANICAL PROPERTIES OF AAR M128-69-B STEEL PLATE SAMPLES TAKEN FROM INSULATION FIRE TESTED TANK CAR RAX 202
Studies were undertaken to measure the elevated-temperature mechanical properties and to determine the elevated-temperature fracture behavior of selected AAR M128-B steel plates. In addition, the ambient-temperature mechanical properties were measured to determine if the requirements of specification AAR M128-69-B were satisfied. The NBS results of check chemical analyses, hardness surveys, thickness measurements, macroscopic observations, and metallographic analyses of the plate samples had been reported previously. The results of hot-tensile tests showed a continuous decrease in strength properties and an increase in tensile ductility as the test temperature was increased from 1100 F to 1250 F. An analysis of stress-rupture data for specimens from all plate samples in the same temperature range indicated that a straight line in a log-log plot of initial stress versus rupture life reasonably represented the data at each test temperature. In the temperature and stress range studied, a decrease in the initial stress of about 20 to 30 percent resulted in a twelvefold increase in rupture life from 15 minutes to three hours. A comparison of the results of the metallographic analysis of hot-tensile and representative stress-rupture specimens with the previously reported metallographic results on the initial rupture site in the failed shell course indicates the presence of the identical fracture mode. This mode is characterized by many intergranular voids which originate primarily at the proeutectoid ferrite-pearlite boundaries. These results confirm the previously reported finding that the initial ruture of the tank car was a stress-rupture crack.

Sponsorship was from Federal Railroad Administration, DOT.

COLLISION TEST OF RAILWAY CAR AND DUMP TRUCK (SECOND SERIES)
Collision test of actual cars is one of the projects for the prevention of railway crossing accidents. The shock, the movement and the deformation of the car body are investigated by the test using actual railway cars and dump trucks at a railroad crossing, and furthermore it is examined how passengers and drivers are affected by the collision. Problems on collision are divided into five items as follows: (1) Shock deceleration, (2) Velocity change and mean deceleration, (3) Deformation of front surface of car, (4) influence on passengers and drivers, (5) Prediction of train collision.

A TRAIN DETECTOR FOR LEVEL CROSSING PROTECTION
A train detector for the use of the level crossing alarm initiation was developed. It does not require any exclusive line wires between the detector and the crossing like in the standard type detector now in use in JNR. The detector is attachable to any part of a conventional AC track circuit and can detect approaching trains by decrease of track voltage to specified value. The detected information is transmitted to the crossing with a carrier frequency over a pair of existing line wires. The effect of attaching the detector on the track relay is negligibly small.

RAILWAY ACCIDENTS IN GREAT BRITAIN DURING 1965
Railway accidents in Great Britain increased by 59 to a total of 1,268 in 1965. The greatest increase was in "other cause" accidents. Malicious acts by the public increased from 76 to 111. Technical defects were responsible for 227 train accidents compared with 259 in 1964. There was a 20 percent increase in 1965 in the rate per million train miles of significant accidents for passenger and freight trains. Maximum permitted speed of freight trains with four-wheeled short wheelbased wagons was reduced from 50 to 45 miles per hour. Total fatalities was 162 compared to 167 in 1964. Of these, 19 occurred in train accidents compared with 30 in 1964. Passenger fatalities numbered 28 of which 2 occurred in train accidents. Overall fatality rate was 1 in 690 million passenger journeys. Railway staff fatalities increased by 7 percent. The accident rate at public level crossings increased over the past two years from 32 to 47 accidents per 1000 crossings. During 1965, 41 public crossings were equipped with automatic half barriers bringing the total number so equipped to 56.

ACCIDENTS ON BRITISH RAILWAYS IN 1960
A comparison of accidents, deaths, and equipment failures for the years 1959 and 1960 show that there were a total of 1213 train accidents in 1959 (1175 in 1960). Out of these, passenger and freight trains were involved in 416 in 1959 (415 in 1960). The total accidents at level crossings were 231 (1959) and 242 (1960). Deaths at level crossings totaled 37 (1959) and 35 (1960). Railway personnel deaths were 160 (1959) and 143 (1960). Failures, including engines, couplings, and rails amounted to 1271 in 1959 and 1395 in 1960.

THE PROBLEMS OF CALCULATING RESPONSE INTERVALS FOR FLASHING LIGHTS (AND GATE PROTECTION) AT RAILWAY GRADE CROSSINGS
The length of the response interval for flashing light signals to be activated depends upon the approach time of the highway vehicle, the speed of the train, and the relationship between certain signalling and operational conditions. Since safety requires the assumption of the fastest train when calculating the response interval, slower trains and trains that come to a stop before reaching the crossing impose longer waiting times, and cause annoyance to the highway users. This can be avoided by having the response made sensitive to the speed of the train, which will cause the response interval to be adjusted accordingly. This article describes this system, presenting mathematical equations, charts and tables of the data.

OPERATING TRAINS ON ELECTRIC VISION--WHY AND HOW?
The author presents the signalling system of today as an example of the way in which much of the present state of the art of the railways reflects the developments from past methods and states of the art. New techniques have been superimposed onto the old, without changing the fundamental principles. A new system is envisioned where the operations would be through constantly moving blocks, with a predetermined time interval controlling the movement of the trains. This system is described in considerable detail, as also its advantages in congested train conditions. Complete safety of operations, including the absolute protection at railroad crossings at grade, and protection to maintenance of way workers, as well as supervision of compliance with speed restrictions, are included in the

functions of this system. Economic considerations are also dealt with. The characteristics and simplicity of this system makes it suitable for application to all transportation systems, including urban rapid transit.

SAFETY ON THE INDIAN RAILWAYS
This is primarily a review of the safety record of Indian Railways. This analysis, for 1962-63, 1963-64, and 1964-65, differentiates between significant and other accidents, such as collisions at level-crossings, fires in trains, and running into cattle and other obstructions. Accidents caused by train-wrecking are included under derailments. Partings of trains which have not resulted in collisions or derailments are excluded, as are other types of failure. In general, there was a substantial drop in accidents in recent years following a big rise in traffic over the last decade and a half. Detailed data are presented throughout the article.

A PROGRAM DEFINITION STUDY FOR RAIL-HIGHWAY GRADE CROSSING IMPROVEMENT
The report describes in general terms the present status of grade crossing inventories, improvement programs and other significant considerations. It identifies available information with respect to the cost of accidents and motor vehicle operations, as well as the preparation of estimates of the number of crossings in classes related to the volume of train movements and the volume of vehicle traffic. From these estimates, the number of crossings at which improvements would yield benefits in excess of costs was estimated, together with the reduction in accidents which those improvements could be expected to bring. It develops a five-year program of study related to policy formulation, program administration and research; also, it identifies and describes projects which can be initiated as action programs, research and special studies. This includes a recommended program to correct data deficiencies and develop a comprehensive information system. (Author)

TECHNOLOGICAL INNOVATION IN GRADE CROSSING PROTECTIVE SYSTEMS
The constraints on innovative grade crossing protective systems are delineated and guidelines for development indicated. Inventory data has been arranged to permit an estimate of the classes of systems needed, the allowable costs, and contribution of various types of crossings to accidents. A number of approaches are discussed for the intermediate cost classes, based on use of conventional signals with low-cost activation systems. Use of similar elements, singly or in combination, is suggested to improve effectiveness of more expensive systems. The very high cost locations may well benefit from interconnection of train and vehicle detectors and small computers. Extensive analysis and laboratory investigation has been carried out relating to a microwave telemetry alternative to conventional track circuits and possible crossing-located radar and impedance train detection systems. THE VISIBILITY AND AUDIBILITY OF TRAINS APPROACHING RAIL- HIGHWAY GRADE CROSSINGS
The study investigates devices and color schemes, proposed or in use on locomotives, which serve to make the train visible or audible to motorists approaching grade crossings. A color scheme using two contrasting colors, each color at least 3 1/2 x 5 feet in area, is recommended for visibility at 1000 feet. One color should be very bright, such as fluorescent or bright yellow. Two high-output xenon strobe lamps are recommended, one on each side of the cab roof, to flash alternately whenever the train is moving. At night, lighted panels are recommended as supplements to the strobe lamps. The sound level required to reliably alert a motorist was found to be 105 dB just outside the vehicle. In high speed encounters, present horns cannot reliably warn motorists early enough. A horn with enough output to be totally effective would not be an unacceptable nuisance. The report includes a bibliography and tables of required ranges. (Author)

THE U.S.A. ACCIDENT SITUATION
In 1941, 5,086 persons were killed and 37,811 were injured on the lines covered by the report, the figure for fatalities shows an increase of 10-28 percent over 1940 nearly the same percentage increase 10-87 as in the number of train-miles the total for which was 969,000,000--making a fatality rate of 5.25 to one million train-miles. These injuries increased, however, by 27.78 percent to 39 in every million train-miles, a higher rate than for the previous three years. The distribution of casualties by types of accidents shows that the highest figures were caused by accidents at level crossings and to persons who were struck or run over at other points. Over 3,600 train accidents in 1941 were attributed to defects of some kind, and over 4,000 to negligence.

RAIL-HIGHWAY GRADE CROSSING SAFETY IMPROVEMENTS ARE SUGGESTED BY TEAM
Technical study of 36 rail-highway grade crossings by a diagnostic team has provided safety recommendations. New advance warning signs were designed and standards for application were prepared. These standards covered the following types of crossings and visibility conditions--protected crossing with obstructed view, protected crossing with unobstructed view, nonprotected crossing with obstructed view, and nonprotected crossing with

unobstructed view. These new standards were implements at eight rail-highway crossings. Evaluations of the crossings using the diagnostic team showed that the advanced warning signs were highly effective.

ACCIDENTS IN 1954
The number of train accidents increased slightly in Great Britian, over 1953; however, there were no passenger fatalities and the total fatalities in all rail movements was the lowest recorded, 0.5 per million train miles. The total main-line train mileage decreased slightly over 1953. The progressive decline in cases due to failure to obey signals was maintained. An encouraging trend was again recorded in accidents resulting from technical defects, probably reflecting better attention to detail in routine maintenance and examination. Warnings to children in schools and at home, and improved fencing of the lines, have led to a continual decline in the number of trespassers killed or injured by contact with live rails. Accidents at grade level crossings continue to be a problem. New signalling methods are briefly introduced.

SIGNALLING ON A MODERN RAILWAY SYSTEM
Signalling techniques on the railways have progressed through the manual block system to the Centralized Traffic Control, where the movement of trains is controlled from a central headquarters, with the track display of a district and the appertaining switch and signal actuating equipment located in the usual desk arrangement, observed and operated manually. Interlocking of crossings at grade are included in this system. The longer braking distances resulting from the 200 km/h and more operation presently necessitate modification of this system to include continuous automatic train control, which can be projected ultimately to automatic train operation and travelling on instrument vision. This article describes the use of computers for this type of control of trains. The computers are presently used for indirect control of train movements through existing signal equipment. The problems of extending this system to direct control of train movements are under consideration. The question whether the direct control of trains is possible or economical without local interlocking frames is at present unresolved. [German]

MANY SIGNS POINT TO SAFER GRADE CROSSINGS
For the fifth straight year, deaths from railway-highway grade crossing accidents declined in 1971. The 1970-71 drop in fatalities was 5.3%. The more optimistic outlook for safer grade crossings is due to several factors, among them more interest and funding for protection equipment by government agencies, improved and expanded driver education programs, improved signs and markings at crossings, and improved devices and systems of crossing protection equipment. Grade crossings statistics for the years 1951-71, and a Buyer's Guide for Crossing Protection are included.

GRADE CROSSING SAFETY GAINS
Rail-highway grade crossing safety is now receiving attention from all levels of government-federal, state and local-the railroads and manufacturers of crossing protection equipment. Factors important to grade crossing safety include the following: Grade crossing accident fatalities represent 2-3% of the total killed on U.S. highways each year; Federal, state, county and city aid are available for installation of automatic protective devices; Nine manufacturers provide automatic protection devices and/or controls in an annual market of approximately $12 million; Automatic flashing-light signals with or without gates are being installed at 1300-1500 rail-highway grade crossings each year.

HOW TO MAKE CROSSING SIGNALS MORE OBSERVABLE TO DRIVERS
About one-third of all grade crossing accidents occur at crossings protected by flashing-light signals. The most common signal in use at crossings today is one in which the horizontal spread angle is 30 deg. and the vertical deflection angle is 14 deg. The minimum brightness necessary for a flashing red signal to be detected in daylight has not been accurately determined but it seems that it probably lies between 100 and 400 candelas for a lamp the size of a crossing signal. Two new bulbs are described; the reflectorized bulb and the quartz-iodine bulb.

CROSSING HAS ONE CIRCUIT
A rail highway grade crossing on the East Erie Commercial at Erie presented some problems since the track is used by General Electric for testing of locomotives and transit cars. The track is equipped with catenary for 50,000 volts at 60 or 25 Hz, and speeds can vary up to 80 miles per hour. Due to light trains a very high shunting sensitivity was required of the track circuit. Due to varying speeds, a constant warning time was required. Also, insulated joints were to be avoided. Transcontrol Corp. furnished a jointless, center fed track circuit using 387 Hz energy modulated at 180 code per minute. The constant warning time unit uses a short measuring section just ahead of the approach track circuit on each side. This unit meets all fail safe requirements.

CROSSING SAFETY DEPENDS ON GOOD MAINTENANCE
It is estimated there are 231,750 highway-railroad grade crossings in the United States. Of these, 20,730 were protected by highway crossing signals, gates or other active protection devices for the motorist. To be useful, these protective devices must be maintained in proper working order for use at anytime. Annual maintenance charges may range from $650 for the simplest type crossing signal to $1,250 for a gate installation.

This article was originally a paper presented at the 4th Annual Crossing Safety Conference of the AAR, held at Ohio State University, Columbus, Ohio, on August 29-31, 1972.

REPORT TO CONGRESS. RAILROAD-HIGHWAY SAFETY PART II: RECOMMENDATIONS FOR RESOLVING THE PROBLEM
A comprehensive analysis is made of the railroad-highway grade crossing problem nationwide. An economic analysis is employed to assess the need for improving public grade crossings. Alternative levels of improvement needs on a nationwide basis are set forth including the number and type of improvements, costs, anticipated reductions in accidents and casualties, and total benefits. Alternative methods of financing an expanded program of public grade crossing improvements are presented to aid the Congress in their deliberations on this matter. An equitable allocation of improvement costs among the railroads, the Federal government, and others is recommended. Specific attention is given to the problems of pedestrian safety along railroad rights-of-way in densely populated urban areas; private crossings; high-speed rail corridors; and railroads in urban areas. AUTO-TRAIN DERAILED IN CROSSING ACCIDENT
Southbound Auto-Train No. 107 was derailed early on the morning of March 13 at Hortense, Ga., after being struck by a pulpwood truck at a grade crossing. No. 107 consisted of two diesel units and 30 cars. It was carrying 298 passengers and 107 automobiles, and was reportedly traveling at 70 to 75 mph. The pulpwood truck, loaded and moving at high speed, is said to have ignored crossing signal lights, plowing into the second diesel unit, causing the derailment of both units and 27 of the 30 cars. The truck driver was killed. Of the 298 passengers, only 35, along with three crew members, were hospitalized. All but four passengers were released. An adjustment to Auto-Train's daily schedules from Lorton, Va., to Sanford, Fla., to trips southbound on odd dates and northbound on even dates has been placed in effect until equipment can be repaired and returned to service. Auto-Train pointed out that this is its first derailment since service was inaugurated Dec. 6, 1971--900 trips have been operated since that time.

B6 044313
RAILROAD--HIGHWAY VEHICULAR MOVEMENT WARNING DEVICES AT GRADE CROSSINGS
Railroad operations have for many years been plagued with poor safety performance at grade crossings. Many lives are lost each year in accidents at crossings, to say nothing of costly injuries and property damage sustained. The situation has gotten worse with the advent of the soundproofed car, being driven at high speed in conditions of poor visibility. Clearly then some improved method of warning motorists as they approach a grade crossing is needed. Analysis of a critical encounter between a road vehicle and a locomotive reveal that the presently used equipment is inadequate to meet the needs of present day high speed vehicles. A system of vehicular movement warning devices is described in this paper, that might improve to some extent, the safety of grade crossing operations. Two methods are detailed; one involves static directional sonic devices positioned at the crossing; warning activation is made on a real time closing velocity determination. The other system employs a special variety of cattle guard in the roadway, to issue a tactile warning. Both systems are designed to give adequate warning to a motorist in a critical encounter situation as he approaches the crossing with a convergent locomotive on the track(s). A bonus feature in the use of selectively activated static directional sound warning sources, would be the curtailment of urban noise levels, where trains presently use the mobile audible source to issue warnings.

This paper was recommended by the IEEE Land Transportation Committee of the IEEE Industry Applications Society for presentation at the 1973 Joint ASME/IEEE Railroad Conference, St. Louis, Mo., April 11-12, 1973. The price is $1.35 for members.

NATIONAL CONFERENCE ON RAILROAD-HIGHWAY GRADE CROSSING SAFETY, AUGUST 29-31, 1972
The keynote speaker of the conference noted that 12,000 motor vehicle-train collisions occur annually. Papers presented are addressed to problems of reducing this number through technology or by altering present traffic patterns. The solution of universal grade separation seemed to be too expensive an investment, and lines of authority and responsibility are not clear. The large number of crossings that carry low volumes of both vehicular traffic and railroad movement complicate possible solutions economically. The technology of passive devices and protective and warning needs were studied.

DEVELOPMENT OF WARRANTS FOR RURAL AT-GRADE INTERSECTION ILLUMINATION
A methodology is formulated that measures the effects of illumination of rural at-grade intersections in quantifiable terms. Previous research indicated that accident reduction is a valid criteria for evaluating lighting effectiveness. The effectiveness of illumination in modifying seven accident measures was evaluated by an analysis of variance. No significant relationship between accident severity and illumination could be inferred from the data. A predictor of accident reduction was developed based on the ratio of night accidents to total accidents after illumination. Values derived using the predictor were found to agree reasonably well with actual values obtained in two previous studies. (Author Modified Abstract)

FACTORS INFLUENCING SAFETY AT HIGHWAY-RAIL GRADE CROSSINGS
In 1961 motor vehicle accidents at highway-rail grade crossings numbered 2,931. In the accidents, 1,173 people were killed and 3,031 people were injured. The highway fatality rate at highway-rail grade crossings is disproportionately high when compared to the national total. Furthermore, almost one-third of the accidents occurred at crossings protected by audible and/or visible signals, 56 occurred despite lowered gates, and 88 occurred in the presence of trainmen or watchmen. It was with these thoughts in mind that this project was initiated by action of a joint committee of the American Association of State Highway Officials and the Association of American Railroads meeting in Miami, Florida, on December 6, 1962. Experimental and conventional signs for crossing protection were designed, installed, and tested in the field. A motion picture of the signs installed in the field was made and a group of engineers subjectively rated the experimental signs. Research findings include the development of a mathematical model for predicting accidents. The model was based on accident data obtained from a wide variety of private sources, state highway departments, and regulatory agencies. From the Interstate Commerce Commission the investigators obtained more than 15,000 accident reports spanning a five-year period. Warrants and criteria for the improvement of railroad crossings are presented in a graphic form.

DRIVER INFORMATION SYSTEMS FOR HIGHWAY-RAILWAY GRADE CROSSINGS
The first objective of this research was to evaluate driver attitudes concerning hazards at highway-railway grade crossings. Respondents considered highway-railway grade crossings relatively more hazardous than other potential highway hazards but considered none of the potential hazards to be very serious. The second objective was to evaluate the economic priorities for improving railroad grade crossings relative to eight other highway improvements. Respondents considered safety at highway-railway grade crossings to be very important. The third objective was to evaluate driver preferences for information systems to be used at highway-railway grade crossings. An overhead changeable-message sign was the most preferred alternative method of warning. The fourth objective was to evaluate driver preferences for messages to be used in an information system for highway-railway grade crossings. The respondents preferred information even when no train was present and preferred full words rather than abbreviations.

CROSSING PROTECTION HAS HIGH INTEREST
It is evident that there is considerable interest in railroad-highway grade crossing safety. And at long last, it appears that Congressional legislation will provide funds for grade crossing protective devices. Heretofore, any federal funds allocated for "increasing safety at rail-highway grade crossings," usually were for grade separations, improved signing and sight distances at existing grade crossings. However, there is some support in the Congress to provide funds for grade crossing protection equipment.

SPEED PROFILES AND TIME DELAY AT RAIL-HIGHWAY GRADE CROSSINGS
Concern for railroad-highway grade crossing safety prompted the Department of Transportation to develop and implement more effective protective systems. The purpose of the study was to provide a data base reflecting the behavior of motorists in the vicinity of crossings. Crossing parameters of urban/rural, two/four lane, high/low volume and active/passive grade crossing protection were considered in the selection of 26 crossings for instrumentation. At each site, the highway was instrumented at five points in each lane using the Traffic Evaluator System. The resulting magnetic tape permitted determination for each of over 40,000 vehicles at each point, speed, lane changing behavior, headway, wheelbase, and number of axles. Manual inputs were made to the system to indicate vehicles which were required to stop at the crossing, the activation of protective devices, the arrival and departure of trains, and train speed. The data base was organized to verify and improve an existing traffic flow model designed to provide information on motorist speed and time delay at crossings.

RAILROAD/HIGHWAY ACCIDENT REPORT. PENN CENTRAL FREIGHT TRAIN/SCHOOLBUS COLLISION NEAR CONGERS, NEW YORK, 24 MARCH 1972
The report describes a schoolbus freight train collision at a railroad highway grade crossing. As a result of the accident five students died, and the bus driver and all 44 remaining students were injured. None of the train crew was injured. The National Transportation Safety Board determines that the cause of the accident was the failure of the schoolbus driver to stop at the stop sign until the crossing was clear of railroad traffic. Contributing to the accident was the unnecessary routing of the schoolbus over a not specially protected railroad/highway grade crossing.

VIEWING OF RAILWAY FLASHING LIGHT SIGNALS
An attempt is made to bridge the gap existing between theoretical knowledge and published material on the one hand, and the practical application to an efficient outdoor flashing light warning system for railway purposes, on the other. The relative effectiveness of flashing light highway crossing signals under the full range of environmental conditions likely to be experienced in service is determined by many diverse factors, the principal ones being contrast brightness, apparent brightness magnitude, intensity of light output, signal colour, alignment and focusing of lights, and signal range. An examination is made of the above items and conclusions are drawn as to the minimum standards necessary for optimum viewing.

CROSSING SAFETY IMPROVES YEARLY
Safety at railroad-highway grade crossings has shown a steady improvement. More grade crossings are being protected with automatic devices and the number of accidents at crossing is declining. Additionally, there is optimism for continued improvement, due mainly to a greater public awareness that is manifesting itself in federal legislative action to provide more funds for grade crossing protective devices to be installed, not only at federal-aid highways, but at other highways as well. The recently passed Federal Aid Highway Act of 1973 includes specific moneys for installation of protective devices at railroad-highway grade crossings.

B6 048183
ROAD-RAIL PROTECTION--AUDIBLE WARNING EFFECTIVENESS
Audible warning is becoming progressively less effective with modern high speed road traffic and noisy vehicles interfering with reception. Subjective examination of warning sounds can be misleading as the ear does not directly compare sound pressure levels. Sound reduces in intensity in accordance with the inverse square law. To double the range of hearing, a fourfold increase in pressure level is required. Suggestions are made on changes in methods of road vehicle operation which would take into consideration high winds and other factors and improve overall safety on crossing approaches. Suggestions are also made on improvements to roadside audible warnings and standardisation of audible signals that it would be practical to carry out without degradation of the total environment. It is concluded that audible warnings still play a vital part in road-rail protection. In many instances revised motor vehicle operation could lead directly to a substantial reduction in the serious type of collision with high noise level road transports during periods of high winds, and an overall improvement in protection levels.

RAILROAD CONSOLIDATION AND RELOCATION
This case study points out the complexity of the railroad "problem" in a medium-sized city, and it shows how one solution is being achieved through public sector and railroad cooperation. This situation posed by rail operations is common in most cities where downtown and urban area railroad crossings create traffic problems and safety hazards. The solution in Lincoln, Nebraska offers one type of legal and financial arrangement possible. Of most importance in this case study is the basic recognition that the city and the railroads shared a problem which is being solved by joint efforts. Lincoln was one of the first cities to come to grips with the "railroad problem" and its relationship to highways and community redevelopment. It offers an example to others across the nation. A recent Federal Railway Administration (FRA), Department of Transportation, study proposal listed the Lincoln program as a primary reference for analysis of railroad and urban area coordination.

PROCEEDINGS 1972 CONFERENCE ON RAILROAD-HIGHWAY GRADE CROSSING SAFETY. 29-31 AUGUST 1972, HELD AT OHIO STATE UNIVERSITY, COLUMBUS
The objective of the conference was to bring together key interest groups to discuss new ways and means to insure increased safety and to achieve optimum efficiency in the use of both highway and railroad facilities. The report contains presentations made by various experts in railroad, highway, and urban affairs. Individual sessions were devoted to urban railroad problems; train-activated rail-highway protection; passive devices at rail-highway crossings; implementation of major crossing protection programs; warrants for safety improvements at crossings; and maintenance of automatic protection devices at grade crossings.

HUMAN FACTORS COUNTERMEASURES TO IMPROVE HIGHWAY-RAILWAY INTERSECTION SAFETY
A field demonstration study in support of the evaluation of alternative railway-highway grade crossing accident countermeasures was conducted. Guidelines were provided for the development of countermeasure concepts. Investigations of the causative factors of accidents showed that maintenance of protective warning devices, driver attention and driver expectancy were precipitating and predisposing factors in accidents. An appraisal of inherent driver safety potential was made which included driver education and licensing, safety programs and law enforcement, attitude and habit components of railway-highway safety and psychophysiological capabilities and limitations. A broad base of data was obtained in a demonstration field study conducted in five states. (Modified author abstract)

GRADE CROSSING PROTECTION IN HIGH-SPEED, HIGH-DENSITY, PASSENGER-SERVICE RAIL CORRIDORS
The report is a preliminary examination of special aspects of grade crossing protection for operation of high-speed passenger trains in rail corridors for which complete grade separation is not possible. Overall system needs and constraints are indicated, and their implications examined. Applications of conventional and improved hardware is considered, with special attention to activation criteria, appropriate motorist-warning devices, stalled-vehicle indicators, and train-mounted components. Non-technical aspects of the problem are also discussed, and areas for which future research efforts may be appropriate are identified.

AN EVALUATION OF SAFETY AT HIGHWAY-RAILWAY GRADE CROSSINGS. FINAL REPORT
An attitudinal survey was used to evaluate driver attitude concerning the hazard at railroad grade crossings, citizen appraisal of properties for improving grade crossing safety, driver evaluation of possible warning systems for crossings, and the development of the general design of a proposed new advance warning system. The research indicates that the respondents considered railroad grade crossings more hazardous than several other highway hazards. However, all hazards were, at most, only considered moderately hazardous. The improvement of safety at railroad grade crossings was given high priority by the respondents. An overhead changeable message sign was the most preferred method of warning at railroad grade crossing. It was concluded that a field installation is desirable. (HSL)

ENHANCEMENT OF TRAIN VISIBILITY
The report describes a study of the most effective and practical means of enhancing the conspicuity of the trailing end of trains, in order to reduce the possibility of train--train collisions. There are five elements: (a) Definition of a usable number of categories of target, background, and ambient conditions which include the great majority of situations actually encountered; (b) estimation of the stimuli required for each category to increase significantly the detection probability for typical observers; (c) examination of all potentially feasible visibility aids in terms of these criteria; (d) determination of estimated costs, lifetime, and power consumption of techniques which appear promising in terms of effectiveness, and (e) delineation of alternative systems, consistent with one another, comprising a hierarchy of effectiveness and cost. Special deficiencies, advantages, and implications for policy which may be associated with particular realizations are indicated. The devices suggested as optimal include large areas of fluorescent material arranged in a distinctive pattern, retro-reflectors at each corner, and flash lamps of moderate intensity. Detailed specifications are given for such aids.

ECONOMIC ANALYSIS OF GRADE CROSSING IMPROVEMENTS
A Rail-Highway Crossing Study was initiated by the Chicago Transportation Study in 1972. The project goal was to develop an analytical tool which

could identify optimal capital investments for improvements to the 3,100 at-grade crossings, and replacements of the 2,000 grade-separated crossings within the region. Using the analytical results, the project set regional priorities for feasible improvements to, and replacements of, rail-highway crossings.

ELIMINATION OF LEVEL CROSSINGS ON THE STRASBOURG-BASLE LINE IN THE HAUT-RHIN DEPARTMENT [SUR LA LIGNE STRASBOURG-BASLE SUPPRESSION DES PASSAGES A NIVEAU DANS LE DEPARTMENT DU HAUT-RHIN]

The Assistant Regional Manager of the SNCF who is the author of this article gives brief historical details of the routing and the construction of the Strasbourg-Basle line across the plain on the left bank of the Rhine which is a particularly fertile and much parcelled out part of the country. This situation and the large number of tracks crossing the line involved the construction of many level crossings (236 between Strasbourg and Basle), and the policy followed subsequently has been to eliminate these level crossings progressively. The final phase has now been reached with the section across the Haut-Rhin department up to Mulhouse, which is being dealt with globally. It is expected that by 1976 the remaining 48 level crossings will have been closed and replaced by 24 new structures. [French]

THE CASE FOR THE WALKOUT CANTILEVER

Cantilevers have received increasing emphasis over the last few years for several reasons. Street and roadways have become wider and safety legislation has required signaling devices to be set back further from the roadway. Unlike the traditional flashing light signal, cantilevers put the signal over the traffic lanes, providing greater safety for both highway and rail traffic. And they can be set further back from the roadway.

NEW PRIORITY FOR GRADE CROSSING SAFETY

Grade crossing safety has a new national priority. For the first time in history, Highway Trust Fund money is authorized specifically for rail-highway crossing safety projects. Also for the first time, Federal money is available for crossing projects off the Federal-aid highway systems. How much money is actually available? What kind of projects can it be used for? Who has charge of planning how it will be spent? The purpose of this article is to provide answers to these and other questions—as a guide for follow-up action at local and state levels.

THE BIG BREAKTHROUGH IN GRADE-CROSSING IMPROVEMENT

The Federal Highway Act of 1973, for the first time in history, authorized the use of Federal Funds for defraying the entire cost of projects designed to eliminate safety hazards at intersections of railways and highways at grade. Betterment of the crossing surfaces is included. In these pages RT&S editors first summarize the essential points of the legislation, particularly those that serve as guide lines on how the money is to be spent. This is followed by a comprehensive report on the "state of the art" in grade-crossing surfaces, and a showcase of the latest developments in this area.

A FORTRAN PROGRAM FOR GRADE CROSSING COLLISIONS STUDIES USING COMPUTER GRAPHICS

A computer program is presented in the FORTRAN language to simulate the co-planar dynamic response of vehicles to the collision situation in which a rail vehicle impacts a highway vehicle at a grade crossing. The simulation incorporates 28 individual parameters associated with vehicle geometry, initial conditions, and other variables describing vehicle structural characteristics and a point-mass occupant situated inside the struck vehicle. A complete listing of the program is given along with descriptions of the program logic, sample input and output. Inputs include the mass, velocity, and force-deflection properties of each vehicle. The displacements and rotations of the vehicles are calculated as well as the penetration of the highway vehicle and the accelerations of its occupant compartment. As a special feature, this program is capable of producing computer generated diagramatic aerial-view movies of the collision event representing a locomotive striking a sedan broadside. (Author)

EVALUATION OF SAFETY IMPROVEMENTS AT HIGHWAY-RAILWAY GRADE CROSSINGS

In recognition that added effort must be placed on reducing the conflict at highway-railroad grade crossings, this research to evaluate means of supplying motorists with more credible and forceful information was developed. Many innovative active protection devices for grade crossings have been tried or proposed. Many such devices are reviewed with evaluations of their effectiveness, if any were available. The "Monon green light" signal, several of which are in Indiana, was field observed for effectiveness and recommendations are made for improvements. A study of speed profiles of vehicles approaching a crossing protected by a standard flashing light system is also reported. A photographic data collection system was developed which allowed determination of vehicle speed profiles, thus indicating driver reaction to the crossing condition. Speed profiles for nonactuated and actuated signal conditions are analyzed. It was determined that drivers approaching the crossing under progressively greater stimulus relative to an approaching train entered the approach at correspondingly slower speeds.

Conducted in cooperation with the U.S. Department of Transportation, Federal Highway Administration.

RAILROAD/HIGHWAY ACCIDENT REPORT: ILLINOIS CENTRAL RAILROAD COMPANY TRAIN NO. 1 COLLISION WITH GASOLINE TANK TRUCK AT SOUTH SECOND STREET GRADE CROSSING, LODA, ILLINOIS, JANUARY 24, 1970
About 9:55 a.m., on January 24, 1970, Illinois Central Railroad southbound passenger train No. 1, moving at a speed of 79 miles per hour on track No. 1, struck a motortruck loaded with gasoline on the South Second street crossing in Loda, Illinois. The tank of the truck was split open, spilling the gasoline which exploded and caught fire. The burning gasoline covered the exterior of the locomotive unit and entered the control compartment through the nose door, damaged nose, and other openings. Three employees of the railroad, who were occupying the control compartment of the lead locomotive unit at the time of the accident, and the driver of the motortruck received fatal injuries from the burning gasoline. The National Transportation Safety Board determines that the probable cause of this accident was that the operator drove the gasoline-laden truck, without stopping, onto the tracks immediately in front of the approaching train, while the crossing warning device was indicating the train's approach.

RAILROAD/HIGHWAY ACCIDENT REPORT: BOSTON AND MAINE CORPORATION SINGLE DIESEL-POWERED PASSENGER CAR 563 COLLISION WITH OXBOW TRANSPORT COMPANY TANK TRUCK AT SECOND STREET RAILROAD-HIGHWAY GRADE CROSSING EVERETT, MASSACHUSETTS, DECEMBER 28, 1966
At 12:10 AM, on December 28, 1966, eastbound firstclass passenger train No. 563, consisting of a single car diesel-powered passenger unit operated by the Boston and Maine Corporation collided with a northbound motor tank truck owned and operated by the Oxbow Transport Corporation stopped across the Second Street grade crossing at Everett, Mass. The collision resulted in the death of 11 of a total of 28 passengers and 2 of the 3 train crew members and other injuries and damage to property. The semi-trailer of the tank truck containing 8,200 gallons of fuel oil ruptured on impact, covering the forward end of the passenger car with the oil. A spread of flames immediately covered the forward section of the car. The fatalities were due to thermal burns and smoke inhalation. There was a lack of emergency exits in the car, in addition to an inward opening rear door which became jammed in a closed position while people were attempting to escape. The truck driver had left the vehicle prior to impact and was not injured. The probable cause of the accident was the loss of air pressure in the brake systems of the tractor-trailer which resulted in an automatic application of the brakes that could not be released from the cab of the tractor and therefore held the tractor-trailer directly across the Boston and Maine track at the collision point.

ANALYSIS OF DRIVER REACTION TO WARNING DEVICES AT A HIGH-ACCIDENT RURAL GRADE CROSSING
The objectives of this research were to analyze the effect on motorists of improving the warning devices at a high-accident, rural grade crossing, from 8-inch flashers to automatic gates and 12-inch flashers activated by a Marquardt speed predictor and having additional strobe lights; to evaluate suitable parameters to make the analysis; to study accident history and site conditions and relate these to motorist reaction to the system-before and after; and to evaluate the data collection system itself. Spot speeds were taken at eight points on each approach to obtain an appraoch speed profile for various groups under various conditions after the signal system was

improved. These were compared to similar data taken before system improvement. It was shown that an activated gate arm can be as effective in slowing the average approaching vehicle as a train across the road. Train and signal conspicuity were a problem and contributed to the poor accident record of older drivers. The Strobe lights made the warning system more visible after activation. Most drivers approach a grade crossing safely and mean speed of various groups shows trends but is a relatively weak parameter to test effectiveness, because they do not insolate the occasional, unsafe driver. Percent reduction of fastest cars, along with examining individual "fastest" cars, is a better parameter than mean speeds and decelerations to show improved effectiveness.

WANTED: NEW STANDARDS FOR AFO
Paper presented by the author, senior research engineer for the General Railway Signal Co., at the 1974 annual meeting of the AAR Telecommunications and Signalling Dept. It deals overall with the problems of audio-frequency track circuits: (1) track impedance in relation to frequency; (2) voltage drop at the end of the circuit, in relation to circuit length and different frequencies; (3) effect of ballast resistance and safety margins for system operating depending on variations in ballast resistance; (4) preshunt and extended shunt phenomena; and (5) choice of the feed and receive end impedances of transmitters and receivers and of the figurative impedance of shunting by a vehicle. The author comments on the diagrams illustrating these phenomenae and draws conclusions as to the beneficial or harmful effects resulting from modifications of: (1) the impedance of the equipment used; (2) the frequency used; and (3) the energy level of the signal transmitted or the receiver gain.

HIGHWAY ACCIDENT REPORT--AUTOMOBILE INTRUSION ONTO THE LONG ISLAND RAILROAD ELECTRIFIED TRACKS, AND FIRE, GARDEN CITY, NEW YORK, AUGUST 8, 1973
At 4:30 p.m., e.d.s.t., on August 8, 1973, an automobile carrying five teenagers was driven onto the electrified tracks of the Long Island Railroad by an unlicensed 15-year-old girl. The car's contact with the third rail caused a momentary short circuit and initiated severe electrical arcing. The car immediately began to burn at the front, and the fire spread to the rear. The two girls in the front seats escaped through the right door. The three girls in the back seat died in the fire. The National Transportation Safety Board determines that the cause of this accident was the driving of the automobile by an unlicensed and untrained juvenile of the roadway onto electrified tracks, where it crashed into the third rail.

TECHNOLOGICAL ASPECTS OF PUBLIC RESPONSIBILITY FOR GRADE CROSSING PROTECTION
Recent interest in improvement of safety at railroad-highway grade crossings has been accompanied by a growing involvement of government at all levels. Public responsibility typically has been confined to providing funding, developing information, planning, and regulating; the design, installation, and maintenance of automatic protection has been exclusively a railroad activity. This paper examines the technical limitations that constrain public authorities from taking total responsibility for crossing protection devices, which are the only highway traffic control devices that are not the responsibility of highway officials. Research directed toward removal of those limitations is described. A review of the legal history and current role of governmental units precedes a description of conventional technology in terms of impact on a wider public role. Means of train detection and motorist warnings are discussed; the conclusion drawn is that the principal technological impediment to non-railroad responsibility for crossing protection is the present dependence on track circuit techniques for determination of train presence. Recent research directed at removing this constraint is presented. Analysis of system requirements and available technology has identified a discrete train detector-microwave communication link concept, and the results of field testing indicate a number of attractive features and general feasibility.

HAMMOND RAIL RELOCATION PROPOSAL
This report, developed by the Railroad Relocation Committee and submitted to the mayor, is proposed to relieve traffic congestion in the Indiana city. The plan would relocate existing operations on a consolidated and greatly simplified track system to be used by all the railroads involved. The result would be elimination of many grade crossings and creation of no new ones. Existing lines of Penn Central would be supplemented with additional tracks to handle the trains of Chesapeake & Ohio, Louisville & Nashville, Erie Lackawanna and Norfolk & Western.

NORTHEAST CORRIDOR HIGH-SPEED RAIL PASSENGER SERVICE IMPROVEMENT PROJECT. TASK 10N GRADE CROSSINGS AND FENCING
Recommendations for the eliminations of at-grade crossings and provisions of fencing programs for safety on the Northeast Corridor from New Haven to Boston are developed. Construction and land acquisition cost estimates are included. Each at-grade crossing site is discussed in detail, including alternate proposals which were considered. The special crossing problem at New London is investigated. Fencing standards are developed. Alternative applications are discussed. Special problem areas such as commuter stations and overhead bridges are investigated.

TRAFFIC AND TECHNICAL ASPECTS AT LEVEL CROSSINGS. USE OF MODERN SAFETY SYSTEMS FOR PROTECTION AGAINST THE DANGER OF SLANTING COLLISIONS AND THEIR EFFECT ON ROAD TRAFFIC [Verkehr und Bahnuebergangstechnik. Anwendung moderner Bahnuebergangssicherung als Flankenschutz und deren Wirkung auf den Strassenverkehr]
Railway priority at level crossings necessitates the protection of both rail and road against the danger of slanting collisions. The author shows how the DB is endeavouring to solve the multiple problems that arise in this sphere, by using modern safety measures. Such devices as barriers, colour-light signals and audible warning signals are simply of an informative character. The installation of reciprocal interlocking between the barriers and the road signals on one hand, and the railway signals on the other, is necessary. The problem of controlling the danger zone remains to be solved. It is essential to re-examine the psychological influence of level crossing devices on road users as regards the recognition, perceptibility and assimilation of the information. [German]

WHAT PROGRESS FOR FEDERAL GRADE-CROSSING SAFETY PROGRAM?
While states got off to a slow start in obligating funds authorized by 1973 legislation, there are signs that the pace could pick up in what is turning out to be a long- range program. For the first time a situation has been created which permits new and modern grade crossing surfaces to be installed without any cost to the railroads. The first phase was an inventory of the 450,000 such crossings, information that is being put into an FRA computer file. Examples of the operation of the pertinent sections of the Highway Safety Act of 1973 in Illinois and Iowa are given. Supplementary information with this article includes descriptions of contemporary commercial grade crossing surfaces.

RAILROAD-HIGHWAY GRADE CROSSING WARNING SYSTEMS
The selection of equipment components and the layout of a grade crossing warning installation should aim at attracting the attention of the motor vehicle operator and assist him in the exercise of his obligations. The object of this bulletin is to serve as a guide for those whose duties include promotion of safety at such crossings. The recommended practices contained in this bulletin are composite evaluations from sources in the railroad industry, Federal and state governments and manufacturers of grade crossing warning devices. These recommendations are intended to serve as guide lines only and are not to be taken or interpreted as absolute standards to be followed in all circumstances.

STATE GRADE CROSSING PROGRAMS: A CASE STUDY
This report reviews the California Railroad-Highway Grade Crossing program, analyzing the factors influencing the reduction in grade crossing accidents. The report concludes that the greater than average success in grade crossing safety in California has resulted from the long standing financial support of the installation and maintenance of grade crossing warning devices, a strong, well managed Public Utilities Commission providing the analytical support for crossing improvement decisions, unusually strong safety efforts by the financially healthy railroads operating within the state, and an effective framework for city-county-state cooperative determination of grade crossing priorities. California ranks eighth overall in terms of active protection installed and first in the percentages of total crossings equipped with automatic gate installations. Areas for potential improvement and refinement of the California program are likewise discussed.

This program was sponsored by US DOT, Federal Railroad Administration's Office of Research and Development.

FIELD EVALUATION OF LOCOMOTIVE CONSPICUITY LIGHTS
Flashing xenon strobe lamps were installed on locomotives in revenue service as a means of alerting motorists to the hazards they are approaching at a rail-highway grade crossing. Effectiveness of these lights in attracting motorists' attention was evaluated. The reactions of both motorists and locomotive crews to the use of strobe lights were also evaluated. Field observations, interviews, and experiments confirmed the attention-getting value of locomotive-mounted strobe lights used in revenue service to alert motorists and suggested operational procedures and device specifications that are the subject of a separate application guideline report. Experimentation and observation of the strobe lights under railroad operating conditions verified that these lights do not interfere with perception of trackside signals or with normal motorist and crew operations. The work reported in this document supports a technical recommendation favoring use of strobe lights on more extensive research tests in railroad operational service.

The project was sponsored by US DOT, Federal Railroad Administration's Office of Research and Development.

GUIDELINES FOR ENHANCEMENT OF VISUAL CONSPICUITY OF TRAINS AT GRADE CROSSINGS
This report summarizes a comprehensive study of potential means of reducing the probability of train-motor vehicle collisions at railroad-highway grade crossings through enhancement of the visual conspicuity of locomotives. Passive techniques are reviewed, and requirements and constraints upon active systems are described. Past research is reviewed, followed by derivation of functional specifications and discussion of practical operating considerations. Operational tests of devices deemed most appropriate to the application are described, with detailed recommendations. The preferred system consists of clear (white) xenon flash-tube beacons mounted on opposite sides of the locomotive cab roof, flashed alternately, used in conjunction with amber incandescent lamps outlining the locomotive.

This project was sponsored by US DOT, Federal Railroad Administration's Office of Research and Development.

P&LE UPGRADES CROSSING PROTECTION
In the course of installing welded rail, the Pittsburg & Lake Erie was confronted with eight grade crossings in a 1 1/2-mile stretch. The goal was to produce a safe system that would not unduely delay vehicular traffic. Audiofrequency overlays of the conventional type would have been extremely complicated. The solution was installation of electronic movement detection through measurement of rail impedance changes. Several frequencies are overlapped for some distance beyond the crossings.

A COMMUNICATION LINK APPROACH TO ACTUATION OF GRADE-CROSSING MOTORIST-WARNING SYSTEMS
Previous studies indicate that one promising avenue to grade-crossing motorist-warning systems, offering lower cost and independent of railroad-track circuits, is use of a radio-communication link for signal activation. By this means, the presence of a train approaching a crossing can be communicated to the crossing from an appropriate distance. This study describes analysis, development, and test activities carried out at the Transportation Systems Center to determine the basic feasibility and practicality of a microwave realization of this approach. A brief review of the conceptual framework is followed by detailed discussion of field-test procedures and results, with special attention then given to train detectors, microwave-propagation aspects, use of solar power, and radar train detection.

OPERATING PROGRAMME AND PRACTICE FOR THE NEW LINES OF THE GERMAN FEDERAL RAILWAY, HAVING REGARD TO THE EXISTING RAILWAY NETWORK AND TO A EUROPEAN HIGH-SPEED NETWORK
In order to realize the corporate plan of the German Federal Railway, and this to stabilize their economic position, the fulfilment of the "Development programme for the network of the German Federal Railway" is an indispensable condition. This development programme has the objective of creating, in the German Federal Republic, a basic network for modern rail

transport of quantitatively and qualitatively high capacity where land use aspects are also taken into account; the core of this network will be formed by the future new and reconstructed lines. In addition to the construction of new lines along the most heavily used traffic corridors, it is envisaged to reconstruct a number of existing lines where, having regard to the expected increase in traffic demand, such reconstruction is called for because of existing bottlenecks or topographical conditions. In addition to the increase in line capacity to match future demands, the qualitative improvement of the lines, too, has an important bearing on the realization of a homogeneous performance pattern. Among the measures involved in the reconstruction of existing lines are, e.g., improvements in the alignment and in the signalling equipment, two-way working between stations, the construction of additional main line tracks and of platform access subways. Other measures such as the reinforcement of the permanent way, the elimination of level crossings or the conversion to push-button signalling are the subject of separate programmes.

URBAN RAILROAD RELOCATION: NATURE AND MAGNITUDE OF THE PROBLEM AND PLANNING FOR REMEDIAL ACTION--EXECUTIVE SUMMARY
This executive summary reports the significant findings and recommendations of a project to analyze the nationwide magnitude and nature of urban railroad relocation and prepares a methodology for future relocation studies. Three other volumes report the results in detail. Volume 2 is a guide for preliminary assessment of the potential for planning/ Volume 3 is a detailed quidebook for planning/ and Volume 4 presents a nationwide estimate of the nature and magnitude of urban railroad relocation. The investigators found that there is a conflict between communities and railroad operations that evidences itself in delays and added costs to highway users at grade crossings, hazards to the safety of the community, community barriers, environmental degradation, incompatible land use, and reduced railroad efficiency. Relocation or consolidation of railroad facilities are potential remedies for the conflict. The nationwide cost of relocating railroad lines in all places where there is a potential conflict is estimated at $3 to $11 billion. However, if projects are restricted to locations where substantial benefits accrue, the program will be closer to $2 billion. Railroad yards could also be relocated with substantial benefits, but at an additional nationwide cost of $1 billion. The high cost of individual projects deters communities and railroad companies from undertaking beneficial projects, so financial assistance and incentives are recommended to encourage relocation projects.

THE EFFECTIVENESS OF AUTOMATIC PROTECTION IN REDUCING ACCIDENT FREQUENCY AND SEVERITY AT PUBLIC GRADE CROSSINGS IN CALIFORNIA
To assist the California PUC in performing its duties related to grade crossing regulation, the Office of Traffic Safety sponsored this project to determine the scope of the vehicle-train accident problem in California, to gauge the effectiveness of various types of protective devices and to investigate critically the possible use of warrants or criteria to assist in recommending where money should be spent on railroad-highway crossing protection improvements. A questionnaire was mailed to all cities and counties. The before-and-after accident histories of 1,552 crossings currently protected by automatic devices were examined. The actual and estimated costs of installing automatic devices at 1,296 locations were summarized. The feasibility of criteria to assist in placing grade crossing protection devices was examined. Information on each crossing was used to develop accident rate predictions and hazard indices.

MORE MONEY FOR CROSSING PROTECTION?
An interview with Patrick J. McCue, executive director of AAR'S Highway-Rail Programs, explains the implications of the funding of the 1975 Federal Highway Act for elimination of grade crossing hazards. Over 3 1/3 years, an inventory has identified 402,000 rail crossings of Federal and non-Federal-aid public roads, private crossings, pedestrian crossing and grade-separated crossings which is now incorporated in FRA's information center files. The $175 million for grade-crossing projects on Federal-aid and other roads should permit automatic warning devices on 10,000 crossings over a 27 month period.

IS A NEAR-ACCIDENT NEARLY AN ACCIDENT? AN EXPLORATIVE ANALYSIS OF NEAR-ACCIDENTS ON RAILWAY-CROSSINGS [Is een Bijna-Ongeval Bijna een Ongeval? Een Exploratieve Analyse van de Bijna-Ongevallen op Overwegen]
1915 so-called near miss accidents on level crossings were counted by railway drivers in 1971 in the Netherlands. A near miss was defined as the traversing of a level crossing when the safety installation was working, or-in absence of this-the traversing when the train according to the judgement of the driver was already very close. With the aid of a prediction formula, by which the number of expected accidents on level crossings can be forecasted, it is possible to pursue a policy based on objective safety norms for example regarding the kind of level crossing safety measures. /TRRL/ [Dutch]

RAILROAD ACCIDENT REPORT: COLLISION OF READING COMPANY COMMUTER TRAIN AND TRACTOR-SEMITRAILER, NEAR YARDLEY, PENNSYLVANIA, JUNE 5, 1975
About 11:06 p.m. on June 5, 1975, a Reading Company commuter train struck a tractor-semitrailer (truck) at a grade crossing near Yardley, Pennsylvania. The truck was transporting three coils of steel, two of which penetrated the first commuter car. The three occupants of the lead car were killed and an occupant of the second car was injured slightly. The truck driver was uninjured. The semitrailer was torn from the tractor and damaged beyond repair and the lead commuter car was damaged extensively. At the time of the collision, the automatic grade crossing signal system was functioning. The truckdriver said he had not seen or heard the warning signals. The National Transportation Safety Board determines that the probable cause of the accident was the failure of the truckdriver to stop the truck in accordance with the warning signals.

ANA ABSERVATIONAL STUDY OF DRIVER BEHAVIOR AT SIGNALIZED RAILROAD CROSSINGS
This is a study of the behavior that normally occurs when drivers approach railroad grade crossings. Observation of 2,344 cars and trucks at six Ontario grade crossings showed that high potential for accident is due primarily to the great variability in vehicles, track configuration and signal duration. A Sequential and Standardized Warning Signal (SSWS) systems is suggested as being unambiguous in that it clearly indicates the specific course of action and reduces the decisional uncertainty of motorists to a minimum. Other changes suggested include a standardized crossing surface, emergency sirens on trains, and slight alteration in the basic SSWS system in proximity to train stations. Further research plans are also indicated.

SIMPLE VIGILANCE AND DEADMAN DEVICE
Current requirements for checking the vigilance of the driver and safeguarding operation, if this falls below an accepted standard, make it clear that two safeguard functions are essential: to provide an effective deadman operation, and to check constantly that the driver is alert. Very recently a completely fresh design approach was made to the way the equipment can be made to fulfill the operating requirements and which lends itself to a much cheaper first cost, a very great reduction in maintenance, and is readily adaptable to fitting to locomotives without or with deadman equipment. The approach has been to provide a completely electronic unit incorporating relatively recently devised equipment, the metallised polycarbonate capacitor which has an infinitely small leakage characteristic and is used as the delay element, and the uni-junction transister which fires off the circuit operation when the voltage in the capacitor reaches a predetermined value. Incorporation of safety and vigilance cycles into the one control circuit provides a compact and straightforward arrangement which does not require the driver to choose between two courses of action to prevent a brake application once he hears the bell.

THE VISIBILITY AND AUDIBILITY OF TRAINS APPROACHING RAIL- HIGHWAY GRADE CROSSINGS
The study investigates devices and color schemes, proposed or in use on locomotives, which serve to make the train visible or audible to motorists approaching grade crossings. A color scheme using two contrasting colors, each color at least 3 1/2 x 5 feet in area, is recommended for visibility at 1000 feet. One color should be very bright, such as fluorescent or bright yellow. Two high-output xenon strobe lamps are recommended, one on each side of the cab roof, to flash alternately whenever the train is moving. At night, lighted panels are recommended as supplements to the strobe lamps. The sound level required to reliably alert a motorist was found to be 105 dB just outside the vehicle. In high speed encounters, present horns cannot reliably warn motorists early enough. A horn with enough output to be totally effective would not be an unacceptable nuisance. The report includes a bibliography and tables of required ranges. (Author)

TRAFFIC-ORIENTED TRAINING FOR LOCOMOTIVE ENGINEERS
There is a need for improvement in the detail design of locomotives and their auxiliary equipment in order to enhance their performance in the various environments and conditions in which they operate. Many shortcomings in design only become apparent when the locomotive is actually at work in traffic and it is concluded that the young locomotive engineer destined to become a designer should undergo a planned period of induction to locomotive operation by riding with the driver working all types of trains at all hours and all seasons. The suggested areas of training include determination of trailing loads and point to point times, methods to avoid wheel burns, making enroute repair to loose or detached parts, use of hand brakes, use of speed indicating to loose or detached parts, use of hand brakes, use of speed indicating gear, fire hazards, use of warning devices, lay-out of the cab and instrument panel, use of the windscreen, use of route indicators, use of heating and ventilation systems, use of the driver's safety device, and re-railing locomotive.

DESIGN AND CONSTRUCTION OF A PORTABLE OCULOMETER FOR USE IN TRANSPORTATION ORIENTED HUMAN FACTORS STUDIES
The report describes development of an instrument designed to acquire and process information about human visual performance. The instrument has the following features: It can be operated in a variety of transportation environments including simulators, cars, trucks, trains, and air traffic control stations; The visual performance measurements are made without alteration of the subjects's normal visual behavior; and The data can be presented to the experimenter as either a video picture of the scene with the fixation point superimposed, or as derived eye-motion parameters. THE INCIDENCE OF DRUGS IN FATALLY INJURED DRIVERS
Methods for the collection of blood, urine, bile and alcohol washes of face and fingers from fatally injured drivers were developed. Specimens were collected from the Alcohol Safety Action Project areas. The samples were supplied by coroners and medical examiners from fatally injured drivers who were dead on arrival at the hospitals. Nine hundred and twenty-nine specimen collection kits were distributed to 44 different areas. Methods for analysis of blood, urine and bile for 44 commonly abused drugs were developed. These methods consisted of extraction of the fluids, followed by a qualitative thin-layer chromatographic screen. Alcohol washes of face and fingers were examined for evidence of marihuana. The analytical results indicated that 51% of the drivers had ingested alcohol and 33% of the drivers were legally drunk (alcohol content of blood greater than 0.15%). Twenty-four percent of the specimens examined evidenced the presence of drugs other than alcohol: 11% evidenced drugs and no alcohol; 13% evidenced drugs and alcohol. (Author)

HUMAN FACTORS CRITERIA FOR VEHICLE CONTROLS AND DISPLAYS
The study was directed toward developing valid criteria for the standardization of control and display location, coding, and operation in passenger cars, trucks, and buses. Five tasks were accomplished. Task 1 comprised an analysis of the commonality of control-display design arrangements in existing vehicles, and an assessment of the degree of the nonstandardization problems. Tasks 2 and 3 were directed toward developing criteria for C/D location and coding/operation respectively. Task 4 involved a study of 3 beam headlamp system control concepts. Task 5 comprised an experimental program to support Tasks 1, 2 and 3. (Author)

DETECTION AND RECOGNITION OF COLORED SIGNAL LIGHTS
Two experiments were designed to determine effective colors for stimulus lights as measured by speed of detection and accuracy of identification. In addition, the nature of the interactions between stimulus color, background

color, and amount of ambient illumination was assessed. Responses to four stimulus lights (red, green, yellow, and white) were evaluated against four colored backgrounds (copper, tan, blue, and green) under two levels of ambient illumination. The overall ordering of stimulus colors as measured by speed of responding was, from fastest to slowest, red, green, yellow, and white. For errors in color naming, the order from least to most was green, red, white, and yellow. Detection and identification were more difficult under bright ambient illumination. The addition of an identification task added about 0.25 second to the response times for each color.

OPERATING RULES--OBSOLETE OR OTHERWISE
A recent DOT report placed the 'human factors' or 'negligence of employees' as the cause of 27.1 percent of the train accidents in 1968. All of these accidents were due to rules violations of one sort or another. A tough policy on rules compliance is badly needed in the industry. The need for improved rules training is chronic. Employees required to operate over foreign line tracks must be qualified on foreign line rules. There are advantages to adopting a common rule book for all railroads. A disadvantage would be the high cost of changing signals to meet a common requirement. Acceptance would be difficult, since each railroad believes its own rules are the best for it. The committee feels that the present rules are not obsolete, but that they need to be streamlined to reflect the changes in operations and technology. The need for common rules is clear. The report concluded with the results of a survey on operating rules. Discussion of the committee report is presented on pages 60-75.

SAFETY THROUGH TRAINING--A COMPUTERIZED LOCOMOTIVE AND TRAIN SIMULATOR
Safety is a major concern not only of everyone in the railroad industry in general, but of those of us responsible for the training of locomotive engineers in particular. Here, as in the acquisition of most skills, the familiar adage 'practice makes perfect' applies. For many decades, locomotive engineers acquired this practice by the familiar on-the-job training (OJT) method. The fireman or prospective locomotive engineer spent years following the procedure practiced by the engineer on numerous runs, perhaps even encountering an occasional emergency. A long period of OJT was necessary before the trainee became a qualified locomotive engineer. Recent advances in simulation technology, including the advent of high performance, low cost mini-computers, have permitted the design of simulators which can subject the trainee to a 'Real World' environment in a training simulator. Through sophisticated mathematical modeling techniques, it is now possible to generate all significant environmental cues with a high degree of fidelity, thereby subjecting the trainee to a synthetically generated and accurately controllable 'Total Environment'.

This paper was recommended by the IEEE Land Transportation Committee of the IEEE Industry Applications Society for presentation at the 1973 Joint ASME/IEEE Railroad Conference, St. Louis, Mo., April 11-12, 1973. The price is $1.35 for members.

THE SANTA FE RAILWAY LOCOMOTIVE SIMULATOR AND CO-ORDINATED ENGINEER'S TRAINING PROGRAMME
The majority of American railroads today are facing a critical shortage in the supply of locomotive engineers. The elimination of the fireman's station from the cab of modern locomotives has deeply eroded the source from which railway companies drew potential engineers. A variety of on-the-job training programmes has been initiated among several railways in an effort to accelerate training processes and to reduce the period of indenture which for so many years represented a costly and time-consuming prerequisite to this vocation; but none have been so revolutionary as the training technique introduced with the advent of locomotive and train simulators. The Santa Fe Railway recently placed in service its first complete simulator, a mobile unit which, in support of an extensive training programme has produced exceptionally well-qualified engineers. The essential details of design and construction of the simulator and the more complex functions of the visual, motion and sound systems are presented in this paper. The effectiveness of the related simulator training exercises, and the classroom instructions are reviewed. Significant applications of train dynamics analyses revealed through computer interpolation of environmental conditions are discussed.

BLOOD PRESSURE: NEGLECTED FACTOR IN SAFETY
This paper proposes that there is a curvilinear relationship between blood pressure and accident involvement (or accident potential), with undesirable conditions prevailing at both extremes of the blood-pressure scale. The diastolic index may be even more significant than the more commonly considered systolic level. This should be duly recognized in safety education and taken into account by driver licensing agencies.

TRAINING LETTERS FOR M/W EMPLOYEES
About two years ago it became evident that the number of young men in the supervisory force of the Rock Island was growing. Some had five years or less of track experience. It was realized that a training program was needed not only to educate the trackmen and supervisors lacking experience but also to serve as a refresher course for the more experienced personnel. To assure having the type of training that was felt to be necessary, it was decided that the railroad would have to conduct this instruction itself. Another decision was that the training could best be handled by issuing a series of "track maintenance letters" in which the various maintenance matters that were considered basic and important would be discussed one at a time.

MAN-MACHINE SYSTEMS ENGINEERING IN FREIGHT SERVICE
In recent years, JNR has constructively advanced the automation and modernization of its enormous traffic operations, and as a consequence, human judegment, manual data processing and manual work are being replaced by a more reliable total system with speedy processing capacity. In order, however, to make efficient use of this total system, it must not only be dealt with as a computer-using system, but also as a large and complex man-machine system so that a high-level total transport system may be realized. For the modernization of freight service, JNR has begun with the automation of terminal yards, and in the Koriyama Marshalling Yard the controlling of freight car movement from hump to classification tracks and a part of the data processing are already automated. However, in order to promptly perform the enormous data processing and various changes of work schedule, it is further necessary to analyze the flow of all sorts of information and the framework of decision making in the light of the various modes of the system and to five an optimum assignment to man and machine. In constructing the control center of the Musashino Marshalling Yard, the most modern automated yard of JNR, studies were carried out based on the results obtained at the Koriyama Marshalling Yard and Shinkansen general control system. As a result, the information and decision-making systems of the new system and the characteristics of operations based on them were derived. Moreover, the requirements, concrete functions and role of the machines most closely connected to man at the control center were obtained, and in addition, an approach was made based on man-machine system engineering so that the criteria for the qualifications of the operators and the number of staff required (for normal and emergency time) can be determined. This paper deals with automation in JNR, giving some examples of the application of man-machine systems engineering, and tells of how the experience and method used therein were used to draw out the various data needed in planning the control center construction for the Musashino Marshalling Yard.

MAN-MACHINE INTERFACE PROBLEMS
Any interface problem between man and machine can affect the input and the resulting output. A key person in our elaborate railroad computer systems is the man at a remote yard or station reading a source document, converting the data into machine language and transmitting this data to a distant computer center that, in all probability, he has never seen. The terminal equipment he uses may be simple or complex. His attitudes, aptitudes, training, frustrations, environment and his supervisor's attitude

can affect the manner in which he operates this equipment, thereby affecting the accuracy of his input. Machine designers, systems analysts and railroad management who are aware of this human and knowledgeable of his problems are in a much better position to find solutions, resulting in a more efficient computer system.

LAWS OF THE SIMPLE VISUAL REACTION TIME
Fourteen studies from the literature on the reaction time (RT) to a flash of light provided sufficient methodological detail and data to allow for a quantitative analysis of the effects of the following selected variables: luminance, duration, size of stimulus, response to onset versus termination of the signal, and monocular versus binocular viewing. Mathematical relationships were developed which can be used to predict binocular rts over a wide range of luminance, signal duration, and signal size. It was also shown that the product of rt and luminance may be used to represent a response criterion in the sense implied by the theory of signal detection as developed in recent latency models. The results were interpreted as suggesting two general energy processing activities--criterion development and an impulse "countdown"--going on in parallel which are in series with a sensory delay.

AUTOMATIC WARNING OF TRACK MAINTENANCE GANGS. ENQUIRY INTO THE USE OF ACOUSTIC AND VISUAL WARNING DEVICES
This report contains the evaluation of the enquiries addressed to the Member Administrations of ORE concerning the state of progress of different acoustic and visual devices to warn track maintenance gangs. Most of the acoustic warning devices are air operated. In addition to the oral horns with a sound intensity of about 80 to 100 dB, which are still frequently used, warning devices operated by manual pumps with an air reservoir and those with compressed air containers are employed. The sound radiated by them varies between about 110 and 120 dB. The frequencies of the warning signals differ very much. A few Railway Administrations also use visual warning signals. These are either variations in the illumination of the working site or flashing lights. The report also includes conclusions referring to the need for further studies.

LOCOMOTIVE SIMULATOR
Training of railroad engineers requires a development of high levels of skill and judgment, which cannot be learned in a classroom environment. It also requires a simulator support program of classroom instruction. Simulator capability for training is available through use of a solid state, high speed, general purpose digital computer. To build a simulator requires a detailed knowledge of electronics, hydraulic and mechanical engineering, systems analyses and integration, mathematical modelling, human factors design, training psychology, and environmental control. A train simulator consists of: (1) an exact reproduction of a locomotive cab with controls and fixtures; (2) an instructor station and console with gages duplicating those of engine console, indicator lights for monitoring operation, and switches for setting up and controlling the training events and runs; (3) a visual system, using a multiple of projectors; (4) a motion system; (5) a sound system; and (6) a computer system. Realistic simulation provides the maximum amount of engineer interest and motivation necessary to efficient learning and retention of skills, and provides high transfer of learning from simulator to real train operation. The digital computer is given information specifying the number and types of engines in consist, number of cars and weights, numerical data on track gradient, curves, speed limits, and milepost locations. During simulation, the computer calculates a complete force balance for each car, up to 200 cars in a train, and up to 164 separate values on each car ten times a second, and determines amount and direction of slack action, coupler force, locomotive tractive effort, braking effort, train speed, wheel action, effects of sand on adhesion, plus other effects a real train would experience. This computational ability provides the real time reaction which allows the trainee to obtain in a few weeks, experience under a wide variety of conditions, which would otherwise require years to acquire.

MAN-MACHINE INTERFACE PROBLEMS
Any interface problem between man and machine can affect the input and the resulting output. A key person in our elaborate railroad computer systems is the man at a remote yard or station reading a source document, converting the data into machine language and transmitting this data to a distant computer center that, in all probability, he has never seen. The terminal equipment he uses may be simple or complex. His attitudes, aptitudes, training, frustrations, environment and his supervisor's attitude can affect the manner in which he operates this equipment, thereby affecting the accuracy of his input. Machine designers, systems analysts and railroad management who are aware of this human and knowledgeable of his problems are in a much better position to find solutions, resulting in a more efficient computer system.

THE HUMAN PROBLEMS AND CHANGES IN MANAGEMENT TECHNIQUES INHERENT IN THE USE OF COMPUTERS FOR DECISION MAKING
Early applications of computers involved the mechanization of existing processes which were already well established and understood. The client had a clear understanding of the input, procedures and output involved and was able to provide a complete specification of his requirements. In recent years computers have been used more and more for applications in which the machine replaces human decisions by using various types of mathematical models. With these applications it is no longer easy to define the precise boundaries of the problem and in particular it becomes very difficult either for the client to express his decision criteria in appropriate terms or for the technician to explain the processes inherent in the model. Furthermore the power of modern computers is so great that their introduction to a particular problem area may so upset the balance of responsibility or span of control

that a major change in management structure is required. All these factors create problems of confidence and communication which must be given particular attention during the development stages of a project. This paper describes some of these problems with specific reference to computer projects developed for the planning of the freight and train movements activities of British Rail.

THE MAN-MACHINE SYSTEM IN THE CONTROL OF TRANSPORT PROCESSES

Transport undertakings must, like all other commercial concerns, be organized in such a way that demand is met at minimum production cost by providing a service of quality. However, as they are public service undertakings in which the customer is directly involved in the production process, they must take special and more extensive measures to eliminate the element of risk in the transport process. This objective can be pursued by taking measures in the following spheres: (1) increase in reliability; (2) technical monitoring of failures; and (3) technical automation. In all, it can be stated that the quality of the solution to the task of safeguarding increases with the degree of automation applied to the safety system. The conditions for the safeguarding of transport processes merely serve to determine certain inviolate limits to the possibilities of movement in a transport network. There still remains a wide margin within which the actual optimization of production, i.e., the most profitable adaptation of the offered services to the demand, must be achieved. In solving the task of optimization, it is obviously necessary to select from among a multiplicity of possible solutions the one which meets a given criterion in the best possible way. It follows that the prospective results of a number of alternative decision options must be compared with each other. Depending on the nature of the task and on the speed at which a decision must be arrived at, the human brain can only deal with a very limited number of alternatives; on the other hand, relying on his knowledge of basic inter-relations and on his experience, the human decision-maker is able to eliminate from the outset a number of theoretically conceivable variants as being unsuitable. In contrast, electronic data processing plants are able to simulate in advance, at an extremely rapid speed, the consequences of certain decisions; but, especially in the case of transport optimization problems, the number of possible alternative decisions is so great that a sufficiently prompt decision cannot be obtained even with the aid of computers of the highest known capacity. While, in regard to the safeguarding of transport processes, it was possible to state that the basic task could best be solved by applying the highest possible degree of automation, it cannot be expected that the human operator can be completely replaced by the machine in the sphere of transport optimization.

RAILWAYMEN AND COMPUTERS: STUDY OF A SELECTION TEST FOR THE RECRUITMENT OF TERMINAL OPERATORS FROM WITHIN A RAILWAY NETWORK

Psychological research for determining the aptitudes required for certain work connected with information processing has been undertaken in numerous circles. In connection with the subject of Section IV of the Washington Symposium on "Human Aspects", the FS have carried out an experimental investigation associated with the study of certain mental functions such as intelligence, attention, memory and perfection, all of which are essential for the preparation of input data. The behaviour of a group of operators responsible for the transmission of input data has been studied, both from the point of view of their aptitudes and from the operational angle, with the conviction that an optimum man-machine relationship will still prove essential in a highly automated production system. The initial results of this investigation, which are limited for the time being to the work of card punching, demonstrate fully the value of extending the research to other work carried out by the staff at large electronic computer centers.

HUMAN ASPECTS OF COMPUTER SYSTEMS

This paper draws from practical experience on British Railways. It discusses the more important human relations and people interface problems which have arisen with the development of computer systems in the Freight Traffic Field and refers to certain applications, including the American Southern Pacific TOPS, which have impacted significantly on attitudes and working relationships. It draws attention to the lesson learned from past shortcomings. Specific issues reviewed include the communication problem between Line Management and the Computer Specialist with suggestions for easement if not solution; the case for joint project management teams headed by the User Department; and the need to include Executive Management in training and education arrangements. Additionally some of the special problems relating to the recruitment, retention, and remuneration of computer personnel within the traditional framework of the highly formalized and unionized railway industry are discussed. Finally, the paper comments on the growing industrial relations influence on computer applications and concludes that future expansion is now more dependent on the solution of the human aspect problems rather than advancement in computer technology.

TRAINING LOCOMOTIVE ENGINEERS
Canadian National opened in June 1972 its Engine Service Training Centre. The course at the training center covers eight weeks with a mid-term break of four days for the students. Students are selected from the ranks of conductors and yard foremen. The classroom training program covers four main areas: Rules and regulations, equipment function, both motive power and rolling stock, air and dynamic brakes, and train handling and track-train dynamics. Following graduation, the students with the assistance of master mechanics and regular locomotive engineers undertake the road part of the training program. While the staff at the Training Centre decides whether or not a student graduates from the Centre, it is a master mechanic who makes the final decision when he is qualified as an engineer. The training aides, such as a locomotive simulator are described in this paper.

LOCOMOTIVE ENGINEER MOTIVATION
Man's thinking is more or less guided or directed by three basic factors: Freedom from hunger, freedom from danger, and security. The locomotive engineer has these three factors. The question then is how to reach this man who has the basic needs of life? By applying the most powerful motivator in the world--usually, it is so personal, so closely identified with each person's ego that most people will not admit even having it or being motivated by it, but it is there, always. It is the need to feel important, and it is the most powerful motivation in the world. The motivation, the need to feel important, supplies the power, the drive, to do something outstanding.

RAILROAD ACCIDENT REPORT. REAR-END COLLISION OF TWO SOUTHERN PACIFIC TRANSPORTATION COMPANY FREIGHT TRAINS, INDIO CALIFORNIA, JUNE 25, 1973
The report describes and analyzes a rear-end collision between two Southern Pacific Transportation Company freight trains in the SP yard at Indio, California, on June 25, 1973. Extra 8992 West, after having entered the yard, struck the rear of Extra 8659 West, which was standing on the westbound main track. All five locomotive units of Extra 8992 West were destroyed, and 25 cars of the two colliding trains were derailed. The engineer and the front brakeman of Extra 8992 West were killed. Eight cars of a train on an adjacent track were also derailed. The National Transportation Safety Board determines that the probable cause of the accident was the failure of the crew of the Extra 8992 West to stop their train, which was being operated at an excessive speed by an engineer under the influence of alcohol. Contributing to this failure was the ineffectiveness of the Southern Pacific in assuring compliance with its operating rules and procedures which were specifically designed to prevent an accident if a crewmember failed to perform his duties.

BIODYNAMICAL PROBLEMS RELATED TO TRANSPORTATION VEHICLES--DIGITAL SIMULATION OF OCCUPANTS
Several parallel efforts are underway to develop and use dynamic occupant simulation computer programs in automobile and aircraft crashworthiness research. This paper reports upon a study funded by the Office of Naval Research evaluating five well known occupant simulation programs. Evaluation factors include numerical integration techniques, mathematical accuracy, computing time, and occupant belt and seat modeling. Additional factors evaluated are graphical output quality, readability of output, usage of documentation, and coding quality. A set of program design specifications was developed concurrently which, if followed by current researchers, should eliminate most of the numerical and user-oriented problems encountered with current occupant simulation programs. Finally, a program structure which is designed for fast turnaround studies is described. The key element in this structure is on-line graphics, which provides a rapid visual summary of the completed results.

BIOMECHANICS AND HUMAN IMPACT TOLERANCE
Human tolerance to impact is discussed with different degrees of trauma identified according to the Abbreviated Injury Scale (AIS). Quantitative values of human tolerance are presented in common engineering terms which permit logical safety system designs based upon the physical laws of mechanics. Tolerance levels for the head and chest in terms of acceleration in g units are used in examples to illustrate design techniques for establishing required deceleration distances. Analytical and graphical analyses are included. Injury criteria for interpreting injury potential from complex deceleration records are included.

EVALUATION OF SAFETY IMPROVEMENTS AT HIGHWAY-RAILWAY GRADE CROSSINGS
In recognition that added effort must be placed on reducing the conflict at highway-railroad grade crossings, this research to evaluate means of supplying motorists with more credible and forceful information was developed. Many innovative active protection devices for grade crossings have been tried or proposed. Many such devices are reviewed with evaluations of their effectiveness, if any were available. The "Monon green light" signal, several of which are in Indiana, was field observed for effectiveness and recommendations are made for improvements. A study of speed profiles of vehicles approaching a crossing protected by a standard flashing light system is also reported. A photographic data collection system was developed which allowed determination of vehicle speed profiles, thus indicating driver reaction to the crossing condition. Speed profiles for nonactuated and actuated signal conditions are analyzed. It was determined that drivers approaching the crossing under progressively greater stimulus relative to an approaching train entered the approach at correspondingly slower speeds.

Conducted in cooperation with the U.S. Department of Transportation, Federal Highway Administration.

ALCOHOL, DRUGS, AND DRIVING
The basic purpose of the Vermont Symposium was publication of the proceedings to incorporate the following specific aims: (1) Systematic, evaluative reviews of the eight major aspects of alcohol and drug problems related to highway safety, with each review written by a leading specialist in that aspect; (2) a synthesis of the edited transcriptions of the discussion periods that followed presentation of the summaries of each of the eight review papers; and (3) ratings of 176 key-word topics on three dimensions of alcohol, drug, and driving problems, i.e., the extent of present knowledge, the relative priorities for basic research in terms of informational yield, and the relative priorities for applied research in highway safety. The critical reviews consist of combinations of the following topics: Alcohol and/or drug influences upon driving-related behavior as studied in laboratory, simulator, and closed-course driving experiments; epidemiologic studies of the role of alcohol and/or drugs in highway crashes and citations; and research on countermeasures for alcohol and/or drug involved problems on the highway.

RAILROAD ACCIDENT REPORT: COLLISION OF MISSOURI PACIFIC RAILROAD COMPANY FREIGHT TRAIN EXTRA 615 SOUTH WITH A STANDING LOCOMOTIVE, COTULLA, TEXAS, DECEMBER 1, 1973
At 8:30 a.m., Saturday, December 1, 1973, Missouri Pacific Railroad Company freight train Extra 615 South (train DMX) entered Cotulla, Texas. Train DMX was traveling on a nonsignalized main track at a speed of 35 to 40 mph. Just after it passed over a grade crossing, the train was diverted through a switch onto an adjacent track where an unmanned locomotive, a caboose, and 11 cars were standing. Train DMX collided with the standing locomotive before any appreciable braking. The collision derailed all of the locomotive units and 29 railroad cars. Three crew-members who were riding in the lead locomotive unit of train DMX were killed. The National Transportation Safety Board determines that the probable cause of this accident was the establishment of a collision route for train DMX by the unauthorized operation of a switch by persons unknown. Contributing to the collision were railroad operating practices which authorize engineers to operate trains at speeds at which they could not stop short of a switch target which indicates the switch is improperly aligned. Contributing to the severity of the collision was the fact that the crewmembers of the locomotive of train DMX did not identify the open switch and apply the train's brakes soon enough to slow the train. The report contains recommendations to the Missouri Pacific Railroad Company and the Federal Railroad Administration.

Railroad Accident Report. This report contains Railroad Safety Recommendations R-74-22 through R-74-28.

RAILROAD/HIGHWAY ACCIDENT REPORT: ILLINOIS CENTRAL RAILROAD COMPANY TRAIN NO. 1 COLLISION WITH GASOLINE TANK TRUCK AT SOUTH SECOND STREET GRADE CROSSING, LODA, ILLINOIS, JANUARY 24, 1970
About 9:55 a.m., on January 24, 1970, Illinois Central Railroad southbound passenger train No. 1, moving at a speed of 79 miles per hour on track No. 1, struck a motortruck loaded with gasoline on the South Second street crossing in Loda, Illinois. The tank of the truck was split open, spilling the gasoline which exploded and caught fire. The burning gasoline covered the exterior of the locomotive unit and entered the control compartment through the nose door, damaged nose, and other openings. Three employees of the railroad, who were occupying the control compartment of the lead locomotive unit at the time of the accident, and the driver of the motortruck received fatal injuries from the burning gasoline. The National Transportation Safety Board determines that the probable cause of this accident was that the operator drove the gasoline-laden truck, without stopping, onto the tracks immediately in front of the approaching train, while the crossing warning device was indicating the train's approach.

RAILROAD ACCIDENT REPORT: ILLINOIS CENTRAL RAILROAD COMPANY AND INDIANA HARBOR BELT RAILROAD COMPANY COLLISION BETWEEN YARD TRAINS AT RIVERDALE, ILLINOIS ON SEPTEMBER 8, 1970
At 11:08 p.m. September 8, 1970, a collision occurred between Illinois Central (IC) Train 1218 and Indiana Harbor Belt (IHB) Train 8717 at Riverdale, Illinois. The collision of the two yard trains resulted in two fatalities and two serious injuries. Five cars and the caboose of the IC train were derailed and the locomotive cab of the IHB train was demolished. The IHB train was crossing over from an interchange track to an IC main track when the locomotive was struck by the unlighted caboose of the IC train. The IC locomotive was shoving 22 cars, and the caboose had passed a signal indicating "Restricted Proceed" 715 feet prior to impact. The safety Board determined that the accident resulted from the failure of the IC crewmembers to operate IC Train 1218 at a speed so as to be able to avoid the collision. Additional contributing factors included: (a) the failure of IC crewmembers to display a light and occupy a conspicuous position when shoving cars as required by rule; (b) the failure of the IC to provide additional protection when track changes initiated a permanent display of "Restricted Proceed" for the involved signal in 1969; and, (c) inadequacies in operating rules, practices, and personnel training. Contributing to the accident severity was the lack of crash protection provided the occupants of the IHB locomotive.

RAILROAD ACCIDENT REPORT: SOUTHERN PACIFIC RAILROAD COMPANY FRUITRIDGE ROAD GRADE CROSSING SACRAMENTO, CALIFORNIA, FEBRUARY 22, 1067
On February 22, 1967 at 12:05 PM, a station wagon traveling east on Fruitridge Road in Sacramento, California collided with a Southern Pacific Company freight train traveling north at the intersections of the Southern Pacific railroad tracks and Fruitridge road. Immediately prior to and after the collision, the flashing lights and bells of the automatic railroad crossing warning devices were functioning properly. In addition, the engineer was sounding the locomotive's horn and bell in the prescribed manner, and the locomotive's regular and oscillating headlights were functioning. The station wagon was destroyed and the nine occupants killed. The train was not derailed nor was the train crew harmed and the lead locomotive suffered only minor damage. The probable cause of the accident was failure of the driver of the station wagon to stop his vehicle short of the grade crossing and to remain clear of the track as required by California State law.

RAILROAD ACCIDENT REPORT: NEW YORK CENTRAL RAILROAD COMPANY TRAIN 1/NY-4 EXTRA 2020 EAST AND TRAIN ND-5 EXTRA 5305 WEST HEAD-ON COLLISION NEW YORK CITY, NEW YORK MAY 22, 1967
The accident occurred on the West 30th Street branch of the New York Central Railroad at approximately 147th Street, New York, New York, at about 9:55 A.M. on May 22, 1967. The collision occurred on Track No. 1, which was being used that morning for train movement in both directions due to repairs which were being conducted on main Track No. 2. Six train service employees were killed, and three train service employees were injured. Six locomotives and 11 cars were destroyed, one locomotive extensively damaged and five cars were also damaged. The probable cause of this accident was the failure of the operator at the 72nd Street Station (DO) to restrict train ND-5.

AN ANALYSIS OF THE JOB OF RAILROAD TRAIN DISPATCHER
The report constitutes a detailed study of the job of railroad train dispatcher, conducted to provide a data base for the derivation of job knowledge, skills and training consonant with safe operations. Documentation was reviewed: specialists were consulted, and selected dispatching operations were observed in detail. The report describes the responsibilities and duties of train dispatchers, their workplaces and job aids, the principal functions they perform, and the records they must maintain. Special characteristics of the job, such as workload, stress, inadequacies in aids, and trends toward improvements are discussed, and estimates are made of the physical and psychological attributes, job knowledge and skills basic to safe operations and possible approaches to assurance of safety through selection, placement and training.

PERSONAL SECURITY ON PUBLIC TRANSIT
While conventional modal choice models consider time and cost, safety has been largely ignored. This study examined the safety aspect of a public transit facility through user-perception survey. A bus and elevated line of the Chicago Transit Authority were chosen as the survey areas. It was found that the variable most frequently cited as decisive in using, or not using, the bus or elevated is freedom from personal attack or harassment. The users' perception of safety is examined. The study cites some shortcomings of the survey method and notes that system design should have a major role in persuading potential riders that safety is assured.

MARKING AND LIGHTING FOR PASSENGER TRAIN VISIBILITY
This investigation was to evaluate various alternative marking designs that could enhance the visibility of the trailing ends of passenger trains. The goal was one overall design that would be optimum during all operating conditions and yet be economical to implement and maintain. For daytime visibility, it was found that coverage and contrast were most important, with fluorescent yellow-orange most effective. At night reflective white stripes and large red marker lights were desirable. The recommended pattern was an inverted V-pattern of the yellow-orange and white stripes and markers on both sides of the lower part of the car end.

MASS TRANSIT TRAINING NEEDS. VOLUME I. EXECUTIVE SUMMARY
The report is the first of a five-volume series summarizing the findings, conclusions, and recommendations of a study of urban mass transit training needs. This study includes a detailed analysis of the training requirements; a discussion of the availability of training programs to meet the needs of the industry; an outline of supplementary material needed to bring training programs up to an acceptable standard; and proposals for programs to upgrade the standard of training as it currently exists. Specifically, this volume summarizes the results of an inquiry into industry needs for standardized programs regarding training of (1) bus operators, (2) bus operator instructors, (3) bus mechanics, (4) bus mechanic instructors, and (5) rapid transit rail car repairmen. Following a description of programs currently in use at transit properties, the general contents of the respective standardized programs are outlined, the role of the Federal government in funding is examined, alternative methods of delivering programs are discussed, and costs of development and demonstration are estimated.

MASS TRANSIT TRAINING NEEDS. VOLUME V. RAILCAR REPAIRMAN TRAINING NEEDS
The report is the fifth of a five-volume series summarizing the findings, conclusions, and recommendations of a study of urban mass transit training needs. This volume is devoted to the railcar repairman. About half of the training is generalized enough to allow a standardized training course to be developed. An outline of such a course, and sources of training material which would be included are presented. One conclusion is that because of the financial difficulties of the mass transit industry, it is recommended that implementation be delayed until funds become available to cover the costs of training.
Paper copy also available in set of 5 reports as PB-235 999-SET, PC$17.00.

AN EVALUATION OF FIVE RAILROAD ENGINE ALERTING AND WARNING LIGHT SYSTEMS
Five lighting systems proposed for improved other-vehicle operator approach warning alerting were evaluated in a simulated grade crossing decision paradigm. Additional evaluations were conducted on system conspicuousness. The systems, a Bicolor Radial Beacon, Slow-rate Strobe 2.5 flash per second (FPS), Fast-rate Strobe 1 FPS, truck clearance lights, and side mounted Flourescent Panels, were examined at 10, 20, 30 miles per hour under daylight and night conditions. Some advantage was found for the strobe systems and for the clearance lights as compared to the usual fixed locomotive headlight. Recommendations for further research were made. (Author)

INFLUENCE OF AGE ON THE FREQUENCY OF PHYSICAL FAILURE OF STAFF EMPLOYED ON DB TRACTIVE STOCK
[Uber den Einfluss des Lebensalters auf die Haufigkeit von Fehlleistungen beim Triebfahrzeugpersonal der DB]
Recordings were made of 2,217 automatic brake applications in cases where the vigilance button for the distant signal in the warning position was not activated, and studies were carried out on the average frequency of release of the automatic acoustic warning signal (SIFA: Sicherheitsfahrschaltung) on 10 powered units during 1,424 running days. There was found to be no relationship between age and an increase in the frequency of human lapses. The maximum values reached show fluctuations of a certain importance at all age levels. Anticipated retirements could represent a selective effect; account is also taken, unofficially, of the age of drivers of powered units on drawing up the rosters.

COACH DESIGN FOR THE HELSINKI UNDERGROUND
After more than 20 years of planning, an underground system will be opened in Helsinki in 1978. In 1972, a short line was constructed, with six coaches for experiments. This article describes an analysis of these coaches from the

point of view of ergonomics. A travelling experiment was organized, designed to simulate the final travelling situation. After the experiment the subjects filled out a questionnaire. During the trip the behavior of the subjects and their moving in and out was observed by two TV recorders and two film cameras.

BART AND THE HANDICAPPED
A ten-year review of BART with regard to special facilities for the handicapped shows a gradual awareness of needs as citizen pressure has mounted. Special facilities for the visually and audibly disabled are not yet provided, and many elevators are awkwardly located for the physically handicapped. A study team in 1974 found many minor elevator operational problems, with an additional barrier for wheelchair users as the lack of level access to and egress from buses that transfer with BART. It is observed that new responsibility is now being taken to provide transportation for the handicapped and that BART has set a planning precedent.

RAILROAD ACCIDENT REPORT: COLLISION OF ST. LOUIS-SAN FRANCISCO RAILWAY TRAINS 3210 AND 3211, MUSTANG, OKLAHOMA, SEPTEMBER 1, 1974
On September 1, 1974, at 1:44 to 1:46 p.m., the St. Louis-San Francisco Railway Company's eastbound freight train 3210 and westbound train 3211 collided head-on 1.7 miles west of Mustang, Oklahoma. The trains were scheduled to meet in Mustang. However, train 3211 passed Mustang ahead of schedule. As a result of the collision, 4 locomotive units were destroyed, 23 cars derailed, and hazardous materials caught fire in the wreckage. As a result of the fire, eight families were evacuated from their homes. A brakeman on train 3211 was killed, and the three other crewmembers of that train were injured seriously. The National Transportation Safety Board determines that the probable cause of this accident was the failure of the crew of train 3211 to take preventive action after the train passed Mustang ahead of schedule.

HEALTH HAZARD EVALUATION/TOXICITY DETERMINATION REPORT H.H.E. 74-28-212, WESTINGHOUSE AIR BRAKE COMPANY, WILMERDING, PENNSYLVANIA
NIOSH conducted a health hazard survey at a plant manufacturing railroad air brake and emergency braking systems. Environmental air samples were collected for cadmium, chromium, cyanides, nitric acid, and organic solvents. Medical histories were also reviewed and cutaneous examinations of exposed employees were performed. A chrome sore was observed on one worker and ten other workers were found to have various types of occupational dermatitis. It was concluded that the dermatitis cases were due to primary irritation to various chemicals, primarily lubricants. Airborne concentrations were judged to be not toxic to exposed employees.

NEW TRAIN-DYNAMICS SIMULATOR
A new approach to train-dynamics simulators has been developed by the Freight Master Company. Unlike units that are mock-ups of a locomotive cab similar to aircraft simulators, the new system uses a mini-computer and cathode ray tube to generate real-life conditions. The system might be further developed to be placed in a locomotive cab to aid the engineer in running his train more effectively. The Train Dynamics Analyzer, as it is called, uses a track profile and train consist data stored on magnetic tape. A locomotive control stand gives throttle action, braking, etc.

HERBICIDE EXPOSURE, MORTALITY AND TUMOR INCIDENCE, AN EPIDEMIOLOGICAL INVESTIGATION ON SWEDISH RAILWAY WORKERS
The investigation shows a slightly dose-dependent and significantly increased tumor incidence and mortality among workers exposed to amitrol (3-animo-1,2,4-triazole), whereas those exposed to phenoxy acids (2,4-dichlorophenoxyacetic acid = 2,4-D and 2,4,5- trichlorophenoxyacetic acid = 2,4,5-T) have about normal tumor incidence and mortality. Based on animal experiments, there is some evidence that amitrol may cause malignant tumors in different tissues, although tumors in the thyroid gland and the liver have been observed and discussed most frequently. Although the investigations may be criticized, the result, being in agreement with animal data, suggests precautions in using amitrol. [Finnish]

INDIVIDUAL DIFFERENCES IN RESPONSE TO THE ENVIRONMENT
In assessing the effects of environmental stress three points are made. (1) Comfort and working efficiency cannot necessarily be equated. (2) The optimal experimental design for assessing individual differences differs fundamentaly from that required for establishing population means. Reliable individual differences will only be revealed by repeated measures of a given effect upon the same people and under the same conditions. (3) Regarding the assessment of what individuals find comfortable as regards temperature, or acceptable as regards noise, two difficulties are noted. (a) In terms of what they are prepared to do about it, individuals may differ in what they mean when they tick one of a number of terms indicating varying degrees of discomfort or annoyance. (b) Where an observer experiences a range of conditions he will tend to place the center point of the rating scale at the center of the range of conditions sampled. Over a group of observers this may bias the average comfort or acceptability vote away from its true point. The presentation of a standard followed by a single test condition will avoid difficulties due to range effects but may encounter others due to suggestion or contrast effects.

COLD-INDUCED VASODILATATION ONSET AND MANUAL PERFORMANCE IN THE COLD
This study is an investigation of manual dexterity capabilities during whole-body cold exposure as a function of time to vasodilatation during local cooling. Thirty male subjects were divided into three equal groups on the basis of the time for a 3deg F (1.7deg C) rise in index finger temperature during immersion of the hand in 4.4deg C water: (450 sec group, 450-900 sec group, and)900 sec group. Subsequently, each subject was exposed to ambient temperatures of 15.6deg and-6.7deg C for three hours while performing a battery of six manual tasks bare-handed. Manual performance on all tasks was affected adversely at the-6.7deg C ambient and worsened with continued cold exposure. The drop in performance on three tasks involving skilled movements of the wrist and fingers was greatest for the 450 sec group. Within the limits of the present study, the early onset of vasodilatation in local cooling per se appears to be associated with initially superior performance and subsequently inferior performance on specific manual tasks with increasing durations of whole-body cold exposure.

MOTION DISCOMFORT AND TRANSPORTATION GUIDEWAY FORM
A three-dimensional theory of motion discomfort is developed by defining scalar indices measuring discomfort due to acceleration and jerk. These indices are functions of effective acceleration and jerk vectors and their orientation to the preferred configuration of a subject. The optimal bank angle of a guideway is defined and shown to minimize acceleration discomfort. Isotropic approximations to the discomfort indices are proposed. Expressions for the indices are obtained in terms of the vehicle motion and guideway geometry. Detailed analyses of motion along optimally banked circular helical and three-dimensional spiral curves are presented. Motion with zero fore-aft thrust on a curve in a vertical plane is also detailed. The approach assumes a smooth guideway and so vibrational inputs are not included. The analysis should be followed up by an experimental program before it is taken too seriously in design.

CONSPICUITY OF BEACONS FOR EMERGENCY VEHICLES
In a large field study red, orange, light blue and dark blue rotating and flashing beacons have been studied mainly from a peripheral conspicuity point of view. Some subjective evaluation has also been made. The results show that from a purely visual point of view the orange beacon is superior. The red beacon is inferior in nighttime conditions but good under bright daylight conditions which seem to be the worst from a safety point of view. The blue beacons are almost too good in nighttime conditions in the respect that they cause discomfort but they are poorly visible in bright daylight conditions. A light blue beacon improves visibility in daylight. Flashing light blue beacons are equally as conspicuous as rotating light blue beacons but cause more discomfort. /TRRL/

TRAIN CONTROL, STRESS AND VIGILANCE
Modern railway operation, due to the control exerted on the man-machine-pathway combination is the safest form of transportation available. The vehicle pathway is continuously monitored and both front and rear end protection is provided to prevent collisions. Man although extremely versatile is known to be the weak link in the man machine system. Consequently, his duties need to be arranged to match his capabilities. An examination is made of human factor research, levels of arousal, driving efficiency and driver stress, fatigue, diurnal bodily rhythm and vigilance. Accident rates have been progressively reduced by various safeguards instituted to guard against human failure. Measurements of driver stress under various conditions of high speed train operation have been carried out and changes in stress in accordance with train speed, hours of duty, periods of rest, and day and night operation determined. There are a series of railway signalling and vigilance control devices which successively reduce the effect of the human element. These have further developed into semi-automatic and automatic train operation.

CONTACT LENSES AND DRIVERS [Kontaktlinsen und Kraftfahrer]
The advantages of adhesive lenses for correcting errors of refraction have to be set against the disadvantages, particularly for drivers. Restrictions of the field of vision are possible because of the optical structure of the edge zones and the firly thick lacrimal film. Alterations in field of vision can be balanced out with use. Special contact lens shapes have to be used under certain conditions in order to achieve good visual acuity. Vision in darkness and dusk is usually impaired by adhesive lenses, night myopia increases, and increased formation of scattered light and over-sensitivity to light lead to greater dazzle. Dark adaptation may be considerably impaired by dark adhesive lenses. After the contact lenses have been removed unclear vision often occurs for up to 21 days, and this is not compensated for by the immediate wearing of spectacles. Smaller lenses are best in this respect. These again cause noticeable formation of scattered light. A questionnaire study of wearers of contact lenses showed that judgment of distance was mostly much better with contact lenses. The greater field of vision was regarded as particularly favourable. /TRRL/ [German]

RAILROAD ACCIDENT REPORT: COLLISION OF PENN CENTRAL FREIGHT TRAIN OV-8 WITH AN OPEN DRAWBRIDGE, CLEVELAND, OHIO, MAY 8, 1974
On May 8, 1974, Penn Central freight train OV-8 collided with the counterweight of a lift-span drawbridge on the Cuyahoga River at Cleveland, Ohio. Shortly before the collision, the eastbound train had been traveling at 33 mph on a main track equipped with automatic block signals when the DB operator contacted the traincrew and advised them that the route was clear ahead. Then, the operator remembered that a boat had been awaiting passage and, without informing the traincrew, he opened the bridge. The train passed the red home signal of the DB interlocking without braking and struck the counterweight of the open bridge about 600 feet beyond the signal. The two crewmembers in the lead locomotive unit died as a result of crash injuries. The National Transportation Safety Board determines that the probable cause of this accident was the failure of the locomotive crewmembers to obey a wayside signal indication to stop and the concurrent opening of the drawbridge by the DB operator after he had advised the oncoming traincrew by radio that the route was clear. Contributing to the accident was the absence of specific rules that either prohibited such a radio message or described the circumstances under which such a radio transmittal could be accepted as an operational control.
This report contains Safety Recommendations R-75-11 through R-75-15.

FIELD EVALUATION OF LOCOMOTIVE CONSPICUITY LIGHTS
Flashing xenon strobe lamps were installed on locomotives in revenue service as a means of alerting motorists to the hazards they are approaching at a rail-highway grade crossing. Effectiveness of these lights in attracting motorists' attention was evaluated. The reactions of both motorists and locomotive crews to the use of strobe lights were also evaluated. Field observations, interviews, and experiments confirmed the attention-getting value of locomotive-mounted strobe lights used in revenue service to alert motorists and suggested operational procedures and device specifications that are the subject of a separate application guideline report. Experimentation and observation of the strobe lights under railroad operating conditions verified that these lights do not interfere with perception of trackside signals or with normal motorist and crew operations. The work reported in this document supports a technical recommendation favoring use of strobe lights on more extensive research tests in railroad operational service.
The project was sponsored by US DOT, Federal Railroad Administration's Office of Research and Development.

HUMAN INFORMATION PROCESSING UNDER VARYING TASK DEMAND
Experiments on the rate of human information transmission show that the relationship between performance and demand depends upon time history of demand; beyond overload, performance does not recover at the expected rate as demand is reduced. The resulting 'hysteresis' effect increases after moderate doses of alcohol. Some implications of these results in real-life situations are discussed. (A) /TRRL/

SAFETY PSYCHOLOGY: A REVIEW OF THE LITERATURE
This paper reviews the major concepts and trends in safety psychology under four headings: (1) personal factors affecting the causation of accidents; (2) environmental factors affecting accident causation; (3) theories in safety psychology; (4) research problems in safety psychology. The most important conclusion reached, is that safety psychology lacks a theoretical framework which is necessary for both predicting accidents before they occur and as a cohesive force for drawing together the immense amount of information that is available in the field of safety. BETTER PERFORMANCE TODAY
Despite a downturn in traffic, the potential for improving operating results still exists. Santa Fe's vice president, operations, calls Santa Fe's people crucial in such efforts and says motivation and training are crucial. Computerized monitoring of train performance following a rationalization of freight train schedules was instituted. Close control over switching costs has also been instituted. The railroad has also taken a close look at supervision of its freight offices and yard offices, instituting standardized procedures vital in introducing machine accounting. Training programs for the new approach involve subject matter rather than job functions.

HUMAN FACTORS IN RAILROAD OPERATIONS: ACTIVITIES IN FISCAL YEAR 1973
This is an interim report covering human factors services rendered by TSC to the FRA under the project: "Human Factors in Railroad Operations," during fiscal year 1973. It reviews all activities briefly and contains more detailed reports on a research plan for use with a locomotive cab simulator, a training survey, studies of train handling, and fault-tree analysis of railroad accident data.

HUMAN CRITERIA IN THE DESIGN AND ARRANGEMENT OF CONTROL ELEMENTS
This article examines some important factors that should be considered in the design and arrangement of control elements from the standpoint of human engineering. The need for ready identification of individual control elements is stressed, and several possibilities for differentiation between control knobs--based on variation of the shape, size, color, texture, position and operating method--are described. The basis for the coding of control elements in either of these ways is human sensibility. Finally, hand controls and foot controls are discussed in terms of selection, best positioning and arrangement.

THE DB'S OPTICAL WARNING SYSTEM FOR PERMANENT WAY MAINTENANCE GANGS [Die optische Rottenwarnanlage der DB]
The use of audible warning signals to gangs working on the line causes much disturbance for people living near the railway, especially at night. The DB has tried to replace audible warnings by optical signals for work on the permanent way at night. The principle is that at the arrival of the train, the lighting intensity at the worksite is varied according to the two frequencies used by the DB to show the track on which the train is arriving. On engines with autonomous lighting, electronic flash-devices are used to warn the gangs. Finally, the author stresses that the present warning system depending on a look-out man, as used by the DB, is unsatisfactory from the safety point of view. Only automatically operated equipment could meet safety requirements. Moreover, this optical warning device saves manpower, as the look-out man is not required. [German]

CAREER DEVELOPMENT OF RAILROAD OPERATING CRAFT EMPLOYEES
This paper investigates the career paths of railroad operating employees (trainmen) from pre-employment to employment, to post-employment (retirement). Its purpose is to determine how a person comes initially to the operating craft; once working, to see how a person's career develops over his period employment (normally more than 30 years); and to consider his retirement. Using a modified version of Schein's career development model, the career of railroad employees is analyzed. A framework is provided within which to analyze forces that are acting to modify and change the current career development procedures.

This paper is from the Proceedings of the 16th Annual Joint Meeting of the Canadian Transportation Research Forum and the Transportation Research Forum, 3-5 November 1975, Toronto, Canada. Complete Volume $20.00.

THE DIESEL-ELECTRIC LOCOMOTIVE AS A WORK ENVIRONMENT: A STUDY IN APPLIED ANTHROPOLOGY
Human factors in the diesel-electric locomotive is the subject of a study in applied ethnology and applied physical anthropology. Working from the viewpoint of locomotive crew members, the study's principal objective is to aid in designing locomotives that will enable crews to work efficiently and safely. Thirty recommendations are made to this end. After a discussion of applied anthropology, general characteristics of present-day locomotives and operations of the crew in the locomotive are covered. Recommendations and background information are presented in the following areas: (1) arrangements of cab displays of warning devices and mechanical indicators, (2) arrangement and design of controls, (3) locomotive structure, (4) impacts, (5) exterior signaling for the locomotive, and (6) vibration on the locomotive.

TROUBLE SHOOTING QUICKENER (TSQ) FOR SHINKANSEN
With extension of the Shin Kansen to Hakata in 1975, the line is now 1,000 km long and 2,100 cars are needed for the operation. Since this is the trunkline of JNR, its operation is characterized by high speed and heavy density. A malfunction on a single car can affect not only the entire Shin Kansen but also connecting services. Intended as a trainer for drivers, this electric railcar simulator was installed in Shin Osaka in 1974. The cab controls and the air conditioning controls are faithfully reproduced. Pantograph and underfloor brake equipment are installed on separate racks. Operators learn to operate under the prevailing Automatic Train Control signals and speed indications. Malfunction indications are coordinated with trouble shooting.

RAILROAD ACCIDENT REPORT: REAR END COLLISION OF TWO TEXAS AND PACIFIC RAILWAY COMPANY FREIGHT TRAINS, MEEKER, LOUISIANA, MAY 30, 1975
About 8:52 a.m. on May 30, 1975, a Texas and Pacific Railway Company freight train, Extra 3311 West, passed an "approach" signal and a "low" signal and collided with the rear of train Extra 551 West, which has stopped on the main track in Meeker, Louisiana. The 4 locomotive units and the first 10 cars of Extra 3311 West and the last 5 cars and the caboose of the standing train were derailed and damaged. The engineer and the front brakeman of Extra 3311 West and the conductor of Extra 551 West were killed. The National Transportation Safety Board determines that the probable cause of the collision was the failure of the engineer of Extra 3311 West, while operating the train in violation of a "low" signal indication, to perceive the train ahead in time to prevent a collision. A cause of the severity of the collision was the subnormal braking capability of a significant number of cars. As a result of this investigation, five recommendations concerning use of radio, backup control system, "Stop and Proceed" procedure and enforcement of braking system regulations have been addressed to the Federal Railroad Administration.

RAILROAD ACCIDENT REPORT: PENN CENTRAL TRANSPORTATION COMPANY, TRAIN COLLISIONS, LEETONIA, OHIO, JUNE 6, 1975
About 11i00 p.m. on June 6, 1975, three freight trains of the Penn Central Transportation Company (PC) were involved in a collision near Leetonia, Ohio. Extra 6330 West collided with the rear of standing Extra 2278 West. Immediately thereafter, Extra 6259 East, which was on an adjacent track, struck the wrecked cars from the other two trains. One employee was killed and seven others were injured. Property damage amounted to about $1.25 million. The National Transportation Safety Board determines that the probable cause of this accident was the failure of the engineer and brakeman to assure the operation of the train at a speed slow enough to stop it within the visibility range. This violated the resitrcted speed rule required by the signal indication. Recommendations were made concerning operating rules and the use of radios.

RAILROAD ACCIDENT REPORT REAR END COLLISION OF AN ALASKA RAILROAD FREIGHT TRAIN WITH A PASSENGER TRAINî NEAR HURRICANEî ALASKAî JULY 5, 1975
About 3i46 p.m. on July 5, 1975, an Alaska Railroad freight train, Extra 1502 South, collided with the rear of passenger train No. 5, which had stopped south of Hurricane, Alaska, to permit the passengers on the train to view Mt. McKinley. All cars of the passenger train and the first four locomotive units of the freight train were derailed. Sixty-two persons were injured and one of the injured subsequently died. The National Transportation Safety Board determines that the probable cause of the accident was the failure of the engineer of Extra 1502 South to operate the braking system on the locomotive properly and the failures of both trancrews to comply with railroad operating rules. As a result of its investigation, the Safety Board made three recommendations to the Federal Railroad Administration concerning improvement and compliance with operating rules and a modification of locomotive brake valves.

BRAKING SYSTEM OF THE HIGH-SPEED TRAIN-QUARTERLY REPORT-1966
The results of running tests carried out in the last fiscal year 1963 to approximately 1964 with the revised prototype and production type C-train, proved that such problems as insufficient braking force and failure of the electric brake, etc., were almost solved. Problems as slippage, heat crack or deformation of the brake disc were not sufficiently solved, and characteristic tests of the anti-skid device and tracing study of the growth of cracks in the brake disc were performed.

TRAIN SAFETY CONTROL SYSTEM (REPORT 2)
When a train safety control system is newly installed in a certain section of railway line, the first problem is to choose the most suitable system for the section in full consideration of its traffic condition, peculiarities and operation system adopted there. Next it is important to organize the working of the system so well that the highest degree of safety may be secured. The present study purports to make investigations of train safety control system, to define the basic requirements of the system on the basis of probability theory, and ultimately to facilitate selection of it.

EXPERIMENTAL RESULTS FOR TEMPERATURE RISE OF RAIL WHEN APPLYING AN EDDY CURRENT RAIL BRAKE
The eddy current rail brake operates without friction between rails and wheels of vehicle. This brake system can be used on a conventional railway as well as on a high speed railway. The brake force is obtained by converting the kinetic energy of the vehicle into heat energy in the rail, the temperature of the rail will be raised. Since the rail is essential equipment for operating railway vehicles, the temperature rise of rail is a very important factor as to whether or not this brake system can be used.

RUNNING TEST FOR THE STUDY OF COMPOSITION BRAKE BLOCKS
The study of composition brake blocks has been advanced in JNR to obtain better brake efficiency for the operation of high speed train. As a part of its study a car running test at Sanyo line (the rail condition is straight and flat) was carried out using the composition brake blocks specially made for trial. Since a part of the brake equipment was provisional in this test, brake cylinder pressure rose slowly and idling time was 0.7 to 1.2 sec longer than usual. If it is possible to shorten the idling time by any brake equipment up to that of the emergency brake, the brake distance will be shortened within 600 m at the initial brake speed 120 km/h. In this case the variance of brake distance may be involved in it.

BRAKING SYSTEM FOR HIGH-SPEED TRAIN-QUARTERLY REPORT-1964
From the results of running tests carried out with the prototype car train in the last year (1962 to approximately 1963) on the test track section, several problems were pointed out to be solved or improved for maximum safety and better traffic service, such as insufficient braking force, failure of electric brake, wheel slip and heat crack or deformation of brake disc. To certify the practical effects of these revised designs in the course of manufacturing of the mass production type cars, several kinds of running tests were carried out using prototype cars, about the modified circuit of electric brake, plans to eliminate the flat of wheel tread, improvement of brake disc and certification of the supposition running resistance formula.

THE RATIO ALARM SYSTEM OF THE WESTERN PACIFIC HOT BOX DETECTOR PROGRAM
Describes the development of the Ratio Alarm system to detect overheating or distressed journals of hot-boxes. Uses a ratio between temperatures at hot end and cold end of the axle. A fixed percentage between the two journals is used. A signal at the scanner is set off, a tape in the dispatcher's office is also marked, which permits an override of the system if the dispatcher feels that the alarm can be ignored.

THE DEVELOPMENT OF SPECIAL SIGNALLING FOR HIGH-SPEED OPERATION ON EXISTING LINES
It is important to develop signal systems when train speeds exceed 160 km/h. Such factors as stopping distance at such speeds preclude the use of the system used in the noraml automation block section. At higher speeds, the warning distance may reach 2 or 3 blocks. One solution is to develop a 3 aspect signaling system which covers 3 blocks with signals fed through cables laid along the track.

DEVELOPMENTS IN BRAKING SYSTEMS FOR EXPRESS TRAINS TO MEET THE DEMANDS OF INCREASING OPERATING SPEEDS
Increase in the speed of trains poses numerous problems, amongst which those concerned with braking are becoming more and more important. Speeds of the order of 200 km/h at the price of relatively inconsiderable modification to the signalling to retain conventional solutions for the rolling stock, such as the cast iron brake block. In the very high-speed field, 250 to 300 km/h on specially constructed new lines. It becomes necessary to resort to combined systems amongst which may be other types of frictional brake.

DERIVATION OF INITIAL SPEEDS AND STOPPING DISTANCES FROM DECELERATION/TIME CURVES
Brake testing involves the measurement of deceleration. This can be obtained by direct means or by calculation knowing the initial speed, stopping distance, and stopping time. The method to be described involving the use of a recording decelerometer and stopwatch only gives a full assessment of the braking performance, and since no electrical or mechanical connection with the test vehicle is required has the obvious advantage of permitting tests on any brake at any time without previous preparation. Success of the method has been proved over a number of train tests where independent measurements of speed and distance have been available.

MINIMUM TRAIN HEADWAYS ON RAPID TRANSIT RAILWAYS WITH ADVANCED TRAIN CONTROL AND CONVENTIONAL SIGNALLING [DIE DICHTESTE ZUGFOLGE AUF STADTSCHNELLBAHNEN BEI NEUZEITLICHER ZUGSTEUERUNG UND BEI HERKOMMLICHER SIGNALISIERUNG]
This article deals with the problems of rapid transit to and from cities, both urban and interurban systems. It describes investigations into the extent to which theoretical train spacing employing "running with elastic vision" can be achieved with various signal and train-control systems. An ideal system based on headways equal to braking distance and a developed practicable system are compared with four conventional signal systems with long and short protected sections and up to three permissive follow-on signals. The comparison, supported by fully developed formulae and diagrams, shows that the time spacing between trains with a refined fixed signalling system with three follow-up signals and immediate speed control is only a few seconds longer than the practicable train control with cab signals for train spacing equal to the braking distance. With the use of more powerful locomotives, and an acceptable slight increase in journey times, the proposed 90 second interval between trains appears to be a reasonable prospect even with trains of 200 meters length. CONTINUOUS AUTOMATIC TRAIN CONTROL FOR SAFETY AND CONTROL OF RAPID TRANSIT RAILWAYS [LINIENZUGBEEINFLUSSUNG ALS MITTEL ZUR SICHERUNG UND STEUERUNG VON STADTSCHNELLBAHNEN]
The emphasis on speed with safety is a necessary consideration in the planning of any railway signaling system. This article describes a system such as used with the operation of the 200 km/h passenger trains on the German Railways. The prerequisite emphasized for properly functioning signal systems is the interdependence existing between train spacing, train length, length of the protected sections and the speed over the route. A further development of the signal system described, where command information is constantly being imparted to the train through a special communications line, is the possibility of programmed automatic operation of these trains. DERAILMENT AT COTON HILL
The running away and consequent derailment of a goods train on January 11, 1965, was ascribed to driver failure to observe the instructions for descent of an incline (falling 1 in 100). The leading 22 wagons were equipped with vacuum brakes and weighed 245 tons. The other 24 wagons and brakevan were unbraked and weighed 530 tons. The 2,750 hp type 4 C-C Brush-Sulzer locomotive weighed 114 tons and was equipped with vacuum/air brake equipment. As a precautionary measure to eliminate the possibility of a complete failure of the locomotive air brakes, it was recommended that the pipe connection between the vacuum train pipe and the triple valves be duplicated as the locomotives go into shops for overhaul.

DERAILMENT OF GOODS TRAIN
On September 10, 1963, the Up Dover Marine continental depot train consisting of 24 loaded continental ferry vans and a bogie brakevan weighing about 618 tons, became derailed on curved track. It was drawn by a Bo-Bo 2,500 hp electric locomotive and travelling at about 60 mile/h at the time of derailment in a valley where a long steep falling gradient changed to a steep rising gradient. The train first parted between the first and second van, but the brakes were not automatically applied on the engine. It was assumed for lack of evidence of materials failure that the parting and derailment were caused by variations in cant which helped an oscillation to develop in the play between the bodies and axles. The failure to automatically apply the engine brakes when the vacuum was severed was traced to a systems design deficiency in the air-vacuum isolating valve. It was agreed that the addition of a magnet valve connected so it was energized when the exhauster switch was at "off" and de-energized when at "on" would correct this braking system deficiency.

RECENT TRENDS IN BRAKING PRACTICE
Developments in brake types and methods of control effected over the past few years are surveyed. Under the stresses imposed by new high speed (200 km/h) and heavy (up to 8500 hp) trains, tyred wheels have not demonstrated the necessary reliability and monoblock wheels do not withstand the braking heat. Disc brakes with grey cast-iron have shown promise on streamlined trains. Flat wagons are under construction in Germany wherein the disc brake is being incorporated in the wheel assembly. In Belgium and Germany successive, short interval applications of air-operated disc brakes followed by electric resistance brakes are being used on moderate speed (120 km/h) passenger trains. British Railsway liner trains have been equipped with monobloc wheels in which the wheel center forms the brake disc; however, some trouble has been encountered within the past two years speed-controlled air-electromagnetic brakes have enabled much greater deceleration on Rheingold trains (1000 m for 160 km/h) than wheel-and-rail adhesion systems permit. Track speeds of 200 km/h are possible using disc-magnetic rail systems, and the recommended 1-1/4-in. through brake pipe and double-pipe air brake system might provide the control and protection needed at this velocity.

INNOVATIONS IN CONTINENTAL BRAKING PRACTICE
The article describes the addition of a quick-action valve to the "U" graduated-release distributor as designed by the Italian Westinghouse company of Turin (Westinghouse Freni e Segnali, Cia). The quick-action feature is the distributor proper gives a rapid drop in brake-pipe pressure all down the train for emergency application, ensuring that brakes apply fully almost in accordance with the timing of the distributor. For example, on a 20-coach train travelling at 140 km/h the stopping distance without quick-action was 940 meters. With quick-action, the stopping distance was 850 meters. A comment is made to the effect that if improvements in service braking and flexibility in release are to be made, the only logical way of achieving this is to incorporate "e.p. control" (electro-pneumatic control).

CONTROL OF RAILWAY BRAKES BY ELECTRICITY
This article surveys the field of electro-pneumatic braking systems as applied to suburban and high speed services, to ensure rapid and simultaneous operation. Consideration is given to brake systems, brake equipment (including valves and (controllers), control systems, and the future development of electro-pneumatic control by extension to main line trains. The latter may be either by providing a straight airbrake in parallel with the existing pneumatic arrangement, with control either on timing or by a code arrangement, or by using the electric control to synchronize brake pipe reduction and recharge down a train, hence reducing the time lag to apply and release the brakes.

A NEW BRAKE TESTING MACHINE
The Inertia Machine Mark V, which can be used for recording deceleration, torque, and friction surface temperature in one operation, is described and illustrated. The machine is capable of dealing with any of the shoe or disc brakes used on railcars, and it should eventually deal in a similar manner with brake blocks for actual wheel rim braking. The design, generally, resembles a fully floating back axle, the motor taking the place of the differential gear, and the flywheels replacing the road wheels. The brake units are mounted on a shaft coupled to a torque recording gear carried in headstocks, which may be retracted axially to remove the brake units from their drums. The machine is a double-ended one to allow two brakes to be tested simultaneously, alternately, or individually. The flywheel specifications, torque recording system, and pyrometer are briefly described.

B8 037299
THE BRAKING OF RAILWAY VEHICLES
The factors affecting the stopping distance of freight trains are: increased length of trains; increased speed; and increased ratio of gross weight to tare. To secure 40 lb per sq. in. brake cylinder pressure on the rear car of 35-, 50-, and 70-car trains required 6.5, 10.5, and 20 sec, respectively. Increasing the

maximum speed of freight trains from 30 to 40 mph almost doubled the stopping distance. To reduce the effect of increasing the ratio of gross weight to tare two methods are suggested: 1) application of an emergency feature whereby air is dumped from the brake pipe to the atmosphere at each equipment causing rapid buildup of brake cylinder pressure, or 2) empty and load brakes procedure, by which the braking power of the loaded vehicle is increased substantially over that of the empty vehicle. The tests were conducted in Australia. Discussion of high-braking forces for high-speed passenger trains focuses on both U.S. and European efforts. Data are presented on the Zephyr showing the relationsip of different braking ratios on stopping distances.

NEW BRAKE SHOE CUTS STOPPING TIME, REDUCES WEAR AND SPARKING
A new brake shoe completely interchangeable with the standard metal shoe promises better train control, increased life and almost total spark suppression. Key to the breakthrough is an alloy of iron which exhibits a vastly different metallurgical structure from that of a standard shoe. The Samson shoe reduced stopping distance 32 percent and confirmed the improvement in train handling. The Samson retained the favorable friction characteristics of the standard metal shoe at static breakaway and low speed. Comparative sparking under drag braking conditions tested with cheese cloth placed in the trajectory of sparks leaving the wheel. At 45 mph, sparks from the standard metal shoe ignited the cheesecloth in seven minutes; Samson caused no fire.

B8 037606
A METHOD FOR DETERMINING A UNIVERSAL BRAKE PIPE PRESSURE
The Central Air Brake Club proposes a method for determining a Universal Brake Pipe Pressure; taking into consideration grade braking, stopping requirements on grades, plus limitations of the shoes and wheels. The fundamental consideration is: any car should have a braking system which will allow it to safely negotiate any downgrade fully loaded, whether as a single car or in a train of similar cars with air brakes alone. An important corollary is that sufficient brake shoe friction material will always be available until the bottom of the grade or next available shoe replacement point is reached. Another corollary is that the braking duty must not be such that wheels are overworked and overheated. Finally, it must be decided what constitutes an adequate margin of retarding force above grade balancing for satisfactory stopping ability. To arrive at this, the stopping distance requirement on the grade must be known. If the grade is block signaled, this is fairly easy to determine. If the track is not block signaled, the most critical stopping requirement must be found. This might be an entrance to a yard, curve, an interlocking, unloading dock, or tipple, etc. There are two primary factors speed and weight.

OPERATING TRAINS ON ELECTRIC VISION--WHY AND HOW?
The author presents the signalling system of today as an example of the way in which much of the present state of the art of the railways reflects the developments from past methods and states of the art. New techniques have been superimposed onto the old, without changing the fundamental principles. A new system is envisioned where the operations would be through constantly moving blocks, with a predetermined time interval

controlling the movement of the trains. This system is described in considerable detail, as also its advantages in congested train conditions. Complete safety of operations, including the absolute protection at railroad crossings at grade, and protection to maintenance of way workers, as well as supervision of compliance with speed restrictions, are included in the functions of this system. Economic considerations are also dealt with. The characteristics and simplicity of this system makes it suitable for application to all transportation systems, including urban rapid transit.

USE OF COMMUNICATIONS TECHNIQUES IN A FUTURE TRAIN AND LINE SYSTEM

The task of communications techniques is not only the transmission of information from one source to the user, but also the processing of this information according to scheduled programs. In transportation safety, the initial information in the form of an oral instruction or a programmed coded order must be transmitted to the vehicle and received by it. From the communications standpoint, it is necessary to differentiate between, (1) one-way transmission from train to track or from track to train, and (2) two-way transmission between track and train. In one-way transmission from train to track, direct current circuits are generally used, together with axle counters. Two-way communication between track and train can be accomplished by superimposing both transmission directions onto a closed circuit. The planning of a linear safety system begins with the desired speed-related headway interval. Three safety systems are described and the economics of expenditures on train and track are discussed with particular reference to the wide variety of signalling tasks on the one hand, and the relationship between the length of line and the quantity of rolling stock on the other. The article describes a digital system, with specially simple vehicle equipment, designed for underground railways.

ADVANTAGES OF HYDRAULIC BUFFERS

The hydraulic buffer automatically produces a steady retarding force of such a value that, whatever the speed of impact, the wagon is brought to rest as the buffer-stroke is completed. These buffers also produce a very low recoil. Hydraulic buffers make it possible for the safe speed of impact, to be raised from something over 4 mph to nearly 10 mph. Present-day marshalling yards already work with impact speeds of 10-12 mph and a survey carried out at one hump yard showed that 4 percent of impacts were at speeds of more than 10 mph. Hydraulic buffers also have a part to play in the reduction of shock in trains fitted with continuous brakes.

DISC BRAKES IN THE U.S.A.

In 1948 the Union Pacific Railraod decided to use disc brakes in new stock. When the first disc-braked cars were put in service, they were mixed with cars equipped with clasp brakes. Trains composed exclusively of cars with disc brakes were assembled. The results have been a reduction in noise and in jolting when trains are being stopped. Thermal cracking of wheel tires has been virtually eliminated. Certain interesting cost figures have been got out comparing the use of clasp and disc brakes on one of the trains over a 12-month period. The cast-iron tread shoes of the clasp brakes required renewal after every round trip of 4,598 miles, 73 changes of shoes thus being made during the year; the disc brake shoes ran an average of 90,000 miles each, and so required an average of 3.73 changes only. Over a full year, the renewals of short clasp brakes cost a total of $48,865.60 and of the long type $65,045.26, whereas the corresponding expenditure for Budd disc brake renewals was $7,221.48.

FRICTION MATERIALS FOR RAILWAY BRAKING

The Ferodo composition brake block is compared to cast iron brake blocks. The braking characteristics are shown for the average of 20 stops using emergency brake applications of a train travelling 50 mph. The deceleration time for the Ferodo brake was greater than the cast iron brake, but the stopping distance was less. A composition brake block is less abrasive to the wheel than a cast iron block, and the product of wear less harmful. Although the Ferodo block still wears more rapidly than the wheel, its life has been found to be equal to as many as five cast iron blocks in some instances. Flange profiles are shown comparing the two types of brake blocks as to flange wear.

AUTOMATIC DIESEL LOCOMOTIVE OPERATIONS ON THE L&N

The drawbar pull on the longer and heavier trains has prompted several railroads to look into different types of operations using automatically controlled locomotives to relieve the drawbar tension. The L&N used a General Railway Signal (GRS) control system with an L&N Unit No. 830, 1500 horsepower EMD F7A locomotive for demonstration. The basis for the GRS control system is a force-velocity determinant, a product of which is correlated to demand horsepower. The parameters are derived by strain gauges on the coupler shank to define the force, and an axle-drive alternator for defining velocity. L&N's experiences with this prototype system are comprehensively reviewed.

ELECTRONIC SURVEILLANCE AND CONTROL SYSTEM FOR ADVANCED TRAIN OPERATION
The "ESACS" concept started as a relatively small advancement in the form of an improvement in automatic couplers. Some means of reducing the complexity of the electric couplers of the MU car type was needed. It became apparent that once a communication means with the capacity to handle hundreds of bits of information in either direction was installed on a train, so as to connect all cars, a great many things could be achieved in the form of surveillance and control with benefits in operation, car utilization, lading damage control, safety and performance. Efforts at developing this system are presented.

A NEW BRAKE SYSTEM FOR DIESEL LOCOMOTIVES
The vacuum brake system is particularly suitable for diesel locomotives where the problem of finding room for orthodox brake cylinders is difficult. It is designed to give augmented locomotive brake power by taking advantage of an increase of cylinder vacuum at the moment of brake application without interference with the normal working vacuum throughout the train. A two-pipe driver's valve is used, which isolates the exhauster side of the system before admitting air to the train pipe. Both vertical and horizontal types are available with pull or push action. The new cylinders are so designed that the driver can manipulate the brakes separately on locomotive and train, or both simultaneously.

CONFINES OF BRAKING--1
Factors reducing braking rates below the limit imposed by adhesion between wheel and rail are discussed. Braking efficiency can be related to adhesion, but only when the braking is straight line from moment of application to standstill. This is never so in practice, and the braking efficiency can therefore be considered only as an average ratio, and not the adhesion value which is the limit in maximum braking. No braking starts at the maximum rate instantaneously, nor does it usually carry on to a stop at the maximum rate. The reasons are regard for passenger comfort and the speed of equipment response. Manufacturing inaccuracies and maintenance problems which cause differences in brake cylinder air pressure are mentioned.

CONFINES OF BRAKING--2
Characteristics in service of electro-pneumatic brakes and calculation of brake rigging efficiency are discussed. If I.P. feed valves are used, a variation in setting can also produce variations in the rate of rise of brake cylinder air. Differences in brake cylinder stroke can also cause considerable variations in rates of rise. A record of an emergency stop is shown where the brake cylinder air has been controlled by a retarder, blow-down valve, and additional relay vent valve. The restrictions which can cause variations in rate of feed through triple valves appear with an E.P. brake in other places, in, for instance, the variation in lift of an application valve.

CONFINES OF BRAKING--3
The factors considered are the brake block itself, and the various conditions of control between wheel tire and block. The variations in braking which occur through the mutual contact of wheel tire and block are as follows: variation of the coefficient of friction of a brake block with speed; block friction and applied force, block friction and tire temperature; block friction and weather; and effect of wheel diameter with drum, disc, and dynamic braking. These effects are briefly described.

BRAKES FOR HIGH SPEED TRAINS
The article gives the background in need for improved brake blocks for trains when speed exceeds 160 km/h. The traditional cast iron block is reliable and simple but the material creates problems at higher speeds. The major problem in selecting braking systems is complicated by the dependence upon adhesion which decreases with speed increase. Cast iron brakes are not suitable for high speed operation therefore either composition blocks or disc brakes are more effective on nonpowered axles as is the rheostatic brake for powered axles.

SIMPLE VIGILANCE AND DEADMAN DEVICE
Current requirements for checking the vigilance of the driver and safeguarding operation, if this falls below an accepted standard, make it clear that two safeguard functions are essential: to provide an effective deadman operation, and to check constantly that the driver is alert. Very recently a completely fresh design approach was made to the way the equipment can be made to fulfill the operating requirements and which lends itself to a much cheaper first cost, a very great reduction in maintenance, and is readily adaptable to fitting to locomotives without or with deadman equipment. The approach has been to provide a completely electronic unit incorporating relatively recently devised equipment, the metallised polycarbonate capacitor which has an infinitely small leakage characteristic and is used as the delay element, and the uni-junction transister which fires off the circuit operation when the voltage in the capacitor reaches a predetermined value. Incorporation of safety and vigilance cycles into the one control circuit provides a compact and straightforward arrangement which does not require the driver to choose between two courses of action to prevent a brake application once he hears the bell.

ITALIAN U-TYPE AIR-BRAKE DISTRIBUTOR
Thousands of Italian Westinghouse brake distributors of U and U-R types are now in use on the Italian State Railways (F.S.) and other systems. An advantage of the basic U distributor is the time delay of 30 sec in the re-opening of the control reservoir after the end of a brake release. This permits the re-charging of the system in full release position of the brake valve for a longer time than permitted by other distributors. It also provides a positive security against exhaustion of the brake. The U-R distributor is in use only on passenger stock, for it is only in these vehicles that the brake cylinder filling time need be as low as 4 to 5 sec.

HYDRODYNAMIC BRAKING FOR LOCOMOTIVES
Dynamic braking has one feature in common with the normal air or vacuum brakes. The limit of its force is dependent on the adhesion between a steel wheel and a steel rail. However, with dynamic braking there is no possibility of slide; over-braking dynamically produces a reverse slip, which is much less damaging to wheels, rails and braking elements. A very detailed description of this type of brake is provided, covering such topics as cooling factors, braking efforts and ranges, decelerating characteristics, driving technique and air control.

AUTOMATIC REGULATION OF TRAIN SPEED
Successful trials on the Belgian National Railways of an inductive control system are reported. Signal aspects are displayed in the driving cab. Transmission of information from the track to the locomotive is carried out by a pair of inductors between the rails, each of which contains a coil of litz wire tuned by a capacitor. Beneath the locomotive there are two detectors. The input and output of a wide-band amplifier are connected to the loops. The effect of an inductor on the track beneath a detector is to couple the two loops by a link having a resonant frequency between 50 and 100 kc/s, and the amplifier will then generate a signal of the same frequency as the inductor. Inductors may be tuned to 15 different frequencies in this range so that a large variety of information can be transmitted to the locomotive as compared with electro-magnetic systems.

NEW DEVELOPMENTS IN AIR BRAKES
The article surveys a number of recent improvements in brake equipment and associated pneumatic controls. The D22 special control valve design differs from the "universal" control valve in that the air is governed by a relay valve. A device called the Decelostat momentarily reduces braking force on slippery wheels permitting them to return to train speed. Hot-box detectors utilizing the Wheatstone bridge principle provide warning when overheating is imminent. A new type of driver's brake valve (No. 24) incorporates five sections to suit various requirements for freight and passenger service. A new variable-load brake has been designed for light-weight wagons. A brake-cylinder release valve device isolates reservoirs and vents the brake cylinder when the "bleed" valve is pulled, thus permitting the shunter to pass from one vehicle to the next without waiting.

THE PROPORTIONING OF BRAKE BLOCKS
Excerpts are presented from an article dealing with the temperature effects produced between two sliding bodies. The investigation had two main aspects: first, the development of a satisfactory method of measuring the surface temperatures and, second, the application of this method to actual railway brake blocks in a full-scale series of tests. In applying the apparatus to the measurement of surface temperatures of a railway tyre, the aim of the experiment was to correlate the results obtained with three variables: speed, block pressure, and contact area. It was found that in all the tests contact area was very small and moved along longitudinal strips parallel to the width of the block. Working on the assumption that contact area should be a function of block material and block pressure, and should thus vary with the ratio of block length to block width, the authors began the most striking part of their research. A block was progressively shortened to give three-quarters, one-half, and one-quarter the original area. Blocks of type 1 and type 2 were used, as well as cast iron, at initial speeds of 60 and 30 m.p.h. and a brake block pressure of 1,240 lb. The result was an astonishing decrease of temperature maxima for both the non-metallic blocks, although there was no such decrease in the cast-iron blocks. Contact areas in the nonmetallic blocks now covered the full tyre width, instead of being confined to narrow longitudinal strips. Measurements of wear show that the normal and half-blocks wear at exactly the same rate. Since cracking of the tyre is known to arise from the true heat spots, it can be taken that by reducing brake block areas from the present standard size, in the case on non-metallic materials, the liability to the formation of cracks is minimized and the life of tyres can thus be greatly increased.

B8 039203
DEVELOPMENT OF NONFRICTION BRAKING SYSTEMS FOR HIGH SPEED TRAINS
Performance potential and approximate cost estimate for three nonfriction braking systems are obtained. The systems are: the air retarder, the hydraulic retarder, and aerodynamic braking. It is shown that the air retarder and the hydraulic retarder have potential to develop full braking deceleration in a

speed range from 250 MPH to 25 MPH. Because of its advantage over the hydraulic retarder in system weight, simplicity and cost, it is recommended that development of the air retarder be undertaken. Aerodynamic braking deceleration is highly dependent on projected braking area. Maximum frontal envelope considered was car frontal area plus an area enclosed by car width and extending three ft. above the roof. For this area, most of the energy of a 250 MPH train can be absorbed by aerodynamic braking. At speeds below 100 MPH (very approximately) aerodynamic braking must be supplemented by friction braking to obtain sufficient deceleration rates. Existing aerodynamic test data for longitudinally spaced braking surfaces are not sufficient to obtain accurate predictions of the friction braking crossover point and the aerodynamic braking deceleration rate. Therefore a wind tunnel test program is recommended. The report includes an extensive bibliography and references covering related aerodynamic material. (Author)

A GENERALIZED SPECIFICATION FOR COMPOSITION BRAKE BLOCKS FOR RAILWAY VEHICLES
The braking of railway vehicles may be improved technically and economically by a direct replacement of cast iron brake blocks by blocks of a composite material of the correct design and functional characteristic. Numerous available composite materials can introduce large savings due to their good wearing properties when compared to cast iron. As a result of excessive heat dissipation rates and thermal shock, rolling stock wheel treads can be seriously overstressed at the higher operating speeds by blocks of incorrect friction characteristic and physical design. This paper deals with the definition of the physical requirements related to the design of composition brake blocks for railway vehicles, and motivates a generalized specification for the performance characteristic.

ADHESION AND FRICTION IN RAIL TRACTION
For dry rails, a coefficient of adhesion of 0.25 may be assumed for speeds up to 40-50 m.p.h. At higher speeds, however, there is less information to draw on. Above the 40-50 m.p.h. range, the dependence of adhesion on speed introduces a bend into the curve connecting speed and power output. For wet rails, the coefficient of adhesion is reduced to about 0.6 of the value determined for dry rails. Of the many variables encountered in brake-block friction, there is abundant evidence of the dependence of coefficient of friction on speed and brake-block pressure. Substances should be saught for blocks for which the coefficient of friction is less affected by speed than in the case of cast iron; the effect would be to allow acceptable braking distances without having to use high braking ratios, so that a reduction in the weight of brake gear could be contemplated.

LOAD-COMPENSATING FREIGHT BRAKES
A variable-capacity brake is required, which automatically compensates for increase in loading. This new equipment uses a double brake-cylinder arrangement to provide a maximum braking force of 60 percent for the empty vehicle, a maximum braking force for fully loaded vehicle, of 20-30 percent, and some intermediate figure for vehicles partly loaded. The mechanism for setting the car braking ratio must be automatic. Setting must take place when the car is stationary. On the engine manual adjustment is needed, as there is no simple means for registering on the locomotive the load of the cars.

WARNING DEVICES OTHER THAN DETONATORS
Luminous torches for signalling used in Europe and Japan were tested as a part of the task of Specialist Commitee B92. Work is now directed toward warning devices with a range of 2-3 km. A Hertzian torch, which is a transmitter, would emit radio warning signals to a receiving device to be installed in every motive power unit. Another solution would be the installation of transmission and reception devices on the motive power units, connected by inductive coupling through conductors along the railway track. This method is especially advantageous in tunnnels and hilly terrain. Cost comparisons are being made.

SPACE-INTERVAL DRIVER'S VIGILANCE DEVICE
The Swiss-developed safety control apparatus operates on a distance interval, and therefore gives the same factor of safety irrespective of the locomotive speed, whereas the more common system based on a time interval does not achieve this feature. The effect of the new apparatus is basically the same as the previous systems, i.e., following the incapacity for duty of the driver, a warning is sounded in the cab and if no action is taken by the driver the traction motors are switched off and the brakes applied. A diagram showing the mechanical and electrical circuits of the safety device is given. Also shown is part of a diagram of the run-down on the safety apparatus expressed in locomotive miles travelled.

SIGNALS AND OPERATING RULES AS CASUAL FACTORS IN TRAIN ACCIDENTS
Railroad signal systems, even though performing as designed, do not compensate for human failure and prevent accidents. Many collisions attributable to negligence of employees result from lack of compliance with operating rules which do not relate compatibly with the signal systems. A relationship is developed between signal systems, operating rules, and the human element that is responsive to both. Specific cases are cited in which the discrepancies are exposed and examined within the context of the foregoing. Recommendations are directed to the Federal Railroad Administration that they take steps under the increased scope of authority of the Federal Railroad Safety Act of 1970, to develop a comprehensive program for future requirements in signal systems and operating rules that will reduce or eliminate the present ambiguities and lax, ill-defined operating rules.

BRITISH RAILWAYS DECISION ON BRAKES
After extensive research and practical trials the British Transport Commission adopted as standard the vacuum type of automatic brake. Although the time needed to couple up and to create the vacuum will mean that a made-up

train will stand longer in the yard than with the present standard coupling for goods vehicles, this disadvantage is believed to be more than offset by the faster running time which will result from fitting throughout. The substitution, by new construction and conversion, of a fully-braked fleet of wagons will enable freight trains to run at maximum speeds of up to 60 mph. The higher average speeds of train movement will lead to reduction of about 2,000 locomotives and will enable the total wagon stock to be reduced.

BRAKING SYSTEMS
After discussing the advantages and disadvantages of the vacuum and the air brake it is concluded that they balance, except the delay of release with the vacuum. Members of the brake industry have undertaken much research into the vacuum brake, and in its latest form, with improved brake cylinders and valves. There seems little doubt that for all freight trains of the length likely to be practicable in this country, taking into consideration yard capacity and loading gauge, it answers well. The faster running possible with a fitted train will more than recoup the greater time required for starting by the vacuum brake.

DUAL AIR BRAKE SYSTEM
The Westinghouse Brake and Signal Company, Ltd. has developed a simple dual brake system, which is claimed to represent an advancement in modern vehicle braking technique. The provision of independence peneumatic storage and control for front and rear brake systems ensures that, in the event of any part of one system being rendered inoperative, braking is obtained from the unaffected system. A typical layout is shown in which a common air compressor, controlled by a single unloader and safety valve, supplies air to two main reservoirs; each of these provides independent, air storage for one part of the dual system, and is isolated from the other by inclusion of check valves in the supply from the compressor. The supply and release of air from the reservoirs to the piston type brake cylinders' or diaphragm brake chambers is by means of a lightweight dual control valve.

LATERAL FORCES ON TRACK AND EQUIPMENT DUE TO DYNAMIC BRAKING ON THE SOUTHERN PACIFIC LINES
This report embraces a description and analysis of data secured during the operation of regular scheduled freight trains on the Southern Pacific Company between Roseville, California and Sparks, Nevada. The purpose of the investigation was to determine the coupler forces and resulting lateral forces exerted on the rails by the passage of an 85 ft. car coupled to a short car in a train with the locomotive using dynamic braking while operating on steep grades and curves up to 10 deg. During the investigation, data were secured on coupler and car angles, lateral and vertical truck forces and longitudinal acceleration of the 85 ft. car with the train operating at various speeds. The analysis of data contained in this report may be summarized as follows: 1. The steady or longitudinal coupler forces for both pull and push conditions, as expected, are in proportion to the weight of that portion of the train behind the point of measurement. The compressive coupler forces were reduced considerably when the train air line pressure was reduced with the locomotive under dynamic braking on the descending grades. 2. The coupler angles are in direct proportion to the track curvature with the values obtained under the pulling condition slightly greater than those under the pushing condition. 3. The data indicate there is a linear relationship between the track curvature or coupler angle and the lateral truck forces acting on the rail. 4. The occurrence of slack action was rather infrequent due to the long and almost continuous grades for but some coupler forces as large as 90,000 lb were obtained by an application of the dynamic brakes which permitted the slack to run-in. 5. The sprung weight of the 85 ft. car was subjected to longitudinal accelerations as large as 2.2 g but there does not appear to be any direct relationship between the direction and magnitude of this acceleration with respect to the direction and magnitude of the slack action coupler force.

MATERIAL CHARACTERISTICS OF RAILWAY BRAKE DISCS OF VARIOUS IRON-CARBON ALLOYS
The results are described of tests and investigations carried out in the Research Station of the Bergische Steel Industry in Remscheid, on various iron-carbon and steel alloy materials for use in disc brakes on railway vehicles. While chrome-molybdenum steel alloy castings showed some desirable characteristics under repeated heatings, the pearlitic cast iron with lamellar graphitic inclusions showed greater resistance to fine hair line cracking. The group of malleable, ductile and pearlitic cast irons appeared to develop relatively few cracks, up to 6 mm depth and widely dispersed, while the cast steels with no or little alloys sustained many short cracks only 1.2 mm deep. There remains the need for further research for combinations of materials that will withstand better the high and repeated high temperature shocks to which brake discs are subjected. [German]

REPORT OF BOARD OF INQUIRY ON ACCIDENT AT COLISEUM STATION, BAY AREA RAPID TRANSIT DISTRICT, SAN FRANCISCO, CALIFORNIA
The accident occurred during test operations at the Coliseum Station on November 2, 1971, when a BART vehicle travelling about 25 MPH, collided with the rear car of a parked BART train. The train operator was injured. The accident, which occurred in manual mode, underscores the wisdom of the early planning decisions to design the BART system on the most fully automatic basis possible. Such a collision will be very unlikely once the automatic system is in operation because of the basic fail-safe design. Despite the speed of impact, there was little damage beyond the bulk heads of the attendant's compartments in the impacting cars. The accident was attributed to human failure to apply the brakes in sufficient time or at a sufficient rate to effect the stop.

THE RAIL MOTOR-BRAKE
Achieving train speeds of 300 to 400 KMH are discussed. Over 200 km/h no conventional technical solution is suitable as to the fundamental aspects

of traction, and mainly the braking. The rail would become an integral part of the electric motor, propulsion and braking systems regenerating linearly, rapidly and indefinitely under the field part of the motor, of which it becomes, electrically, the armature. The motor or braking effort, the system being reversible, hence are produced between the rail head, wherein flows induced currents producing the effort. A magnetic core, provided with windings, constitutes this part of the motor which provides the inductor field necessary for propulsion, asynchronous sliding field, by its feed with variable frequency, polyphase, alternating current. This motive power unit would employ classical railway, yet would be independent of traction adhesion and braking limits.

INFLUENCE OF TRAIN HANDLING ON DERAILMENT TENDENCY

Test runs were made with an instrumented 4-axle EMD model GP-35 locomotive and a 50-ft. box car as base test units. Subsequent tests were made with 6-axle EMD model SD-45 locomotive and a 50-ft. box car and tests were then made between Los Angeles and Pine Bluff with the EMD Model SD-45 and an 85-ft. TFC flat car. Dynamic brake tests were run using the instrumented EMD SD-45 unit and the SP dynamometer car. A comparison of results of these tests with those from AAR tests in 1966 shows much higher buff force was attained in current tests than with the three Alco 623 locomotives. There were a number of occasions where steady state L/V ratio approached or exceeded 0.82 which predicts impending wheel lift. Although maintenance of alignment control features on locomotive couplers will serve to prevent excessive lateral force and rail climbing by diesel locomotives, the increase in dynamic braking power above that afforded by 24 axles does not appear feasible on mountain grades. As a result of several derailments of unexplained cause, a task force investigate the dynamic forces exerted by locomotive and freight car wheels against the rail.

SIGNALLING ON A MODERN RAILWAY SYSTEM

Signalling techniques on the railways have progressed through the manual block system to the Centralized Traffic Control, where the movement of trains is controlled from a central headquarters, with the track display of a district and the appertaining switch and signal actuating equipment located in the usual desk arrangement, observed and operated manually. Interlocking of crossings at grade are included in this system. The longer braking distances resulting from the 200 km/h and more operation presently necessitate modification of this system to include continuous automatic train control, which can be projected ultimately to automatic train operation and travelling on instrument vision. This article describes the use of computers for this type of control of trains. The computers are presently used for indirect control of train movements through existing signal equipment. The problems of extending this system to direct control of train movements are under consideration. The question whether the direct control of trains is possible or economical without local interlocking frames is at present unresolved. [German]

PERFORMANCE OF FREIGHT CAR BRAKE REGULATORS DURING STATIC AND DYNAMIC CONDITIONS

The continued observation of improper brake piston travel on freight cars equipped with automatic brake regulators prompted an investigation of factors affecting the operation of these devices. Tests made statically and dynamically showed a marked difference in performance of regulators. The factors surrounding this problem and the effect on train braking are discussed. Selected for the test were representative cars of a large group of covered hopper cars. These 2929 cu ft 100-ton cars are virtually identical, having 12 in. by 10 in. brake cylinders, cast iron shoes and four types of brake regulators. Conclusions would include: brake regulators do not adjust for false or running piston travel, improvements of rigging efficiency will yield more uniform piston travel, lower leverage ratios make piston travel variation less susceptible to rigging dynamics and stretch; piston travel increases with speed of train regardless of cylinder pressures; vibration or impacts caused by rough track or train slack action appear to have no effect on operation of the brake regulator after the unit locks up and although greater than nominal piston travel occurs on cars at speed, the brakes still retain effective stopping ability.

BRAKING HIGH-SPEED FREIGHT TRAINS AND EFFECTS ON RAILROAD CAPACITY

The effect of improving freight train braking levels is to increase railroad capacity by allowing higher speeds with heavier cars within present or specific signal spacings. Freight train braking abilities can be improved 20 to 30 percent by equipping cars with WABCOPAC truck-contained foundation brake equipment and by converting existing cars to the use of COBRA high-friction composition brake shoes. Combining these two improvements give improved train braking abilities from 30 to 50 percent which will allow speeds to be increased from approximately 10 to 20 mph within existing signal spacings. Establishing a basically higher loaded-car braking level some 50-70 percent higher than the existing minimum with a load-sensitive brake equipment would allow raising the maximum speed, based on braking considerations only, close to 100 mph within signal spacing now suitable for 65 to 70 mph. Freight train braking abilities can be improved 10 to 30 percent by adding modern-design continuous quick service valves to all freight cars.

CARRIAGE AND RAILCAR BOGIES: THEIR DESIGN AND DEVELOPMENT–IV

Design factors considered in this part include brake ratios; axle fatigue; adhesion, and P.D. More effective braking will require ratios 1:1.5 to 2.2 of the tare weight, cut back to 0.8 at lower speeds. A routine method of axle fatigue calculation indicating the influence of such design variables as fillet radii, type of vehicle, speeds, whether four-wheeler or bogie, and so on, relating to dynamic load allowance and other factors is long overdue. Adhesion improvement through truck linkage to the body at low level requires care that bogie pitching will not cause high stress peaks at the kingpin or cause intense shuttle of the body.

THE PROBLEMS OF TRACKWAY AND SIGNAL TECHNIQUES FOR RAIL

The problems relating to high speed travel are outlined. For speeds up to 250 km/h, the conventional form of track structure, with ties on the ballasted road bed, will suffice, using the presently available equipment and motive power systems. The following improvements in the present rail permanent way are suggested for attaining the full benefit in travel time reduction from the high speed operation: strengthening the present track structure system; improving the soil foundation under the track structure; improving the track with consideration for the centrifugal forces of vehicles on curves; elimination of close track spacing; elimination of railway road crossings; and equipping the high speed sections with continuous train control. SAFETY AND RELIABILITY OF COMPUTER-CONTROLLED RAILWAY OPERATION

The application of computer techniques to the problem of handling train movements is discussed. All phases of such a system and its workability are investigated for safety and reliability. The chances of an erroneous output from the computer that could affect a train movement are computed to be extremely small. The duplex computer system provides a method of safeguarding against a failure in the output. The conclusions reached in all questions relating to this possible means of controlling train operations gives the go ahead for computer-controlled railway train operation. [German]

STUDIES ON INTERVAL DISTANCE BRAKING WITH PRIMARY AND SECONDARY RETARDERS IN THE HUMP INSTALLATIONS IN TRAIN YARDS

One important problem of the automation of train hump yards is the automatic control of the speed of all cars in the distribution track zone between the hump and the last of the distribution switches. The results of the studies of this problem are described, which the Swiss Federal Railways researched with the aid of their Computer-Program. The basic observations of the free-running of cars in the distribution zone were considered, which required the distinction between "free-rollers" and "hard-rollers". To equalize this situation, the "hard-rollers" required acceleration and the "free-rollers" required deceleration or braking. In addition, the basic considerations of braking in the distribution zone required studies to attain the desired speed interval braking of the various types of rolling cars. A detailed description of the programmed braking is given, as well as its application to these hump yard operations. [German]

THE EFFECT OF BRAKE SHOE ACTION ON THERMAL CRACKING AND ON FAILURE OF WROUGHT STEEL RAILWAY CAR WHEELS
Laboratory test were made on 369 wrought steel railway car wheels. Two types of tests were performed: the wheels were stopped from high speed by using high brake shoe pressure, and the wheels were tested under long-continued applications of the brake shoes. The stop tests were intended to produce thermal cracks in the wheel treads. The long-continued brake shoe applications were intended to produce fractures through the rims and plates of the wheels. In both types of tests the conditions imposed on the wheels were more severe than the wheels should receive in normal railway operation. The studies of the effect of carbon content of the wheel material, various methods of heat treatment, and changes in wheel design, together with a qualitative analysis of the stresses developed in the wheels are presented.

SD-45 LOCOMOTIVE DYNAMIC BRAKE TRAIN HANDLING TESTS ON PENNSYLVANIA RAILROAD
Because of a major derailment near Johnstown, Pa., a series of dynamics brake handling tests were conducted between Harrisburgh and Pittsburgh, on severe grades and curves. The trains in which the test unit and the adjacent long overhang boxcar operated were varied in nature, ranging from tonnage trains while operating in a two-unit consist to trailer trains and PR trains in four-and eight-unit consists. In general, with the loaded long overhang boxcar leading the train, the records indicate that at no time did the danger of derailing due to drawbar forces exist. No instances in the entire test program exhibited lateral force levels which would be of concern with respect to derailment. The boxcar was loaded with freight during all of the tests.

THE CONTRIBUTION OF SIGNALLING TECHNIQUES
Since the braking distance for the 200 Km/h trains is 2200 m for emergency and 3500 m for service brake applications, additional changes in signalling systems are necessary. The lengthening of the signal blocks is neither appropriate nor desirable to accommodate all kinds of trains. The alternate was the development of the continuous train control system. The effective distance between blocks is lengthened for the high speed trains, by changing the intervening blocks to display caution, whereby the affected train must reduce its speed to 160 Km/h. The control system provides automatic control of the high speed train by binary coded information which is transmitted through a separate signal communication line to the locomotive. Signal messages can be transmitted over the same frequency back to the control headquarters. The technical processes of this interchange of information and the manner of control of the train through the programmed cab signals and information and the automatic operation of the locomotive controls are described in detail. ROAD TESTS WITH TYPE AB FREIGHT BRAKE EQUIPMENT--CHAPTER VII GENERAL SUMMARY AND CONCLUSIONS
Demonstration tests of the "AB" freight brake equipment are summarized. This series of tests was made for the purpose of (1) checking the operation of the new "AB" equipment with the operation of the "FC-3A" equipment as developed during the American Railway Association tests on the Southern Pacific Lines in Oregon; (2) investigation the operation of the new "AB" equipment with trains containing both empty and loaded cars; (3) investigating the effect of the "AB" equipment when operated in trains composed of both "AB" and "K" equipments, and (4) determining whether the "AB" equipment would meet road conditions safely in service. Sixty-one tests consisting of 234 trials were made during the demonstration tests. The different types of trains tested included "AB" equipment trains of all empty cars, mixed loaded and empty car trains, all loaded car trains, and also mixed "K" and "AB" equipment trains of all empty cars. In conclusion it may be stated that the "AB" equipment would meet road conditions safely in service.

LOCOMOTIVE WHEEL-TO-RAIL TRACTION
It is shown (on the basis of laboratory data) that the low values of locomotive wheel-to-rail traction caused by contaminants can be increased and stabilized under both driving and braking conditions by the application of a high-frequency (HF) induction-coupled air plasma torch to each rail ahead of the lead drive wheel. Descriptions are given of experiments to investigate friction effects of RF ionized gases, corona discharge, an acetylene torch, a do argon plasma torch, and an HF induction-coupled air plasma torch. The plasma torch has given a two to three-fold friction increase under laboratory conditions, even with oiled surfaces.

BRAKE-SHOES MADE FROM SYNTHETIC MATERIALS--REPORT OF ENQUIRY
An enquiry was made to member organizations to gather information on the interest in and experience with the use of non-metallic brake blocks for railway brakes. Information was also sought from the literature on this subject. The interest in non-metallic brake blocks is very great, and it seems that there introduction may result in economical advantages, no steps of any importance have so far been taken for the drawing-up, on an international level, of specifications for these brake blocks. Only a few organizations have gained sufficient experience of many years standing or have introduced these brake blocks on any appreciable scale.

COMPOSITION BRAKE BLOCKS--COMPARATIVE TESTS ON THE TESTING PLANT
This report contains the results of braking tests from speeds of up to 160 km/h to a stop, and continuous braking tests at about 60 km/h. These were made employing 15 different existing types of composition brake blocks, on the brake block testing plant of the SNCF. The various types of brake blocks investigated had coefficients of friction remarkably similar both in character and magnitude. At the moment of coming to rest, the percentage increases in the instantaneous coefficient of friction is up to one tenth of that when braking is affected with cast iron blocks.

COMPOSITION BRAKE BLOCKS--INTERACTION BETWEEN COMPOSITION BRAKE BLOCKS AND WHEELS
The service tests with various makes of K-block on the Berliner S-Bahn are described. The object of the tests was to study the interaction of the two friction elements, block/wheel. Although a strong tendency for the formation of cracks in wheel tires had occasionally been observed with K-blocks, in the service tests such a tendency could not be detected. All the stages of grooving and follow-wear were present on the tires. Similar phenomena had been observed by the SNCF on suburban services. Experience gained by the DB showed that some difficulty arose due to metallic particles sometimes becoming embedded in the braking surface of the block. K-blocks were used extensively on the London Transport Underground lines. Thermal cracking, tire spalling and wear constituted a special problem on the frequently-stopping motor coaches with heavily-loaded small diameter wheels, running in tube tunnels. The performance of a K-block depended on various parameters: characteristics of the block and of the wheel steel, application conditions, service conditions, weather, and shape of block. The development of a universal K-block would be difficult.

COMPOSITION BRAKE-BLOCKS-EFFECTS ON ADHESION
The effects of composition brake blocks on adhesion were investigated by the DB. The measurements were analyzed statistically and the results plotted in the form of curves. Generally, lower adhesion values were ascertained when braking with K blocks than when using cast-iron blocks. As such an effect is only acceptable if it is small, severe testing is, in this respect, considered to be necessary when submitting K blocks to acceptance tests.

Restrictions on the use of this document are contained in the explanatory material.

COMPOSITION BRAKE-BLOCKS-EFFECTS OF HUMIDITY ON BRAKING
Tests carried out by the SNCF, to determine the effects of humidity on braking; were made with 20 different types of existing composition brake-block. On the test rig at Vitry, braking tests were made from speeds of up to 160 km/h to a stop, and continuous braking tests were made with single cars at about 60 km/h. In service, fly-shunting tests at speeds of up to 140 km/h were made. The brake-block wear was not measured during the tests on wet rails. The similarity of the curves obtained with the different makes of block on dry wheels was not repeated on wet wheels. It would seem that not all the blocks have been designed and manufactured with the same object of obtaining satisfactory performances under wet conditions.

B8 040405
COMPOSITION BRAKE-BLOCKS. EFFECTS OF ICE AND SNOW
The effect of winter conditions on the braking distance proved to be considerable. Using the results of all the tests undertaken in winter with composition brake-shoes it was calculated that the braking distances in winter were on average 36% longer than in summer. The great amount of humidity due to the melting of the snow and the ice probably contributed considerably to the increase in the braking distances. With one type of composition brake-shoes, the braking distances were, on the whole, shorter in the winter tests than in the summer tests. This might have been due to the effect of the temperature on the coefficient of friction with these types of brake-shoes. The braking distances obtained with the low-friction brake-shoes were in certain instances more than 100% longer than those obtained during the summer tests, because of the effect of the snow and ice adhering to the blocks. Since only a small number of preliminary-braking tests were carried out it is not possible to deduce from the results any valid conclusions concerning the effect of preliminary braking.

Restrictions on the use of this document are contained in the explanatory material.

DEVELOPMENT OF THE DISC BRAKE WITH PARTICULAR REFERENCE TO BRITISH RAILWAYS APPLICATION
The development of disc brakes for passenger vehicles for British Railways is reviewed. In the last year a brake has been developed for service up to 125 mph incorporating wheel cheek discs and lightweight cylinders. A 12-car train has now been built and is also fitted with a new design of electronic Wheel Slide Prevention equipment. This is completely self-contained in two units, one fitted to the axlebox and containing the sensing and control modules, the other comprising a pneumatic valve fitting in the adjacent bogie pipe work. No external electrical supply is needed and no wiring is used other than a flexible cable joining the two units. Design trends are now towards one cylinder for each brake. To reduce costs, light pressed steel cylinders, mass produced for road vehicles are being introduced. This paper describes in some detail the design and operation of some disc brake installations within the period 1954-1968.

RHEOSTATIC BRAKING WITHOUT MOTORING ALL AXLES
The power circuits for the system are shown. The detailed sequence of events during a stop using rheostatic braking is as follows: A command is received to brake at one of the specified rates (1.5, 2.1, or 2.6 mph p.s.), both electro-pneumatic and rheostatic brake circuits are energized. When a rheostatic braking current has been established on every equipment on the train a change-over relay is energized and this releases the air brakes on all cars. The rheostatic braking continues to build up through the operation of a camshaft switching unit, which reduces progressively the degree of field divert until it is checked by the operation of the rheostatic current limit relay (RCLR) when the current value is reached which represents the maximum which can reasonably be permitted under tare conditions. The performance is shown which was obtained with the equipment in terms of percentage of train energy dissipated rheostatically for various speeds of entry and various rates of retardation. The degree of success which is achieved with this scheme will be revealed by the extent to which wheel wear is reduced.

COMPOSITION BRAKE BLOCKS AND TYRES
This paper describes some of the problem which have arisen from the use of composition brake blocks in the past. For at least two of these, wet stopping performance and thermal cracking, there is now an understanding of the problem and possible solutions. Present-day production has also resulted in blocks free from the other difficulties. Other methods of avoiding the dangers associated with thermal cracking have been indicated: these involve moving away from the classic wheel and tire arrangement and the materials which have persisted for many years.

MODERN DEVELOPMENTS IN WHEELSLIP CONTROL ON ELECTRIC LOCOMOTIVES
The reasons for wheelslip are discussed indicating what happens when it does occur on different types of locomotive and under different circumstances, and what action can be taken to correct it. The coefficient of friction is shown versus slip speed and the probably maximum useful adhesion is shown for various speeds on wet and dry rail. The natural and slipping characteristics of a number of motors shows why some locomotives are less steady on their feet than others. Wheelslip results in loss of tractive effort and at a standstill or at low speeds can cause wheel burns. Ways of avoiding wheelslip by correcting weight transfer problems, by controlling the acceleration cycle with small notches in the contactors and by limiting the tractive effect. When slip is detected, one of the following actions is recommended: reduction of tractive effort, applications of sand, light application of air brakes, and armature shunting.

VACUUM BRAKING OF HEAVY FREIGHT TRAINS ON THE BROAD GAUGE, INDIAN RAILWAYS
Indian Railways are the largest system using vacuum brakes. Braking distances for 2200 ton trains are shown. Clasp brakes improved the coefficient of friction; the shoe pressure and friction are plotted as a function of speed. The initial developments comprising emply-load change-over devices, slack adjusters, clasp brakes, etc., have made possible the running of 3,200 ton trains without increasing braking distances over those obtaining with 2,200 ton four-wheeler trains. With the rapidly increasing transportation requirements, running of 4,500 ton trains is an immediate necessity. Improvements under consideration to permit 4500 ton trains include, modified cages, direct admission valves, and 80 mm train-pipe. Incorporation of the developments now under study, such as higher brake ratios, improved rigging, composition brake shoes, etc., will enable the vacuum brake to meet the future transportation requirements of 6,000 to 7,000 ton trains at higher speeds.

SIGNALLING FOR HIGH SPEED TRAINS
In this paper the author has tried to analyze the signaling problems of high-speed operation, and to bring them into perspective. The paper discusses the limitations of contemporary modern signaling when applied to higher speeds and the principles upon which an acceptable solution might be based. Speeds higher than 100 mph bring other problems than signaling, notably those of line capacity, track maintenance, and automatic train control. It was claimed that signaling requirements for speeds of 100 to 125 mph and 100 to 150 mph are different. In one case existing signaling can be modified to achieve desired safety requirements, and in the other a new and additional system must be considered.

AIR BRAKE EQUIPMENT: PERFORMANCE AND MAINTENANCE
This paper discusses some of the more troublesome problems that have been experienced together with the remedies and maintenance procedures adopted to overcome them on air brake equipment. These problems relate to (1) teething troubles which require modifications to equipment, (2) training of both the operating and maintenance staff, (3) having to maintain a more sophisticated system of braking which has tight operating tolerances, and (4) operating two completely different systems during the transition period. In conclusion it is important to emphasize that the two-pipe air brake system as adopted by British Railways for locomotive-hauled trains, is considered to give the best performance that can be obtained from a purely pneumatic system, being second only to the electro-pneumatic brake such as is used on electric multiple units.

B8 040829
DISCUSSION ON "THE ENGINEERING ASPECTS OF HIGH-SPEED TRAINS" (1) MOTIVE POWER; (2) PASSENGER ROLLING STOCK; (3) BRAKING AND SIGNALLING; (4) PERMANENT WAY
This paper surveys the engineering aspects of high-speed trains in terms of motive power, passenger rolling stock, braking and signaling, and permanent way. In developing high-speed trains there is clearly a need to examine all aspects of vehicle performance on the track, and also a need to subject every item of traction equipment to the closest secrutiny to ensure that it is suitable for onerous high-speed duties. The car of the future will probably be lower and smoother, and with smaller windows than present-day cars. It will be pressurized and adjacent body ends will be closer to incorporate peripheral coupling and improve passenger access. It will also cost more. A basic consideration in obtaining the best brake performance of high-speed trains is the maximum braking retardation. When high retardations are used and as the maximum speed of trains increases from about 100 mph to 120 mph (or even 150 mph) two problems of braking which become increasingly important are adhesion and heat dissipation. Both necessitate modifications to present braking practice when higher speed stops are to be made. It is generally agreed that at high speeds some form of cab signaling is essential, and systems in use vary from the relatively simple A.W.S. as used in this country to apparatus which starts, controls, and stops the train automatically. There is every justification to believe that, from the point of construction, modern track would be quite suitable for speeds up to 160 mph--possibly more--where it is straight or flat-curved.

STUDY OF FRICTIONAL CHARACTERISTICS OF COMPOSITION COMPARED TO CAST IRON BRAKE SHOES
An investigation was made to study the braking characteristics of various types of brake shoes on switching locomotives. This work was conducted on the Seaboard Coast Line Railroad at Waycross, Georgia, in 1968. The field work was supplemented with laboratory work conducted at the AAR Research Department on the brake shoe dynamometer machine. The frictional effect of breakaway resistance of wheels was also studied by the use of this machine. It was concluded that: 1. Braking force developed by the brake system is dependent upon the fundamentals of friction of the brake shoe on the wheel and pressure applied on the shoe. 2. The stopping distances are independent of the type brake shoe or whether single or clasp brakes are used, provided that proper coefficient of friction of brake shoes and brake shoe pressure are used in the design. 3. Brake shoe pressures that develop restraining forces greater than can be withstood by the wheel-rail contact will result in the tendency to reduce braking effort and cause slid flat wheels. 4. The coefficient of friction values for the cast iron shoe compared with the composition shoes are sufficiently similar to permit use of either type of shoe provided proper brake cylinder pressure is maintained and suitable lever ratios are used in the design.

MICROWAVE NETWORK IS VITAL TO IC'S TELEPROCESSING SYSTEM
Illinois Central's 900 mile microwave system between Chicago and New Orleans serves their MAIN Teleprocessing System, serves their centralized dispatching from Chicago, and provides voice communications for their telephone system. Information from 27 hotbox detectors is sent to MAIN over the microwave system, and MAIN has two way radio communication with train crews as an integral part of the communications capability. Information from Automatic Car Identification installations is transmitted over the microwave system. Hot standby/space diversity is used for path protection. All microwave stations have an eight hour backup battery plant. GTE Lenkurt provided engineering, microwave equipment, and acted as prime contractor for the towers.

FCC GRANTS PETITION ON TONE MODULATION
The Federal Communications Commission granted an AAR petition to permit tone modulation on a secondary basis to voice operations on railroad frequencies in the 160 MHz band and on certain 450 MHz band frequencies for remote control of locomotives and cab indicators. The FCC also agreed to permit use of two pairs of frequencies in the 450-460 MHz band, now reserved for slave locomotive control, for the additional functions requested. The FCC amended frequency tolerance rules to permit use of mobile transmitting equipment as base stations on two frequency pairs in railroad yards and terminals. The FCC denied the request to permit use of two splinter frequencies of 157.450 and 159.480 MHz for control of slave locomotives.

RAILROAD FAX USAGE HAS GROWN
This article summarizes the replies of thirteen railroads to a survey of railroad usage of facsimilie transmission. Southern Railway's LDX system, with 38 locations transmitting to Atlanta, is the largest installation. Fax usage on the thirteen railroads includes both short distance yard and terminal applications and long distance inter-city applications. Information transmitted includes passenger reservations, switch lists, work orders, waybills, car inventories, train lists, office memos, and general operating information.

SAFETY BOARD ASKS FRA TO WRITE RADIO RULES
The National Transportation Safety recommends that the Federal Railroad Administration: 1) Issues as soon as possible regulations to provide for the use of radio in railroad operations. These regulations should include the traditional safeguards found in existing railroads operating rules where they apply to train movements. It is further recommended that, in drafting such regulations, consideration be given to the principles and procedures for radio used by military and civilian aviation authorities. 2) Review and revise as necessary its accident reporting requirements and investigation procedures to insure that all facets of the involvement of radio or the absence of radio are determined and reported.

This article is a reprint of National Transportation Safety Board's Safety recommendations No. R-72-9 and R-72-10, released May 17, 1972.

RADIO NETWORK BLANKET LIRR
Long Island Rail Road recently put in operation what is probably one of the most extensive VHF radio communications systems on any commuter line. The new network is made up of four VHF radio communications systems, costing about $800,000. The four, each complete and distinct, operate in the 160 MHz band and are used as follows: 1) Police department--all vehicles, walkie-talkies and pocket-pagers. 2) Maintenance of Way No. 1--communications, electric traction, substations and signals. 3) Maintenance of Way No. 2--track, structures, bridges, buildings and miscellany. 4) Train to Wayside--diesel locomotives, electric trains, both communicating direct to wayside towers and/or the movement bureau at Jamaica station.

CP HAS PROCESS CONTROL AT ALYTH
Canadian Pacific has modernized the old Alyth Yard to the standards of today. The new yard has a sustainable throughput of 3,000 cars per day and incorporates the greatest number of automation features to date in one yard. Located at the junction of four main lines, Alyth Yard is the keystone of CP operations in the west. The problem is to keep everyone informed of factors affecting their work, and the objective is to supply each yard supervisor with the information he needs. Two Honeywell DDP-516 process control computers with associated peripherals provide process control, data processing, and back-up protection. The punched card format used is the same as that at the central computer system in Montreal. Seven cathode ray tubes with keyboards are used for input-output devices, and printers are used for hard copy. Complete data on every car in the yard is available in the computers. Ten Automatic Car Identification scanners will be used, eight at yard entrances, one at an interchange, and one on the hump approach track. Computer enhancement of the ACI data will be performed.

INDUCTIVE CIRCUIT WORKS AT CROSSINGS
The MIPCO inductive track circuit (ITC) is for use in "dead" section protection. The high-frequency inductive track circuit (ITC-HF) operates at frequencies in the range of 55 to 160 KHz for track length of 4 to 600 ft with shunting sensitivity generally above one ohm. The track is terminated with low impedance at both ends, either or both of which may be an uninsulated rail of a crossing frog (dead section) and serves as a single-turn secondary of the transmitting circuit connected to a single-turn primary of the receiving circuit.

VHF RADIO COVERAGE TESTED
With the increasing use of unit trains, and longer freight trains, the use of remotely-controlled helper, or slave locomotives, placed toward the rear of these long trains has become quite commonplace. Controls from the lead unit, and indication or status responses from the slave unit are sent between units using VHF radio. Continuity of radio service is essential for satisfactory slave locomotive operation. Several railroads have made radio propagation tests to determine the extent of radio coverage along lines where such slave locomotive operations take place. These tests and the results are described in this article.

PCM USED FOR REMOTE CONTROLS
The General Electric pulse code modulated PCM radio remote control system is designed to meet the complete requirements for remote operation of mining, industrial and railroad locomotives by an operator who is up to 2,000 ft from the unit. Up to 30 locomotives, with 15 commands to each, can be controlled from separate transmitters operating on a single licensed frequency. A self synchronous feature of the system insures reliability of transmissions to the locomotives. The equipment operates in the 72-76 MHz or 150-174 MHz frequency range and meets all FCC requirements for permanent licensing, including the 0.5 watt transmitter output maximum.

SIGNALING HIGHLIGHTS MEETING
This article presents subjects discussed at the ASME/IEEE April 1971 Railroad Conference, principally a cybernetic system to improve line capacity and the impact of electrification on signaling and communications. An analysis of electrical noise currents in the running rails included: noise currents produced by conventional switched resistor and new chopper propulsion systems, currents produced by substation power systems incorporating rotary convertors and mercury and silicon controlled rectifiers. The best potential for electrification in North America is some 20,000 miles of track averaging over 40 trains per day. One thousand amperes flowing in the catenary with a deep ground return will induce about 500 to 700 volts per mile in parallel signal and communications lines at the usual locations. A completely new signaling system may cost less than a retrofit. Development of a cybernetic system to improve line capacity was reported by the French National Railroads for a route on which freight, passenger, and commuter trains all converge on two tracks. The cybernetic system consists of three subsystems: signaling and routes, traction control on commuter trains,and dispatching.

HOW GTE INFORMATION SYSTEMS AIDS RAILROADS
Railroads have failed to meet the fifth deadline for equipping all cars used in interchange with Automatic Car Identification labels. Some railroads are reluctant to spend money to label cars when the railroad has no ACI scanners. Other railroads are reluctant to spend money for scanners when the cars are not all labeled. GTE Information Systems has made economic and operational analyses of ACI in these areas: terminal analysis procedure, ACI checking of pullout in a hump yard, ACI checking of inbound and outbound consists, ACI site survey worksheet, communications criteria for ACI. The ACI checking of pullout in a hump yard indicates a return of from 48 to 145 percent. Checking the inbound and outbound consists indicates a return of 29 percent. Copies of the reports are available to railroads.

RADIO IS KEY LINK IN CONTROLLING SWITCHES AT COPPER MINE

Frequent relocations of tracks, heavy traffic 24 hr daily, plus possible damage from debris resulting from blasting, are but three factors making radio control of power switches practical at Bingham Canyon open-pit copper mine, in Utah. Moving trackage is common at Bingham Canyon. It takes approximately two tons of waste or overburden and one ton of ore to produce 14 lb of pure copper. Thus, there is a continuous excavating to step-back the mine, which requires moving trackage to the newly opened mining areas. Controls and indications of the signals and power switches in the mine are sent to and from control panels via radio, eliminating the need for a pole line or cable communications.

RADIO CONTROLLED UNITS HELP STEEL COMPANY

Locomotives and self-propelled scrap vehicles are remotely controlled via radio at the Burns Harbor plant of Bethlehem Steel Corporation in northern Indiana. Remote control equipment and systems including the retarders at the Burns Harbor plant were designed and furnished by the General Railway Signal Company. The GRS radio remote control system is capable of controlling as many as 128 vehicles, each up to 16 commands, simultaneously on the same radio frequency, without interference. Transmitting range is kept down to approximately half a mile to further minimize interference. The 154 MHz signal is transmitted in the form of random pulses, at the rate of one pulse during each 100 millisecond period of time. This technique practically eliminates the possibility of two simultaneously-transmitted pulses blocking one another.

HVDC TRANSMISSION MAY CAUSE INTERFERENCE TO COMMUNICATIONS CIRCUITS

A high-voltage direct current transmission line, constructed in the western United States, operates at 800,000 volts and carries 1800 amperes current. Tests made on the 853-mile line indicate that serious interference does exist in the portion of the spectrum 3 KHz to 150 KHz. In the portion between 3 KHz and 124 KHz, the converter/inverter stations were generating noise of considerable magnitude into railroads' communication facilities. Very little effect was noted from those frequencies above 124 KHz. Further, little effect was noted in the frequency range 0 KHz to 3 KHz. Railroad communication facilities using superimposed carrier techniques normally operate in the range 4 to 150 KHz; therefore the noise being generated by the Celilo converter/inverter station falls directly within the operating range of the railroad's carrier derived communications systems. The carrier systems affected are utilized for voice transmission, dispatchers' telephones, for analog data, i.e., hotbox detectors and other systems of this type and digital data, i.e., teleprinter circuits, centralized train control coding equipment and systems of this type.

This paper was presented at the 10th Annual Meeting, Communication & Signal Section, AAR, San Francisco, California, September 17, 1970.

WHAT IS TRAIN-STOP

Experience indicates that in recent years railroads may be stopping too many trains for suspected hot boxes. Two railroads, Southern and Norfolk & Western, have examined the situation. Their findings are that many trains having roller-bearing equipped cars are being stopped because the journals are running at above normal temperatures. Also, the train crew which makes the judgement in the field takes the safest course of action, that is set the suspected car rather than take the chance of having a bearing fail with possible resultant derailment. Over lubrication appears to be one possible cause of these bearings to run at elevated temperatures which actuates hot box detectors. Improved journal bearing maintenance practices may reduce abnormal running bearings and decrease the number of train stops.

This article contains the abstracts of two papers presented at the recent annual meeting of the Communication & Signal Section, AAR.

MICROWAVE USES PCM

In the railroad industry, communications have been strained to stay one step ahead of rolling-stock technology. Railroad technology is becoming increasingly dependent on the computer. The communication systems must be optimized in such a way that they will not choke on the vast amount of information that has to be handled every day of the year. And an effective, economical system must handle both voice communication and data efficiently. Canadian Marconi has developed a new microwave (PCM) system-MCS6900-which meets these objectives and is presented here.

B8 041071
TRANSIT COMMUNICATIONS HAS RADIO, INTERCOMS

Comfort and convenience are now considered important along with the physical act of transportation. Hence, dissemination of information about operations, especially helpful when delays occur, plays a key role in today's transit systems. Improved operations control result from extensive use of instant two-way communication between dispatchers, train operators, conductors and law enforcement personnel. Three basic communications systems are being employed by transit authorities and commuter railroads, namely two-way radio, intercommunications and public address systems. In some cases, it is possible to combine these three systems employing much common equipment. However, some communications experts prefer to keep the radio system separate from PA and intercom equipment. Failure of a common unit shared by radio, PA or intercom systems might cause one or more systems to become inoperable. Radio is commonly used for train-to-wayside communications between train crews and operating officials and law enforcement personnel so that failure of the radio equipment

could be critical. However, intercoms and PA systems are often combined, using much common equipment.

AUTOMATIC TRAIN STOPPING HAS BEEN DEVELOPED FOR RAPID TRANSIT
Precision stopping equipment has become a requirement for most modern rapid transit systems for two reasons. First, modern systems require air-conditioned platforms for passenger comfort requiring stops with very tight tolerances which will permit the vehicle door to line up with the platform doors. Secondly, if the position of the train can be specified accurately, the passengers can station themselves along the platform and save time and confusion. This article describes a system developed for BART trains. The automatic stopping feature is also used by the Port Authority Transit Corporation on its trains operating between Philadelphia, Pennsylvania and Lindenwold, New Jersey.

TRACK CIRCUIT SHUNTING TESTED ON ELECTRIFIED SUBURBAN LINE
Following reports from several Australian State Railways that unsafe track circuit switch failures had increased with the general introduction of synthetic resin brake shoes, a series of comparative tests, under controlled conditions, have been carried out on various types of rolling stock and rail surfaces on the Victorian system. Tests conducted under the most adverse conditions indicate that wheel-to-rail resistance was generally up to ten times greater for cars fitted with synthetic resin brake shoes than those fitted with cast iron brake shoes. One of the conditions encountered is that of rail film caused by rainy or humid weather. One result of the tests was that wheels fitted with cast iron brake shoes had superior film penetration and rail cleaning action to those fitted with synthetic brake shoes. In one series of tests conducted on equivalent type of rail surfaces, wheel-to-rail contact resistance was 0.138 ohms for trailer wheels with synthetic resin brake shoes and 0.0145 ohms for wheels with cast iron brake shoes. A description of how the track circuit switch tests were carreid out, methods of upgrading track circuits to handle lightweight trains fitted with synthetic resin brake shoes, and an explanation for the defective switching sometimes experienced with lightweight passenger vehicles on branch lines are included.

RAPID TRANSIT TRAINS RUN AUTOMATICALLY TO SERVE PHILADELPHIA AREA
To handle upwards of 30,000 commuters daily, a Philadelphia area transit line has found that automatic train operation and centralized control provide a successful operation. Port Authority Transit Corp., operates a 14.5-mile, double-track line from 16th and Locust Streets in down town Philadelphia to Lindenwold, N.J., via Camden. PATCO runs expresses mixed with locals during rush hours to provide headways down to three minutes. An attendant

operates door controls and "Start" button to start the train. After the "start" button is pressed (with doors closed-an interlock prevents starting with doors open), the train runs automatically to the next station where it is brought to a stop near the center of the platform. Supervisory control of ten interlockings, the power system for traction current and three communications systems are all controlled from Center Tower at Broadway, Camden. To communicate with passengers in stations, a public address system was provided. Also tied in with the Trainphone radio system on trains, announcements can be made to passengers riding the trains. Dispatcher-to-train attendants' communication is carried out via the Trainphone radio system. An automatic dial telephone system provides service between Center Tower, all power substations, passenger stations and repair shops.

D&RGW HAS DISPATCHER-CONTROL OF RADIO STATIONS OVER ENTIRE SYSTEM

To keep everyone informed about train movements, reliable and complete communications coverage is necessary. Denver & Rio Grande Western has achieved such communications coverage via its recently completed dispatcher-controlled, base-radio station program. Radio coverage provides two-way communications between dispatchers and personnel on rolling stock on main and branch lines, totaling some 1300 miles. Also, personnel in radio-equipped vehicles on adjacent highways can talk to or be called by dispatchers. By use of special tones, men in the field can alert the dispatcher to the fact that they wish to talk to him. A special muting device enables the dispatcher to have "peace and quiet" for planning moves, yet a light and bell will call his attention to a call from the field. This muting feature enables D&RGW to conserve radio frequencies in that only one frequency can serve for both end-to-end and train-to-wayside service. Dispatchers at Denver, Grand Junction and Salt Lake City can cover the entire system.

BN BURIES FIVE CONTROL CABLES

Burlington Northern has used a cable-laying machine to bury signaling and communications cables. Six cables were buried five feet deep along seven miles of main line. Five cables were buried along three miles of branch line. Static wire and cables were buried in 3,000 to 5,000 foot lengths. High voltage power lines parallel to the tracks were interfering with the railroad signals and communications. The ac induction into the tracks was dangerous. On the first pass, the cables are buried in the trench cut by the plow. Work train speed is one mile per hour. Plow operator and workmen on the reel car had radio contact with the locomotive engineer.

KCS EXTENDS REMOTE CONTROLLED LOCOMOTIVE OPERATION AND CTC

By the end of 1972, Kansas City Southern will have 11 sets of remote locomotive control equipment installed in its units. Synchronous power to the rear permits slashing drawbar and knuckle failures 50% compared with all power at the head end. Location of rear consists must be varied depending on loading, train length, and weather. With remote control locomotives in the train, there is a reduction in slack action, faster charging of the brake pipe at terminals, an improvement in starting, and a reduction in sticking brakes. Since braking response is improved, train speeds can be increased. Splitting power reduces the potential for derailing long cars, and reduces wheel and flange wear. The characteristics of handling short trains are imparted to the longest. Heavier trains can be moved over the ruling grades.

WASHINGTON SUBWAY AUTOMATES

The Washington Metro will be an automated transit system. Train operation will be automatic, but an attendent will be on board. Maximum speed will be 75 mph, with headways as close as 90 seconds. The control system, to be supplied by General Railway Signal Company, will consist of three control subsystems and a computerized central control facility. The subsystems are: automatic train protection, automatic train supervision, and automatic train operation. This article presents information on these subsystems, and includes block diagrams and illustrative diagrams. Train Detection, Automatic Speed Commands, Metro-Link Hardware, Flyby Receivers and Transmitters, and the Door Operating system are discussed. Also discussed are Dispatching of Trains, Interlockings, and the No-Break Power Supply.

SAFETY APPLIANCES AND POWER BRAKES

This current compilation of standards established for cars and locomotives by Federal regulation is a successor to the ICC's Safety Appliance Standards, last published in 1946, and to the Power Brake Law pamphlet, issued in 1958. It incorporates requirements for today's rolling stock, including tank cars without underframes, hi-cube box cars and cars of special design.

This book was published by the Bureau of Railroad Safety, Federal Railroad Administration and announced in Railway Locomotives and Cars, V145, N9, September 1971.

ELECTRICATION--ITS EFFECT ON SIGNALING AND COMMUNICATIONS

Electrification of a railroad generally involves costly changes to the signaling and communications facilities. Electrification provides significant benefits to the railroads and to the public. Power circuits will produce extraneous voltages and currents in communication circuits, caused by magnetic induction, electric induction, ground potential conduction, or accidental connection. Rails are grounded through ballast, and part of the return

current flows through the ground. One means of reducing the induced voltages over long distances is the three-wire system using autotransformers and a negative feeder. Fault currents can cause high induced voltages and currents. Unless preventive steps are taken, hazards can exist for personnel and equipment. Electification will generally be applied to high density lines which already have extensive communications and signaling facilities. Installation will have to be accomplished under traffic without disruption of traffic. The challenge is to make the changes to signaling and communications add to the benefits rather than just to the costs. Several diagrams are included illustrating the induction effects.

This paper was presented at the Tenth Annual Meeting of the Communication and Signal Section of the Association of American Railroads, San Francisco, California, September 15-17, 1970.

A PRESCRIPTION FOR BART
As the result of a sequence of mishaps and incidents occurring in the automated operation of the Bay Area Rapid Transit (BART) system since partial revenue service was inaugurated last September 11, considerable skepticism has been expressed by many sources as to the safety of this ultrasophisticated mass-transit system. These critical evaluations led to the empaneling of a select three-man committee to report on the safety of the BART ATC system. In brief, the panel did not find the system's present mode of operation unsafe, but said the present system would not provide adequate passenger safety under full-scale operation, and recommended modifications and redesign to correct the deficiencies.

BART'S HARDWARE--FROM BOLTS TO COMPUTERS
In 1965 BART began the Mt. Diablo Test Track. Three laboratory cars were built and used to test new technology. The testing program included reduction of sound and vibration, propulsion equipment and power supply, transit vehicle trucks, automatic train operation, rails and rail support, and aerial structures, tubes, and tunnels. Five propulsion system were tested, and dc chopper control was selected. The Rohr built transit cars, 250 of them, feature cantilever seat construction, noise suppression, air conditioning, and glare free lighting. The car trucks are equipped with derail detectors connected into the automatic train operation system. On aerial structures and in tunnels, rail is fastened directly to the concrete slab or tunnel invert. For the Berkeley Hills tunnel, which crosses the Hayward Fault, rails were mounted on timber ties to permit speedy realignment. The Trans Bay Tube contains both horizontal and vertical curvature. Fifty-seven prefabricated sections were floated into position, then sunk. The Trans Bay Tube terminates in a ventilation building at each end. Cathodic protection is used. Welded rail was used, and the second pour technique for concrete. BART purchases power at 34.5 kvac. This power system has seven sections. An I section steel third rail provides strength and the top running surface for overrunning pickup shoes. Aluminum inserts carry the current. A J shaped cover protects against accidental contact. Automatic train operation handles speed regulation, programmed station stops, and train door operation. Line supervision provides best possible service schedules. Train protection maintains the safety of the operation.

This article is the third of a series on BART. Refer to RRIS #041625 Section 23 for a note on special availability.

MORE BART HARDWARE
BART's central control at Lake Merritt is the nerve center for its communications network. More than 300 discrete channels and four radio channels are used. Wireline carrier uses a double sideband suppressed carrier AM modem that can carry 24 channels over two pairs of wires. BART uses a PBX dial system leased from the telephone company. However, for wayside maintenance use, there is a separate maintenance telephone throughout the entire BART system. Emergency phones are located along the route. BART has a fully automatic fare collection system. A ticket console produces a magnetic card ticket with the amount the passenger wishes to purchase. Upon entering a station, a ticket console encodes entry data. Upon departure from the passenger's final station, the gate console deducts the proper amount and recodes the balance. For exact fare remaining, the console captures the ticket. For insufficient fare, the ticket is rejected and a lighted display directs the passenger to the Addfare machine. Subway construction near Civic Center required working well below the water table. A wall was constructed down to an impervious layer of soil by a special technique. Land beneath aerial structures has been made into Linear Parks.

This article is the fourth of a series on BART. Refer to RRIS #041625 Section 23 for a note on special availability.

RAILROAD OPERATION AND RAILWAY SIGNALING
The basic text which explains the relationship between train operation and railway signaling is now available in reprint form. The text is in the form of questions and answers so that the reader may know the objective of the information given, and to place emphasis upon the "why" and "how" of railway signaling and railroad operation. Topics covered include fixed signals, block signaling, interlockings, centralized traffic control, cab signals and highway grade crossing protection.

This is a reprint of the 1953 edition. The price for 1 to 9 copies is $5.95 each, and for 10 or more it is $5.00 each.

TELECOMMUNICATION SYSTEMS IN RELATION TO 50 HZ A.C. ELECTRIC TRACTION
Current methods for reducing the effects of inductive interference in lineside telecommunication cables on railroads, electrified at industrial frequency, are summarized. The methods employed by British Railways for calculating

induced longtudinal voltages in cables are outlined, together with standard calculated values in tabular form. The degree of electromagnetic shielding which can be obtained by the use of high-conductivity cable sheaths and steel-tape armoring is illustrated. The effects of the method of traction-current control in motive-power units, with respect to the generation of noise in cables, are discussed.

NONFRICTION BRAKING METHODS FOR RAILWAY VEHICLES
Performance potential and approximate cost estimates are presented for three nonfriction braking systems: air retarder, hydraulic retarder, and aerodynamic braking. It is shown that the air and the hydraulic retarders have potential to develop full braking deceleration in a speed range from 250 to 25 mph. Because of the air retarder's potential advantages in system weight, simplicity and cost, prototype development of the retarder is indicated. Aerodynamic braking deceleration is highly dependent on the cumulative effect of longitudinally spaced braking surfaces. Further wind tunnel testing is required for complete evaluation.

BIGGER BUGS IN BART?
Six months in partial service have raised questions about BART's automation and its safety features. On October 2, 1972 a computer-controlled BART train overshot the Fremont station and plunged the lead car onto a

sand bank. The cause was a malfunction of a crystal oscillator on board the lead car. This article reviews some of the problems that have occurred, and summarizes some of the reports that have been released. A report by State Legislative Analyst Alan Post has two principal stipulations: (1) that BART's service began without adequate checks and with train control deficiencies, and (2) that BART was overcharged for the system engineering and construction-management services. Post's report explains that the low-power circuit in the tracks may not detect a train under certain conditions. BART has run 28 million passenger miles in automatic mode with manual block as backup for train separation. Present operations, according to BART, are fully automatic more than 95% of the time. A report by Battelle Institute concluded that under normal conditions the system appears to operate in a manner that is not unsafe; under conditions of single malfunctions no clearly defined unsafe operating condition was identified, and that the operating safety of the vehicle system depends on redundant rather than fail-safe circuits. The article also presents some of the reactions of the consultants and of the supplier of the automatic control system. The article notes that off-the-shelf mechanical wheel scrubbers may solve the train detection problem. The article concludes with some findings of a blue ribbon panel.

INDUCTIVE COORDINATION GETS SYSTEMS APPROACH
To help solve the problems of inductive interference that might result when a high-voltage power line is constructed along a railroad right-of-way, Northern States Power Co. used the system approach. When NSP was about to build an 11-mile parallel of high-voltage transmission lines along Burlington Northern lines in Minnesota, the approach taken was to determine correct solutions for the problems that the induced voltages might cause. Subjects considered high-speed protective relaying, protection for signal and communications circuits, and grounding, among others.

This article is essentially the full text of a paper delivered at the Communications and Signal Section, AAR, 1972 annual meeting.

DETECTION AND RECOGNITION OF COLORED SIGNAL LIGHTS
Two experiments were designed to determine effective colors for stimulus lights as measured by speed of detection and accuracy of identification. In addition, the nature of the interactions between stimulus color, background color, and amount of ambient illumination was assessed. Responses to four stimulus lights (red, green, yellow, and white) were evaluated against four colored backgrounds (copper, tan, blue, and green) under two levels of ambient illumination. The overall ordering of stimulus colors as measured by speed of responding was, from fastest to slowest, red, green, yellow, and

white. For errors in color naming, the order from least to most was green, red, white, and yellow. Detection and identification were more difficult under bright ambient illumination. The addition of an identification task added about 0.25 second to the response times for each color.

A SCHEME FOR INSTALLING C.T.C. ON THE CHEAP
Centralised traffic control is almost invariably introduced in under-developed countries to increase the capacity of busy sections of line. Indeed, the associated reduction in station staff can be an embarrassment rather than an advantage where high unemployment is a problem. David Thornber points out that c.t.c. can be introduced at perhaps one-fifth of the present cost if it is regarded only as a better means of communication between the controller and signalmen, while still achieving the desired increase in line capacity.

TWO-WAY RADIO COMMUNICATION MASS TRANSPORTATION DEMONSTRATION PROJECT
Existing equipment prior to the demonstration required that train crews descend to the tracks to report trouble, while police had to rely on conventional telephones available only in station clerks' booths. A variety of alternative mobile systems and components were considered, including train-to-wayside intercom systems currently used in Chicago, Toronto, and London. These proved too limited in scope for the complex New York City subway network. A portable, transistorized transmitter/receiver was judged ideal, particularly for the policemen who required compact, durable equipment. The engineering, operation, and maintenance of the selected system is documented. The improved communications were evaluated primarily in terms of reduced train delays and police reaction time. The latter was demonstrated to be particularly effective. Message delays between police dispatchers and transit patrollmen were reduced by 99%, and the ratio between crimes and arrests improved by 8% during daylight hours and rose to 95% at night. Overall operational efficiency also showed substantial improvement. The average number of train delays per month decreased 41%, and the average duration of such delays decreased 9% in the test area as compared with the system as a whole. Ridership within the test area was also shown to increase during the demonstration. It is concluded that overall, the project was successful enough to warrant the use of two-way radio equipment throughout the New York subway system. Appendices deal with capital and overhead costs for the project, and requirements for extension of the system to other divisions of the subway network.

DIGITAL-VOICE OVERLAY FOR LAND MOBILE COMMUNICATIONS
The technical feasibility of alternative means of multiplexing data and voice transmissions in a vehicle location and communications system is treated. Multiplexing refers to the sharing of a transmitter, a receiver, and a radio frequency channel by different users. Two multiplexing techniques are discussed: "time division" methods (tdm), in which each broadcaster is given a particular time slot during which he may transmit data and all other users remain silent; and frequency slot separated by guard bands to minimize cross-channel effects. Because tdm technology cannot easily or economically handle both voice and digital transmissions, the report focuses on fdm applications. Fdm systems necessarily employ equipment to modulate voice and data inputs in order to channel them into their appropriate slots. Considerations in applying channel modulation in location and communications systems are (1) frequency modulation, which is standard for land mobile services but requires potentially undesirable bandwidth occupancy requirements; (2) amplitude modulation, which suffers potential fading and drifting problems; (3) frequency shift keying; (4) phase-shift keying; and (5) on-off keying. Bandwidth requirements and data rate capability are discussed with reference to alternative fdm applications. Trade-offs in voice-data multiplex are considered in terms of power requirements for switching between voice and digital transmissions in the same frequency subchannel. Baseband spectrum occupancy, power requirements, and on operational considerations are also examined. The report concludes with a brief discussion of federal communications regulations that apply to implementation.

COMPUTER SIMULATION OF RAIL VEHICLE BRAKING PERFORMANCE
The ability to predict rail vehicle braking performance has been of vital interest to the railroads and railway brake equipment suppliers. A computer program developed to simulate rail vehicle braking performance provides a practical and efficient method of calculating braking performance and permits study and analysis of all elements of braking. For background information this paper briefly reviews the factors that affect braking performance, provides information on how the data for evaluating these factors was obtained, and describes the logic used in devising the computer program. The accuracy of the program is demonstrated by comparing calculated test results with actual field test and dynamometer test data. The potential usage of the program for the analysis of rail vehicle braking is described in general terms.

USE OF MINICOMPUTERS IN CTC OPERATION

This paper is organized into four divisions such that each division is an attempt to answer one of four questions. The four questions are: (1) What is computerized cTc? (2) How does computerized cTc function? (3) What need does computerized cTc fill? and (4) To what will the acceptance of computerized cTc lead: what may be the time frame? Centralized Traffic Control (cTc) is a method for controlling the traffic on a railroad system from a central location. The application of cTc has generally been restricted to main line operation between distant points so that railroad lines covering hundreds of miles are controlled over a telemetry system from a single location. The cTc system may therefore be considered in three parts; that is, the field circuits or field stations, the communications circuit or circuits which link the field to the single central location (office), and the central location or office itself. Computerized cTc is an office device which interfaces to the communications circuits to interrogate the status of the field locations and control these field locations. As computerized cTc is presently viewed by General Railway Signal, the computerization of the office need have no immediate impact on any existing field circuit design.

This paper was recommended by the IEEE Land Transportation Committee of the IEEE Industry Applications Society for presentation at the 1973 Joint ASME/IEEE Railroad Conference, St. Louis, Mo., April 11-12, 1973. The price is $1.35 for members.

SURGE PROTECTION FOR SOLID STATE RAILROAD SIGNAL EQUIPMENT

Railroad signaling and communications equipment must operate under conditions that causes electrical surges. The problem of surge protection has been solved for conventional devices, and is now being solved for solid state devices. Electrical surges can be caused by lightning discharges, by power system switching and fault surges, and by the space charge associated with a cloud. Solid state devices are generally subject to damage by breakdown in the reverse direction. Protection problems can be grouped into three general areas: (1) AC power lines, (2) battery power supplies, and (3) information circuits of AC or modulated DC. The report describes the approaches taken for each of the three areas. Various methods of protection are explained and are illustrated with circuit diagrams.

ELECTRIFICATION HAS IMPACT ON SIGNALING

Electrification with its parallel power lines can interfere with signal systems. The effects of earth voltage gradients can cause foreign current to flow in track circuits. Electrostatic and electromagnetic induction due to inductive coupling exists between the power lines, track circuits and open wire C&S lines. Accidental contact between phase wires of the power line and some part of the signal system cause interference to the latter.

MODERNIZATION OF SIGNALING MAINTENANCE

The mode of signaling maintenance presently being promoted which is claimed to be the most effective one, aims at preventing a fault in the facilities and assuring high efficiency in their operation. It is natural that even if JNR developments in equipment maintenance follow the same course as in general industries, the maintenance of signaling facilities in JNR is characterized by the early introduction (about 50 years ago) of the idea of "preventive maintenance." Preventive maintenance as contrasted to "break-down maintenance," means that, through periodic inspection, signs of functional deterioration in the equipment are detected early and the necessary steps are taken to restore its function and thereby maintain the functional integrity of the equipment. Thus, a progressive step was taken in this direction and since 1965, what might be called "corrective maintenance" has been positively introduced. More recently, another approach is being promoted in addition to the above-mentioned corrective maintenance approach; namely, the so-called "maintenance-free" principle: that is, the idea of securing the individual reliability of each component in a piece of equipment and improving the overall reliability of the unit as a whole.

CONTINUOUS-ACCESS GUIDED COMMUNICATION (CAGC) FOR GROUND-TRANSPORTATION SYSTEMS

Electromagnetic open-guiding structures, or surface waveguides, for continuous-access guided communication (CAGC) and obstacle detection ("guided radar"), are described for use in ground transportation, such as railways, highways, and more advanced guided systems. The experimental and theoretical work at Queen's University on surface-wave devices and their application to obstacle detection are reviewed in detail. It is concluded that there is considerable promise in these techniques and that obstacle detection, in particular, deserves much more attention than it appears to have received.

Special issue on ground transportation for the eighties.

ALTERNATIVE SYSTEMS FOR RAPID-TRANSIT PROPULSION AND ELECTRICAL BRAKING

The need for rapid transit is stimulating further development in the technology and equipment for propulsion and electrical braking. Although the traditional cam-controller equipment is being improved, control systems

based on thyristors have some advantages over it, achieved at a cost in weight and complexity of the control equipment. The thyristor approaches overcome 2 basic problems of cam-controller equipment: the need for continual maintenance on the cam switch contacts and the power losses incurred when voltage is controlled by resistors.

B8 046426
RAILROAD SIGNALING TECHNOLOGY: A NEW APPROACH
The ever increasing volume of rail traffic demands an increase in capacity, which can only be met with higher traffic speeds and greater traffic density. Traffic control is essentially vehicle and track control and should therefore be automated to meet the demand. Control technologies using special circuit elements should not be employed. The aim should be to use standard, universally applicable circuit elements, as for example, large scale integrated circuits. Failure should be detected and corrected by software techniques tht ensure the fail-safe principle. Modified and improved existing systems using these techniques should be constructed on a building block principle and capable of change and expansion to enable any future system modification to be integrated.

AUTOMATION IN RAILWAY TRAFFIC CONTROL
The aim of railway traffic control is safety of operation coupled with maximum traffic density. The use of track circuits, automatic train control, centralized train control and the mechanised hump yard for marshalling trains is described. This control in addition to enhancing the safety of operation, produces considerable economics and large increases in revenue but its wholesale application is restricted by the lack of trained technicians. The author concludes that this deficiency requires a vast investment in staff training.

SURFACE WAVE CORRIDORS. COMMUNICATIONS FOR HIGH SPEED GROUND TRANSPORTATION SYSTEMS
A surface wave travels around a single conductor within a space of limited radius. Its low loss and broad bandwidth permit this line to replace coaxial cable and microwave relays for CATV and power distribution. The surface wave field can be extended to envelop a railroad track or a highway, and act as a continuous sensor for trains or vehicular traffic, and when surrounding a security area, to pinpoint an intruder. Essentially non-radiating, a number of surface wave corridors could coexist side by side, without interfering with each other or with the public wave spectrum.

S&C CAN LIVE WITH 50KV, 60 HZ AC
Signal and communications facilities can be converted for satisfactory operation in electrified territory on railroads. There is no simple formula for determining conversion costs. Studies have indicated a variety of costs ranging from a low of $9,000 per track mile to a high of $30,000 per track mile. The type of signal and communications facilities in the existing railroad plant determine to a large extent the cost of making them compatible with electrified operations. Techniques for conversion are now known and proved feasible.

INTERCONNECTION IS VITAL TO RAILROADS
Railroads are vitally concerned with interconnection of their communications facilities with those of the public telephone network. At present, the Federal Communications Commission is looking into the matter. Generally, the telephone companies desire to install their own protective devices at the interface of customer-owned facilities and those of the phone companies. Railroads which have the expertise and ability to interconnect their own communications networks without harm to the public systems do not want to have this additional expense. Working with the AAR Communication & Signal Section, railroads can report on their experiences and problems in the interconnection field.

VIEWING OF RAILWAY FLASHING LIGHT SIGNALS
An attempt is made to bridge the gap existing between theoretical knowledge and published material on the one hand, and the practical application to an efficient outdoor flashing light warning system for railway purposes, on the other. The relative effectiveness of flashing light highway crossing signals under the full range of environmental conditions likely to be experienced in service is determined by many diverse factors, the principal ones being contrast brightness, apparent brightness magnitude, intensity of light output, signal colour, alignment and focusing of lights, and signal range. An examination is made of the above items and conclusions are drawn as to the minimum standards necessary for optimum viewing.

B8 047476
ELECTRIC BRAKING-PART 1: MULTIPLE UNITS
Braking is simply a means of converting energy from one form into another. The moving train has kinetic energy which can be calculated. If the train slows down for any reason, its kinetic energy must be converted into some other kind of energy. If a simple mechanical brake is used, the energy appears as heat; similarly, if the vehicle is coasting to a lower speed, heat appears in the bearings as a result of friction. If an electric brake is used, electricity is the new form of energy. This article is the first of two dealing with electric brakes on railways; it deals mainly with electric braking on multiple-unit trains.

DISC BRAKES : CONTRIBUTION TO THE STUDY OF THEIR RATIONAL USE ON RAILWAY VEHICLES [LE FREIN A DISQUES CONTRIBUTION A L'ETUDE DE SON UTILIZATION RATIONELLE SUR LES VEHICULES FERROVIAIRES]
Braking problems have become more complicated with highspeed running and, in solving them, greater consideration must be given to the inherent characteristics of disc brakes which are quite different from those of conventional brakes with cast-iron blocks. Initially, disc brakes are generally more expensive to install than shoe brakes but under actual operating conditions they can be more economical provided the discs last sufficiently long and the quality of the linings is good. The study of the basic phenomena which distinguish the operation of this brake system has been undertaken at the international level by the UIC Braking Sub-Committee. The article draws attention to the importance of the assembly of the discs and their mechanical arrangement which must allow for the expansion caused by heating when the brakes are applied. The work carried out includes the determination, on the brake testing plant at Vitry, of the maximum performance obtainable both for holding braking and braking to a stop, with given axle loads, average decelerations and speeds. A further study, based initially on theoretical calculations and the use of a computer, has shown the importance of the average diameter of the disc on the performance obtainable. The study also includes the examination of the adhesion conditions that are feasible on polluted rail, compared with brakes with cast-iron blocks. An effective solution has been proposed for curing the adhesion defects noted with disc brakes in the case of high performances. The study has also highlighted the importance of the linings on the performance that can be obtained with disc brakes, and how this performance can drop in the case of exceptional weather conditions (snow and low temperatures). Line tests, under difficult winter conditions, have enabled these phenomena to be determined with precision. [French]

DEVELOPMENT OF LOCAL SIGNAL BOXES ON THE PARIS UNDERGROUND [L'EVOLUTION DES POSTES DE MANOEUVRE LOCAUX DU "METRO" URBAIN DE PARIS]
The authors (respectively Chief Engineer at the Electric Equipment Department and Chief Divisional Engineers at the Research Department of the RATP) explain the nature of the two types of shunting carried out in the Underground: a) ordinary: change of tracks at termini and stabling of trains; b) exceptional: change of tracks on the line and change of lines. They give historical details of earlier systems and describe the characteristics of the boxes used, whose efficiency is measured by their speed of action and their degree of automation and which incorporate two distinct techniques: one traditional for safety requirements, the other industrial for associated functions to simplify operations. The first all-relay boxes were installed in 1940; a new type of box known as the PEX (box recently been opened and the article gives its main characteristics. [French]

SIGNAL BOXES DEVELOPMENT AND CURRENT TRENDS [LES POSTES DE SIGNALISATION-EVOLUTION ET TENDANCES ACTUELLES]
The development of signal boxes on the SNCF has been directed mainly to concentration and extension of the area controlled by each box. In the circumstances, mechanical and electro-mechanical boxes have been practically eliminated. "All-relay" electric boxes have reached a satisfactory stage of technological development in the form of PRS-NS1 boxes. Certain variants of the conventional PRS box are however of special interest. The main variant is the PRGS or the Simplified Geographical All-Relay Box. This is an adaptation to SNCF requirements of boxes with a geographical structure and an "entry-exit" pubh-button table, as used by several European railways. The PRGS boxes are not equipped for pre-setting which is no disadvantage for the applications planned, i.e. for medium-sized stations, and consequently they represent an appreciable saving. Another variant is the "turn-push" handle type of box. The handles may be "individual" ones and form the basis of the PRMI which is replacing the PELI: track handle boxes can also be built especially for controlling the head of a set of service sidings. From the technological aspect, NS1 relays are being introduced at the same time as static components which seem to be very suitable for PRGS boxes. [French]

THE COMPOSITION SHOE CONTRIBUTION TO MODERN RAILROAD SERVICE
Something over ten years ago an intensive investigation was started to determine the specification for the ideal friction material for tread brake shoes to be used in railroad service. The general conclusions of this research were: 1. The coefficient of friction of the material should be uniform through out the speed range but with a slightly rising characteristic to substantially match the wheel-rail adhesion as the speed reduces. 2. Brake shoes made of such material should have a service life which would make the economics of its use highly attractive. 3. The friction material should have a higher coefficient of friction than conventionally employed to make possible greater simplification of control equipment and brake rigging. 4. The friction material must operate compatibly with existing wheels to improve wheel performance and economics. 5. Reliable braking performance must be assured under all normal operating conditions, including wet weather. Shortly after the above period, Westinghouse Air Brake Company, working with John-Manville Corporation, began their search for composition friction materials which would possess the foregoing characteristics to the greatest extent possible. Approximately four years ago, a modern composition shoe, called the COBRA shoe was offered for commercial use. There are now over 80 million vehicle miles of service experience with the shoe. Considerable pertinent data have been gathered with respect to its characteristics and performance.

THE COBRA SHOE IN LOCOMOTIVE SERVICE
The braking forces when COBRA shoes are applied to a locomotive must be less then when metal shoes are used, since the COBRA shoe has a higher coefficient of friction. The spread between the coefficients of friction of COBRA and metal shoes increases as the speed increases; therefore, the nominal operating speed must be taken into account when COBRA shoes are applied. For this reason, the amount of braking force varies with type of service and with the brake system. One amount of force is used for the independent brake system which is normally used in low speed switching service. A different amount of force is used for the automatic brake system which is sused at the higher speeds encountered in road service. With this in mind, the tabulation lists the general recommended braking ratios for application of CoBRA shoes to locomotives.

WABCOPAC BRAKE ASSEMBLY TODAY-DESIGN AND PERFORMANCE
The WABCOPAC brake assembly has now been in service for approximately 12 years with over 120,000 cars presently equipped. Most of these cars are of the high utilization, high capacity types. As occurs with any equipment offered for general interchange service, many evolutionary improvements have been made over this 12-year period. Some were made as a result of changing operating requirements, others because of the extensive service experience reflecting all types of operating and environmental conditions. This paper will discuss the design improvements incorporated into the WABCOPAC brake assembly over this period, the test criteria used to evaluate the effectiveness of these changes, and the improved braking performance that the WABCOPAC brake assembly is presently providing.

BRAKE SHOE PERFORMANCE ON 100 TON FREIGHT CARS
The braking performance of 100-ton cars should be viewed from the ability to provide a braking level or stopping capability no less favorable than lighter weight cars. Such a performance level can not be matched by 100-ton cars with cast metal shoes at a reasonable braking ratio. However the performance criteria for COBRA shoes on 100-ton cars is to provide a stopping ability, at minimum, on less favorable than a 50-ton car with cast metal shoes. This has obvious benefits in the areas of signal spacing, high speed consideration, etc. With this stopping ability however the most advantageous maintenance and economic relationships available should be realized. With the number of existing 100-ton cars with metal shoes presently in service, together with the majority of new 100-ton cars having COBRA shoes, it has been possible to accurately measure the economic and braking performance relationships between the two brake shoe concepts. The information contained in this presentation provides a summary of data in both of these areas.

CONVERTING FREIGHT CARS TO COBRA SHOES BY MEANS OF A 7 1/2 INCH CONVERSION KIT IN A 10 INCH AB BRAKE CYLINDER
A simple method to obtain the benefits of COBRA shoes on existing 50 and 70-ton freight cars equipped with cast metal brake shoes is to use the 7-1/2" brake cylinder conversion kit in the AB-10" brake cylinder. This presentation illustrates the upgraded braking performance and the resulting brake shoe and wheel savings when such cars are converted to COBRA shoes by this means. This conversion is also a simple solution to the problem of meeting the recommended braking ratio level on rebuilt cars affected by the 5% increase in gross rail load limit.

UPGRADED TRAIN BRAKE PERFORMANCE RESULTING FROM 1972 BRAKING RATIO DEFINITIONS
Braking ration in its specific terminology is merely an expression of the percentage of car weight which is translatable to total brake shoe force. In the past few years the AAR has systematically addressed their attention to recognizing and establishing some degree of limits on several of the variables which effect brake performance. With the advent of composition brake shoes, a performance specification was adopted which, in effect, set acceptable maximum and minimum friction levels for this type of brake shoe in both "stop" type braking and continous horsepower or grade braking. Essentially this redefinition of braking ratio eliminated the rigging loss variable as a factor influencing brake performance.

INCREASED STOPPING DISTANCES DUE TO ICE ON BRAKE BLOCKS
A theory is proposed which predicts increased stopping distances due to ice on brake blocks by assuming that an initial low brake friction is maintained until the ice layer is melted by frictional heating. The friction then becomes that of the dry block. Reasonable agreement is obtained with Winter stopping distances published by O.R.E. which reveal that all types of block, including cast iron, are similary affected by pre-formed ice layers.

ELECTRIC BRAKING, PART 2: LOCOMOTIVES
While, for multiple units the emphasis with braking is usually on stopping the train, for locomotives it is more usual to want to use the electric brake to hold a steady speed, supplementing this with air (or vacuum) to bring the train to a stop. Locomotives fitted with dynamic brake are therefore usually found on railway systems with long grades. The basic problems for multiple unit and locomotives are the same (slow-speed fade-out matching regenerated energy to the receptivity of the supply) but they have differing degrees of urgency for the two types of vehicle. Again, for locomotives, both rheostatic and regenerative brakes are available and either can be operated alone or blended with air/vacuum.

Electric Braking, Part 1, dealing with braking of multiple units, was published in Modern Railways, August 1973.

AUTOMATION IN THE SUBURBS: OPERATION, SIGNALLING, DRIVING AIDS AND TRAFFIC CONTROL
In this article, the authors, who are senior officials at the SNCF responsible respectively for cybernetics matters at the Transport Management and the Research Department, explain the objectives sought by automation when it is particularly desirable as is the case for very dense suburban traffic varying from day to day and from hour to hour, and which can have a detrimental effect on main line traffic. They give details of the essential operational functions that must be carried out, the need to rectify as possible any incidents which may occur so that normal running can be resumed, how driving and other railway staff are involved, the systems in operation and the results obtained. They place special emphasis on the importance of strict traffic monitoring and control, especially in suburban areas, which, by employing a sophisticated driving programme (acceleration or deceleration) depending on the actual or predicted line occupation, enable more trains to be worked through during a given period of time. PRESENT KNOWLEDGE OF ADHESION AND ITS UTILISATION
The phenomenon of adhesion has since become the vital problem, representing the principal limitation to the increase in the magnitude of the tractive and braking forces at low speed as well as at medium speed. Scope and nature of the investigations concerning adhesion and its utilization have obviously developed in parallel to the importance attached to the problem itself. During the last decades, research on the subject of adhesion has not only developed considerably but its nature has also undergone a remarkable development. These different research programmes have already enabled several countries to achieve substantial improvements in the values of the adhesion coefficient which were applied in connection with the calculation of maximum train loads.

AUTOMATION OF MOTIVE POWER UNITS AS REGARDS THE CONSTRUCTION OF ELECTRIC LOCOMOTIVES
The author shows the reasons for which the railways are particularly suitable for automation, from both a technical and an economic point of view, and then examines automatic train running control, continuous automatic control and cab signals, and automatic running and braking control, describing, as an example, the DB's type 103 high-speed locomotive and its equipment. He also describes the experiments carried out on series 110 300 and 110 299 locomotives, as well as on locomotive 112 270, equipped for braking to a stop, and refers to the ultimate object of research, which should result in the rationalization, as well as in an improvement and speeding-up, of the whole process of transport.

RECENT DEVELOPMENTS IN THE REGULATION OF THE MOVEMENT OF TRAINS
The above article deals with the studies which are now being carried out on British Railway with the object of improving the flow of traffic. A description is given of the necessary equipment, which is now being perfected, for the creation of a system of communications enabling permanent bilateral communications to be established, as well as a more material link for the tramsission of data between the control centres and the moving trains, and a special computer is being constructed which, when placed on the train, will constantly keep the driver informed of the maximum speed to be observed. It should be noted that the control centres will not transmit information concerning safety, so that, even in the case of breakdown, it will be possible for the trains to continue to run in complete security. A computer, known as a "safety computer" will record, on punched cards, the safety details relating specifically to a train, and will process them with the help of the information obtained from the track.

DEVELOPMENTS IN TRAIN CONTROL ON BRITISH RAILWAYS
After commenting briefly on the equipment available up to 1970, the authors provide a description of the Southern Region Automatic Warning Systems (STRAWS), which is used on the line between Totton and Bournemouth. This installation is to be improved by means of the following additional equipment; (1) automatic speed control with an integrated programme on the motive-power unit; (2) introduction of a central cabin for the control of programme alternations; (3) marshalling and running control of trains in the event of delay. This equipment has been designed in such a way as to remain compatible with the later development of train control by means of a central computer. Provision has been made for two types of equipment--that which is directly concerned with operating safety, and that which is independent of it. During 1972, an automatic installation for bringing a train alongside a platform by means of centralized control will be tested at Glasgow Central Station. It comprises a computer with store which optimises the use of the 13 tracks in accordance with the schedules of the trains running through a 6-track bottleneck at the entrance to the station.

PERFORMANCE TEST OF AN AUTOMATIC TRAIN POSITIONED STOP SYSTEM
The author shows the lay-outs provided on a vehicle incorporated in a train, as well as between the tracks on the Shin-Kansen line, in order to ensure that trains stop at a given point in Kyoto station. The installation operates at an approach speed of 70 km/h using multiplex equipment, with transmission and reception of signals on 72 KHz. The conventional train equipment has not been altered--the brakes are operated by this equipment, and by the control device, which receives the signals in accordance with the running speeds and the distance to the stopping point. The stopping distance is adjusted to some 0.05 m. As this technique has now been perfected, its practical application is expected very soon.

THE WASHINGTON METRO AUTOMATIC TRAIN SUPERVISION SYSTEM
The Washington Metro will be operated as a fully automated rapid transit system. Normal system operation will be controlled by the Automatic Train Control System which is comprised of the Automatic Train Protection, Operation and Supervision subsystems. This paper is divided into two parts: Part I provides an overview of system operation, including the role played by each of the subsystems in providing control of train separation and train speed, route security, control of acceleration and station stopping, and maintenance of schedules through computer-directed performance level and dwell adjustments. Part II provides a detailed description of the Automatic Train Supervision system and the methods employed by the computer software to exercise supervisory control of the system. The major programs and the software-hardware interface which provide the supervisory functions for train and terminal operations are described. A discussion of the strategies employed during major service disruptions closes the paper.

TELECOMMUNICATIONS RESEARCH IN THE UNITED STATES AND SELECTED FOREIGN COUNTRIES: A PRELIMINARY SURVEY
A preliminary investigation has been carried out on the command and control of rail transportation, both in the U.S. and overseas. An overriding consideration of rail transportation is safety, both for reasons of preservation of human life and for the high cost of a failure in potential damage to property. As such, railway signaling has evolved not only in a "fail-safe" mode, but in one where innovation must pass a series of slowly ascending levels of trial before being generally accepted in the industry. The second consideration is that of low R&D funding levels. In recent years gross investment in rail transportation has been low as the high technology fields of air and space have preoccupied governments.

TRACK CIRCUITS FOR MODERN RAPID TRANSIT SYSTEMS
Track circuits have been used in American Railroads for over a hundred years. Although the basic idea (use of rails as part of detection circuit) remains the same, changes in implementation have been made constantly to meet new requirements and to take advantage of advances in technology. In modern rapid transit applications track circuits must meet certain requirements in performing their function of train detection and broken rail protection. The track circuits must operate reliably without insulating joints and with lightweight cars using disk brakes. As modern rapid transit systems use chopper controlled propulsion systems the track circuits have to be designed for operation without interference from chopper harmonics. Track circuits without insulating joints result in problems which must be solved for safe and reliable operation.

BIBLIOGRAPHY ON RAILWAY SIGNALLING 1960-1972
The purpose of this study was to examine present-day railway signalling systems with a view to formulating recommendations for improved signalling on Canadian railways. Such recommendations were to be made on the basis of increasing efficiency and/or safety and reducing maintenance and operating costs. The present bibliography list reference published during the period of 1960 to the present, with an emphasis on references after 1965. No attempt has been made to list all titles available during this period. However, where possible representative titles of those subject areas considered relevant to advanced railway signalling systems have been included.

THE AUTOMATIC DIGITAL COMPUTER CONTROL OF VEHICLES IN RAPID TRANSIT SYSTEMS FOR URBAN TRANSPORTATION
This paper considers the problem of controlling vehicles in a rapid transit system using an on-line digital computer. Vehicle speeds and spacings are obtained periodically and are used by the control computer to calculate the required driving or braking forces for the next time period. A largely non-mathematical description is given of multivariable control methods which allow rapid transit schemes to operate efficiently for any number of vehicles with maximum capacity consistent with safety requirements and comfort. Difficulties which arise because of uncertainties in data in practical cases due to measurement errors, interference, or malfunction are alleviated by the control method and produce no significant deterioration in system performance. Consideration is given to non-linearities, merging, starting, etc., which are inherent in any overall scheme. Practicality is borne in mind throughout the description.

B8 052101
THE DISC BRAKE. A CONTRIBUTION TOWARDS THE STUDY OF ITS RATIONAL USE ON RAIL VEHICLES
From the point of view of their conventional methods of production, and given the same wheel diameters, the disc brake enables, in the case of braking to a stop, a greater amount of energy to be dissipated than does a cast-iron brake block. There exists, therefore, a field, which is that of high speeds and heavy axle loads, in which the use of the disc brake is more appropriate than of the brake block. It is, however, difficult to define where precisely the limits of this field lay, as they also depend, in fact, on the braking performance, i.e. the average rate of deceleration required and, therefore, on the signalling system used. The brake lining pads play an outstanding part. The results which can be expected from a disc brake depend, in the first place, on the lining pads, which should be capable of satisfactory performance, both when the temperature is high, and under special atmospheric conditions (low temperatures, and considerable humidity).

BRAKING MOVEMENT OF TRANSPORT VEHICLES WITH HYDRAULIC RETARDATION [DVIZHENIE TRANSPORTNYKH SREDSTV V TORMOZNOM REZHIME S GIDROZAMEDLENIEM]

Conditions of hydraulic braking are given in the form of mathematical dependence formulas. Base equations of motion in the braking mode of operation and of speed change during the period of braking are presented. Conditions are defined for the absence of wheel sliding, formulas are given for determining the path and time of braking in different conditions. Dependence relations are given determining the necessary hydraulic counter-pressures. Results of this work can be utilized for designing hydraulic braking systems for mine cars railroad rolling stock, automobiles and other types of transport. [Russian]

APPLICATION OF THYRISTORS IN RAILWAY TECHNOLOGY: CONSEQUENCES AND REMEDIES. INVESTIGATIONS ON A.C. MOTIVE POWER UNITS WITH SEVERAL THYRISTOR CIRCUITS (TESTS AND RESULTS OBTAINED FROM THE BLS-LOCOMOTIVE RE4/4 NO. 161)

This report concerns the tests undertaken with the BLS-Locomotive Re 4/4 161 fitted with several thyristor circuits. The object of the tests was to clarify the changes in the power factor and the harmonic wave content-the latter in view of its effects on signalling and telecommunication installations-resulting from the increased number of inverter steps and the limitation of the firing angle of the thyristor bridges to 35 degrees. The tests conducted have shown that in the case of thyristor-controlled motive power units, a multi-step control of the voltage regulation leads to a reduction of the harmonics of the line current and to an improvement in the power factor during acceleration and running below full power. The limitation of the firing angle of the thyristor bridges of 35 degrees, considered in its entirety, does not bring any advantages however.

APPLICATION OF THYRISTORS IN RAILWAY TECHNOLOGY: CONSEQUENCES AND REMEDIES. TESTS WITH A STATIC FREQUENCY CONVERTER FOR 50-16 2/3 HZ

The Swedish State Railways (SJ) have conducted several comparative measurements on the Moholm-Skovde line, using a prototype of a static frequency converter (power 6 MVA) During the tests the equivalent disturbing currents and the weighted longitudinal e.m.f. induced in telecommunication circuits were measured; for these tests, the test line was fed through the static converter or through rotary converters. When the feeding took place through the static converter, the levels of the disturbing current in the overhead contact system and the induced weighted longitudinal e.m.f. were raised. However, a lowering of the levels measured may be expected, after the filter for the static converter has been modified. On the three-phase side there are no adverse effects, as long as the power of the static converter is very small in comparison with the short-circuit power of the high voltage network. The SJ have ordered, for two sub-stations, two static converters each with a power of 15 MVA each.

ELASTIC SYSTEMS FOR TRACTION AND SHOCK GEAR (SIDE BUFFERS AND CENTRE BUFFERS). THEORETICAL STUDIES OF THE DEVELOPMENT OF LONGITUDINAL FORCES IN GOODS TRAINS EQUIPPED WITH CONVENTIONAL ELASTIC ELEMENTS (FORCE A FUNCTION OF STROKE ONLY)

The influence of the characteristics of the elastic elements on the occurrence, on the development (in time and space) and on the value of the longitudinal forces in trains has been examined for several variants of spring-mass systems. Examination of the braking process has shown that the longitudinal force can be considered as being composed of a "rigid" component, an "elastic" component and a "coefficent of friction" component. With a suitable spring stiffness, combined with a brake-cylinder filling time adjusted accordingly, a "sub-critical development of the longitudinal forces"-and thus a substantial reduction in the values of the maximum longitudinal forces-can be achieved. The development of the longitudinal forces during gradual braking and during starting is also dealt with. The validity of the mathematical model has been confirmed on the basis of the results obtained during tests with actual trains. Future running trials can thus be restricted to an absolute minimum. Finally, the report indicates the optimum spring characteristics for permitting a "sub-critical development of the longitudinal forces" to be obtained during braking.

APPLICATION OF THYRISTORS IN RAILWAY TECHNOLOGY: CONSEQUENCES AND REMEDIES. STUDY OF THE EFFECT OF INTERFERENCE ON TRACK CIRCUITS

This report contains a general equivalent circuit model valid for all track circuits and permitting analysis of the distribution of the interference produced in the different elements of the circuit model (which also constitute the different elements of the track circuit). These elements are studied from the point of view of their structure, in taking as a basis the theory of circuits and lines, as well as from the point of view of the penetration mechanism of which each of these is subjected. A list of electrical quantities of the track circuit is established, for which it is advisable to fix limits (criteria). The results of the evaluation of a questionnaire relating to track circuits are given, which permit a preliminary general idea to be gained of the types of installations which are affected by interference and those which are not. Finally, several practical measures taken so far for protecting track circuits against the harmful effects of interference are mentioned.

OPERATING PRINCIPLES ENABLING A SINGLE TRACK TO BE USED IN EITHER RUNNING DIRECTION OVER A SECTION OF DOUBLE TRACK

Over a line with double track, it may be necessary to make arrangements for trains to run temporarily in both directions over a single track, the other track being unusable due to repairs, a traffic incident, an obstacle, etc.; this happens more and more due to modern methods of maintaining the track and catenaries, which require such long periods of work that it is generally not possible to do them without transfering the running of a certain number of trains to the other track. This document sets out the measures taken by certain UIC Member Railways (SNCF, BR, CFF, DB, DSB, FS, NS, OBB, PKP, RENFE, SJ, SNCB) in order to reduce delays due to the running of trains in the wrong direction, without endangering safety of operation.

SIMULATION OF THE LOCOMOTIVE RUNNING DIAGRAM
The basis of the program is a simulation model. The object of our investigation is to establish a program by means of which we are able to produce locomotive running diagrams on the computer within a relatively short time. In the case of inexact groups of trains to be routed, and for waiting times between two trains which exceed a given time interval, the program constructs suitable individual locomotive runs. Critical cases in the locomotive running diagram which require human decisions are indicated by the computer. These decisions modify the inputs of the program. With these modified inputs, the process for establishing the working diagram must be repeated. The optimum criterion is the minimum time for the realization of the produced diagram. The basis of the model is a graphical structure. The points of this structure signify the arrival of trains for subsequent routing to their destination stations. In this structure, a "hamiltonian way" must be determined which satisfies the optimum criterion and all the conditions which are necessary for achieving the diagram. This process is accomplished by means of a combinative method. The program produces different variants of the diagram satisfying the indicated conditions. From these variants, the optimum solution is determined and the calculation of the indices of the diagram are carried out. Finally, the process outputs are printed.

PROGRAMME OF TESTS ON THE BRAKE RIG. DESCRIPTION OF VIENNA ARSENAL BRAKE TEST RIG AND CALIBRATION TESTS ON LINE
The report contains a technical description of the Vienna Arsenal Brake Test Rig and its associated instrumentation. The tests made on the line during the winter of 1972/73 to establish the mechanical conditions in the brake equipment and the climatic conditions near the bogies are summarised. The relationship between weather conditions (quantity of snow, temperature, humidity, etc.) and brake performance (stopping distance, etc.) is demonstrated. The tests are fully described in Appendices 1, 2 and 3.

ELECTRONIC TEST INSTALLATION (VIENNA-ARSENAL). TESTS MADE BY THE ELECTRONIC TEST INSTALLATION DURING THE TIME FROM SEPTEMBER 1, 1971 TO AUGUST 31, 1972
This is the fifth annual report of the electronic test installation (formerly installation for testing data transmission equipment), erected and operated in Vienna jointly by the Office for Research and Experiments (ORE) of the International Union of Railways (UIC) and the Austrian Federal Research and Test Institute. In the course of the financial year, one modem for a modulation rate of 600/1200 bauds was tested. As a result of this, the number of modem types entered in the comparative table and in the comparative curves has risen to 16. This report also contains the results of measuring the interference on the telephone circuits of the NS, UBB, and FS due to thyristor-controlled electric locomotives. In addition, the report contains CCITT documents on recommendations for testing modems, the tests being based on the design of the installations for testing data transmission equipment at Vienna Arsenal.

This is a confidential report available only to the Member Administrations of ORE. Restrictions on the use of this document are contained in the explanatory material.

BRAKE PADS FOR DISC BRAKES AND COMPOSITION BRAKE BLOCKS. DEVELOPMENT OF PHYSICAL-MECHANICAL AND CHEMICAL-ANALYTICAL TEST PROCEDURES FOR ACCEPTANCE TESTING AND QUALITY CONTROL OF BRAKE PADS
Provisional specifications for the acceptance testing of disc brake pads have been compiled in B 126/RP 1. For the final version of this document, further tests need to be carried out. Some of these, covering physical, mechanical and chemical properties of pad "composition" materials are described in the present report. Considerable variations in property levels due to material heterogeneity have been noted. The application of a number of the test methods studied as quality control and acceptance testing techniques seems quite feasible. Further experimental work will be required before correlation between the properties studied and the braking performance of "composition" materials is possible.

AUTOMATIC ROUTE SETTING BY TRAIN NUMBER EVALUATION
Automatic setting of train movements at junctions requires routing criteria. For this purpose the train number which includes the train destination and the route to it is well adapted. A limited capacity computer is especially suited for evaluation of the train number and the resulting route setting. SBB will use the reconstruction of the track system in Zurich Oerlikon station, an important junction, to install an automatic train routing system with a processor. INTEGRA AG has in this connection developed a simulation program for a PDP 8e computer which, in off-line operation, permits the simulation of all technical and operating conditions which need to be allowed for. Every train entering the control area is guided over a predetermined route to its destination without being diverted and, in accordance with the criterion of "first come-first served" decision principle, without considering any priorities. This type of automatic train routing provides an economical and flexible solution which will enable even more complicated decision algorithms to be performed when the time comes.

B8 052616
COMPARISON OF DECISION ALGORITHMS FOR SOLVING INCOMPATIBLE TRAFFIC SITUATIONS BY MEANS OF SIMULATION
Train control decisions on the sequence of trains in cases of conflict in traffic are now being taken over by machine (e.g. process computers) from man (e.g. traffic controller). This means that considerations extend to more complex decision algorithms, which for time reasons were unable to be used by man. These new decision making rules can in certain circumstances bring important advantages in traffic and train working. The choice of the most suitable decision algorithm is to be made from case to case according to predetermined criteria. Such comparison requires model testing and hence simulation on a large electronic computer. With this in mind the SBB has applied the "small junction" simulation model, which is written in Simula I for the Univac 1108, and conclusive results were obtained. The SBB is currently working on a second generation simulation model, which will make it possible to extend the comparison of decision algorithms to large junctions and is written in Simula 67 for processing on the CDC computer.

B8 052617
THE IDENTIFICATION AND CORRECTION OF CONFLICTS IN TRAIN RUNNING CONTROL
An on-line decision making program run off on a process computer for space and time reasons cannot in all cases produce optimum decisions. The intention is to solve satisfactorily as high as possible a percentage of conflict situations encountered by the application of simple and manageable decision making rules. In the remaining decisions to be taken by the controller he is assisted by computer prepared decision aids in the form of tables and graphs. The program described here consists of several modules, the first of which relates to a route traffic control system intended to be further developed parallel to practical testing. The control process is initiated in cycles and when special events occur (e.g. track closure). After each start, the timetables are generally compiled in advance for all trains, covering almost the next half hour (block sections and occupation times). The controller is advised of all conflict situations and how they can be corrected. Decisions by the controller override computer decisions.

SIMULATION MODEL FOR THE STUDY OF TRAIN RUNNING
The author describes a simulation model applicable to the case of a line equipped with automatic block the "exit-from-line" of which gives multi-directional access. The model is constructed in modular form and is of the type with variable time increment (simulation in the form of separate distinct events). The model is well-suited for studying the stability of a train running schedule during peak hours, as a function of the signalling installation. It permits the sensitivity of the train schedules to different parameters to be determined: length of block sections, speed restriction zones, characteristics of the rolling stock, closure time of signal controlled from end of line. etc.

DETERMINATION OF THE HIGHEST-DENSITY RUNNING SCHEDULE ON AN ARBITRARY LINE TIME-SHARING PROGRAM
To be able to determine the theoretical validity of a given line equipment it is essential to be able to measure this validity in terms of operation i.e. in terms of running schedule flexibility. In this connection, the maximum number of trains which it is possible to run can be considered as a sufficiently valid and selective criterion for being applied a priori to a more complete and finer study. The simplicity of application, through the combined technique of Branch and Bound, makes it an ideal tool for determining the most advantageous running schedules on an arbitrary line.

STUDIES IN CONNECTION WITH THE LAYOUT AND OPERATION OF FIXED INSTALLATIONS FOR WRONG-TRACK RUNNING
This report deals with the elaboration of new methods applicable to studies in connection with the layout of fixed installations for wrong-track running and the operation of lines equipped with such installations. Three models have been developed. The first is designed for analyzing a priori the best layout of fixed installations for wrong-track running and the influence of the parameters involved. It has permitted a number of general results to be obtained with regard to the number of fixed installations for wrong-track running, the number of trains to be run in 'groups", etc. The second model is devoted to the pre-planning of the train running diagram, when single-track working is required as a result, for example, of work planned in advance; this running diagram is designed to approximate as closely as possible the normal train running graph for double-track working. The object of the third model is to organize the train traffic in real time in such that the delay incurred by the trains is reduced to the minimum on a line where, as a result of an incident, a fixed installation for wrong-track running must be unexpectedly placed in service. The first model is a theoretical one where certain simplifying hypotheses have been used. The last two models take the case of the Channel Tunnel (1970 or 1971 hypotheses) by way of concrete example.

BRAKING AND ACCELERATION FORCES ON BRIDGES. BRAKING TESTS ON STRAIGHT TRACK WITH A LONG TRAIN
The tests were designed to establish whether some reduction of peak braking effort might be obtained due to propagation time in a long train. Performed, more expediently on plain line with a train of oil tank wagons, some advantage for long bridges was proved, particularly with loose coupling. The tests serve to explain how, in a long train of 20 wagons, the resultant frictional coefficient falls below the value of 0.15 of the individual wagons. For economy they were performed in a station track at Reichertshofen with full and with shortened train, and with both close and loose coupling.

APPLICATION OF THYRISTORS IN RAILWAY TECHNOLOGY: CONSEQUENCES AND REMEDIES. INVESTIGATION OF INTERFERENCE IN TRACK CIRCUITS FROM STATIC CONVERTERS USED FOR ELECTRIC PASSENGER TRAIN HEATING
The present report gives an account of tests made by the German Federal Railways (DB) on the Jugoslav Railways (JZ) route system with the object of investigating whether static converters for 1000 V, 16-2/3 Hz heating supply systems cause interference in track circuits. Measurements were obtained with 6 different single-rail insulated track circuits (a.c. and d.c.) under different earthed rail conditions. In every case and even under the most adverse conditions, which would in practice only rarely be met, misfunctioning of track circuits did not occur. Under certain circumstances described in more detail in the report it may become necessary to use a fundamental frequency of 22 Hz (A) instead of 16-2/3 Hz.

CONSTRUCTIONAL ARRANGEMENTS FOR IMPROVING THE RIDING STABILITY AND THE GUIDING QUALITY OF ELECTRIC AND DIESEL LOCOMOTIVES AND VEHICLES. MEASUREMENTS OF THE FORCES EXERTED ON THE RAILS BY VARIOUS TYPES OF MOTIVE POWER UINTS (MEASURED IN A CURVE OF 300M RADIUS AT GIORNICO)
In 1955 the CFF decided to intitiate investigations in order to determine by means of experiments the extent of the wear to which the track would be subjected in a curve of 300 m radius by the then newly developed locomtive types of the series Ac 4/4 (BoBo) and Ae 6/6 (CoCo). The measuring rail working according to the Schlumpf system was used as measuring apparatus. The results of these measurements have shown that the modern bogie locomotives subject the track to less wear at the same speed (BoBo) or to hardly any heavier wear (CoCo) than the rigid frame locomotives of not so recent date. Following the tests which had been made at the suggestion of the Working Group "Measurements on the track" of the B 10 Specialists Committee, for the comparison between three different measuring methods (see B 10 RP 4), arose the possibility of repeating the tests made in 1955. The measuring rail was again used as measuring apparatus, as it had been done for the tests made in 1957, but the tests included a larger number of locomotive types and a considerable versine error was intentionally arranged in the test track. The tests made in 1957 have confirmed the fundamental results of 1955, moreover they have shown that 1) a transverse coupling between the bogies and 2) the lateral movement of the rubber cushioned leading axles of the CoCo locomotives considerably reduce the forces exerted on the track.

ANALYSIS OF DISTORTION CHARACTERS IN TRANSMISSION OF BASEBAND CODE AND ITS APPLICATIONS
The present situation of a baseband code transmission in a cable line is reviewed, and its trend in the future is taken into consideration with some expectations, then it is noticed that the qualities of the code, expecially the distortion character, have to be studied. The calculation method for the distortion degree has been derived from the step response function of a cable circuit. Applying the method to practical problems in lines of JNR's systems, the distortion characters have been evaluated. A quite simple method for improving the character also has been studied, and its application to pratical usages is illustrated.

BRAKING PERFORMANCE OF FREIGHT TRAIN--BRAKING RATIO AND BRAKING DISTANCE

The braking distance of trains on JNR's narrow gauge lines is stipulated in a regulation as to be within 600m in any case. This must be a primary consideration in designing either vehicles or ground facilities. In order to have more traffic available, train speed must be increased and each train must be composed much longer. These are contradictory requirements for freight trains with conventional air brake equipment. These circumstances brought the study on this theme. This paper deals with (1) the survey of actual trains on their consist, their loading conditions and so on, (2) method of simulation for making up train consist, and (3) the result obtained therefrom.

FRISCO'S TRAIN MEET CALCULATOR

Traditionally, the Frisco and many other railroads have determined the location and length of passing tracks by rather unsophisticated means, usually based on intuition and experience. This computer simulation model offers the ability to weigh alternatives and to predict the probable consequences of decisions more precisely in the operations planning of a single-track railroad concerning (a) operating policy and procedures, and (b) physical plant. It is run on an IBM 360/50 and contains all of the dispatching logic deemed necessary. The model permits running trains on schedule, if desired, but all runs to date have made maximum use of the randomization of events based on history. These include (but are not limited to) train generation, departure times, delays (all types), and length of delay (if incurred) for each segment of track. The ability to isolate delays by type and measure their effects on a system by type has proved to be a valuable tool. This simulation effort was conceived, designed and developed entirely by Frisco Railway personnel beginning in mid-1970. The program was validated to the complete satisfaction of both line and staff operating personnel in early 1972. Since that time it has been used continuously and all decisions concerning passing track placement and lengthening, train schedules, priorities, and power and train configurations are based on analysis of the output.

AN OPTIMIZING NETWORK MODEL FOR THE CANADIAN RAILWAYS

A network model of the mainline operation of a railroad has been developed. This model predicts the optimal routing of traffic and the congestion at each yard and over each track section in the model. Input to the model is the required origin-destination flow of railcars, together with a set of physical parameters which describe each yard and the connecting track sections. Time delays in the yards are derived from queueing models of the actual system. Also, an expression has been developed which describes the over-the-road running time as a function of the traffic intensities. Output of the model gives details of the flow pattern that minimize the total car-hours required to accomplish all desired origin-destination movements, together with the delays encountered at each yard, and running times over each road section. The concept of the model is described, the component parts of this model are explained, and some potential applications in transport planning are indicated.

Presented at Fourth International Symposium on Railroad Cybernetics, AAR/UIC/IRCA, 21-26 April 1974, Washington, D.C. This paper was also published in the November-December, 1973 issue of Rail International, which is available from E.S.L.

B8 053774
A MINI-NETWORK COMPUTER SIMULATION MODEL FOR RAILROAD PLANNING

Operating management of a large railroad must frequently deal with problems which effect major segments of the railroad or possibly even the entire railway system. These types of problems include train scheduling, routing, major track and signal improvements, as well as changes in operating policies. The Chessie System has developed the Mini-Network Model as a tool for aiding management in evaluating the impact of these types of problems and the effect of proposed solutions on operations. The Mini-Network Model is a computer simulation model which has the ability to duplicate over-the-road train operations on single and multiple track territories. The modifier, Mini, is used because, unlike other network models, simulation is performed at the train rather than the car level. When required for the specific application, yard and terminal functions can also be simulated. On single track territory, the model will arrange meets and passes with due consideration given to train priorities, track occupancy and trackwork configurations. The major application of the model has been in preparing for the federal (USA) 12-hours of service law. Under this rule, train crews cannot exceed 12 hours on continuous duty between call and relieve times, which represents a change from the 14 hours previously permitted. The model was used on certain regions of the Chessie System to project what will happen under the new law if schedules and facilities remain unchanged. The effect of proposed additional main tracks, yard improvements, and schedule changes to relieve the operating difficulties imposed by the constraint on crew service hours were also simulated. The end product was a recommendation for train schedule revisions providing satisfactory operations under the new law. The model has also been used to aid in the scheduling of a new train service over an already busy territory and it is currently proposed to use the model in studying the effects of single tracking of a multiple main track territory.

Presented at Fourth International Symposium on Railroad Cybernetics, AAR/UIC/IRCA, 21-26 April 1974, Washington, D.C. This paper was also published in the November-December, 1973 issue of Rail International, which is available from E.S.L.

LOCOMOTIVE SIMULATOR

Training of railroad engineers requires a development of high levels of skill and judgment, which cannot be learned in a classroom environment. It also requires a simulator support program of classroom instruction. Simulator capability for training is available through use of a solid state, high speed, general purpose digital computer. To build a simulator requires a detailed knowledge of electronics, hydraulic and mechanical engineering, systems analyses and integration, mathematical modelling, human factors design, training psychology, and environmental control. A train simulator consists of: (1) an exact reproduction of a locomotive cab with controls and fixtures; (2) an instructor station and console with gages duplicating those of engine console, indicator lights for monitoring operation, and switches for setting up and controlling the training events and runs; (3) a visual system, using a multiple of projectors; (4) a motion system; (5) a sound system; and (6) a computer system. Realistic simulation provides the maximum amount of

engineer interest and motivation necessary to efficient learning and retention of skills, and provides high transfer of learning from simulator to real train operation. The digital computer is given information specifying the number and types of engines in consist, number of cars and weights, numerical data on track gradient, curves, speed limits, and milepost locations. During simulation, the computer calculates a complete force balance for each car, up to 200 cars in a train, and up to 164 separate values on each car ten times a second, and determines amount and direction of slack action, coupler force, locomotive tractive effort, braking effort, train speed, wheel action, effects of sand on adhesion, plus other effects a real train would experience. This computational ability provides the real time reaction which allows the trainee to obtain in a few weeks, experience under a wide variety of conditions, which would otherwise require years to acquire.

APPLICATION OF THYRISTORS IN RAILWAY TECHNOLOGY: CONSEQUENCES AND REMEDIES. 1. TESTS TO COMPARE THYRISTOR-CONTROLLED TRACTIVE UNITS FOR 16-2/3 HZ ON THE SAME TEST TRACK

A comparison of the measured results which had been obtained from tests made with thyristor-controlled locomotives of about the same type showed variations in the interfering currents measured by some railway administrations (DB and SJ) which could not be explained as having been caused only by the connection for feeding the overhead contact system. After an adjusted measuring technique had not produced appreciable changes, it was held that the type and magnitude of the supplying overhead contact systems and high voltage systems exerted a certain effect on the interfering current.

AXLE COUNTERS DEFINE BLOCK SECTIONS IN ELECTRIFIED TERRITORY

Indian Railways has installed electronic axle counters in a section of railway line having 25 kv, 50 Hz electric traction. The railway had the requirement of increasing capacity on the double-track Grand Chord line from Mughalsarai to Asansol which carries a major portion of the country's vital coal traffic. Due to hilly terrain, construction of a third main track would have been difficult and costly. Steel ties are used extensively because wood ties are in short supply. Hence track circuiting on an extensive scale is difficult. It was decided to provide electronic axle counters for splitting up some of the block sections with intermediate signaling and thereby reducing headway between trains.

EFFECT ON THE SYSTEM OF A.C. LOCOMOTIVES REGULATED BY THE ASSEMBLY IN STAGES OF THYRISTOR BRIDGES CONNECTED IN SERIES [NETZVERHALTEN VON WECHSELSTROM-TRIEBFAHRZEUGEN MIT MEHRFACH-FOLGESTEUERUNGEN IM STROMICHTERSPARSCHALTUNG]

A report submitted at the 14th meeting dealing with "Modern railway stock", held in Graz. The assembly in question was designed by Brown Boveri, in order to: 1. Suppress, in the supply system, the high-frequency harmonics, as well as their induced effects causing interference on the lines carrying weak current. 2. Suppress the low-frequency harmonics capable of having an effect on the track circuits. 3. Improve the power factor. This assembly was tested on an RC 4/4 locomotive No. 161. The report contains a theory covering this assembly, as well as details, set out in the very numerous diagrams, of the results obtained during tests, and conclusions concerning the conditions under which the desired effects can be obtained. BRAKE BLOCK SHOE MADE OF COMPOSITE MATERIALS

The final report consists of a summary, in which the different partial problems are shown, as they exist at the beginning of 1972. In addition to a brief outline of the work carried out previously, the report contains a more detailed description of a number of more recent studies (comparative bench tests, effect of composite brake block shoes on adhesion, and chemical and physical alterations to the friction surfaces of brake block shoes made of composite materials, and the wheels). In addition to the considerable information obtained concerning brake block shoes, the positive advantages include the use--although, of course, to a provisionally limited extent--of brake block shoes made of composite materials, ensuring advantages from the point of view of profitability and the braking technique. Finally, there is also shown, as one result, a proposal concerning a provisional specification for approval, which takes into account the existing stage of developments. The negative side includes the defects and disadvantages which still affect composite brake block shoes, and which must be taken into account, as they are capable of restricting the latters' use and profitability. Amongst the problems which are still in suspense, the most important are those concerning adhesion between wheel and rail, metal inclusions, and the effect of atmospheric conditions (particularly in winter), and, they are, therefore, problems which affect braking efficiency. The Committee leaves it to braking experts on the different railways to decide themselves, on the basis of the information obtained and placed at their disposal, whether to make use of composite brake block shoes.

Restrictions on the use of this document are contained in the explanatory material.

HOW TO OBTAIN BETTER TRANSMISSION FROM CABLE
With considerable interest in communications, especially with increasing demands for data transmission facilities, railroads are looking with greater intensity at the possibilities of using cable systems. The following article from TELEPHONY describes the basics of cable pressurization and how it can reduce or avoid service interruptions. Some of the advantages of cable pressurization are: 1) Positive internal dry gas pressure prevents moisture or damp air from entering sheath openings, and the resulting dryness helps minimize electrical leaks and noise, prevents cross talk and guards against complete loss of the cable's transmission capabilities. 2) Even in PIC cable, pressurization prevents serious transmission loss and facilitates locating leaks or breaks. 3) Maintenance costs are reduced greatly.

IMPROVEMENTS IN THE DESIGN OF AIR BRAKE CONTROL VALVES
The paper traces the development of the air brake control valve from its earliest ancestor, the original triple valve invented by George Westinghouse, up until the present day. Emphasis is placed on the way in which constructional techniques evolved, developments on both sides of the Atlantic being considered. The desire for improved performance, reduced costs and an extended maintenance period is shown to be the driving force towards change, which is inevitable once the required skills and techniques become available. The authors show how worthwhile improvements are still feasible and introduce a new design of control valve based on constructional techniques intended to realize these.

ANALYTICAL APPROACH TO RAILWAY SIGNAL BLOCK DESIGN
Originally intended for rapid transit systems, it is also applicable to any rail system where high-speed, short-headway characteristics are required to maintain a smooth and efficient flow of passengers of goods. Analytical techniques are used to select system speed commands using a cost-benefit analysis; to determine the speed-location operating profile; to locate signal block boundaries; and to determine signal logic. Four computer programs are used to calculate station dwell times, to simulate train performance, to calculate safe braking distance, and to determine headway. These programs determine the highest feasible speeds, consistent with civil design restrictions, at which trains can travel while at design headways. The algorithm for block layout then ensures that the minimum number of blocks will be used to provide the design headway subject to all system limitations. Program inputs include car characteristics and track profile, user demand statistics, and the design headway.

WANTED: NEW STANDARDS FOR AFO
With the advent of AFO track circuits many problems have been presented since impedance is the primary attenuating factor, not resistance. With a given shunt, the resistance will remain constant, but as the audio frequency goes up, the impedance goes up, thus less attenuation. If the standard .06 ohm shunt is used for aligning AFO track circuits, the impedance is affected by frequency, track conditions and ballast conditions. This spring General Railway Signal Co. will start an extensive project to compile the information needed for developing new standards and new equipment which will make the alignment of AFO track circuits more accurate.

MEASUREMENTS AND ANALYSIS OF 115 KV POWER LINE NOISE AND ITS EFFECT ON PUEBLO TEST SITE RADIO LINKS
Noise measurements were made for 115 KV power lines near the frequencies 166, 217 and 406.8 MHz with a receiver bandwidth of 1 MHz. The measurements consisted of counting the numbers of pulses per minute at preset threshold values and RMS. The variations of the noise level vs the lateral distance from the power line were also measured. The worst noise level,-40 dBm, was observed at 217 MHz under a noisy power line. The results of these measurements show that, under normal conditions, power line noise will not have significant effects on the radio links at the Pueblo Test Site.

SIGNALLING AND TELECOMMUNICATIONS WORKS ON THE EUSTON MAIN LINE ELECTRIFICATION
The basic requirements of the signalling and telecommunications scheme are presented in this paper. Details of maximum speed of various types of trains, average headway, desirability for consistency of aspects, all necessitated the provision of four-aspect colour-light signalling with continuous track circuiting. Originally, power signal boxes with limited range were programmed, but economic conditions necessitated reconsideration for some electromechanical boxes. Difficulties arising in the manning of the signal boxes later caused replanning for power signal boxes throughout with much longer sections controlled from each box following technical developments. Particulars are given of the telecommunications requirements in principle. The planning of the signalling and telecommunications schemes are dealt with in some detail with special reference to the various factors to be met. Sections of the paper deal with design factors and equipment both for signalling and telecommunications with special reference to the methods which had to be adopted to give immunization against inductive effects from the 25 000 V 50 c/s traction system. Particular reference is also made to the instances where other electrical factors had to be met. Developments which occurred during the progress of the scheme are detailed and their effect on the original design is mentioned. The planning and execution of the installation work and the testing and commissioning are described, with some reference to the maintenance of the works. At the end of the paper reference is made to present-day experiences and some remarks are presented about the future.

TRAIN BRAKE SYSTEMS APPLICATION AND RELEASE
Unusual and unpredictable braking actions were reported by engine men around 1970 on Canadian Railways. The problems coincided with changes in train consists that now include a greater number of 70 and 100-ton cars. The ratio of horsepower to locomotive weight had increased to the point where the independent brake was no longer capable of holding trains on grades while the train was being recharged. These problems are outlined in detail and general recommendations to prevent unusual braking are given.

AUTOMATIC ANALYSIS OF BRAKE TESTS
The authors, who are Inspecteurs at the SNCF Rolling Stock and Research Departments, explain in this article the method adopted to determine the braking performance of modern highspeed trains (TGV 001), i.e., the distance needed to bring the train to a halt from various speeds with all the brakes in operation, then with all or part of each braking system isolated. This method is possible because the results of the tests are analysed by computer, and details are given of the programme and the principles on which it operates. The results are printed out directly and form an extremely useful catalogue with which all the brake equipment and the performance of future tractive stock can be defined with precision. [French]

COMBINED REGENERATIVE AND RHEOSTATIC BRAKE ON ELECTRIC RAILCARS POWERED BY DIRECT CURRENT [GEMISCHTE NUTZ--UND WIDERSTANDSBREMSE BEI GLEICHSTROMTRIEBFAHRZEUGEN]
Most rectifier-type sub-stations feeding catenaries are fitted with values that can allow current flow in both directions. This is impossible in a system with three-phase current. When catenary absorption capacity is variable, regenerative and rheostatic braking should be possible with electric brakes. In a braking situation the first step consists of increasing the braking current supply through a direct current converter; then this current is fed into the system by a diode for as long as the system can absorb it. If the circuit system does not require any power, there is a brake thyristor to activate and maintain a braking resistance right up until the end of the direct-current converter cycle. [German]

ELECTRO-MAGNETIC COMPATIBILITY DESIGN FOR RAPID TRANSIT SYSTEMS
Design criteria and techniques used to minimize the interference levels between the communication and signal channels for control of rapid transit vehicles and other working systems (such as propulsion, power system, auxiliaries, etc.) or the environment, are analyzed in this paper. The particular system under consideration utilizes a higher frequency band to allow a wide separation from signal to noise, but below 10 KHz and at low power level so that it does not require special license to operate. In addition, the use of FSK and the well known features of signal capture as developed in fm systems, are used to further increase the EMC of the overall system. The techniques presented in this paper have been successfully implemented in various transit systems which are presently in operation.

ELECTROMAGNETIC COMPATIBILITY BETWEEN THRYSITOR-CHOPPER CONTROLLED CARS AND ELECTRIC FIXED INSTALLATIONS IN TOKYO SUBWAYS
When commercial operation was initiated between Ayase and Kasumigaseki stations on the Chiyoda Line (Tokyo) in March, 1971, the Teito Rapid Transit Authority put into service 130 chopper-controlled cars made up of thirteen 10-car trains. In February 1972, 60 chopper-controlled cars were put into service. Compared with conventional rheostat-controlled cars, chopper-controlled cars offer improved riding comfort, reduced electric power consumption, and low temperature rise in subway tunnels. However, the thyristor-chopper control generated ripple currents in the trolley wires and rails causing problems with the signaling and communication installations. Analytical studies and tests provided a solution to these problems by employing such measures as filtering and adopting a 660 Hz chopper frequency. As a result of the tests, compatibility between chopper-controlled cars and electric fixed installations was established

ELECTROMAGNETIC COMPATIBILITY BETWEEN ELECTRIC TRACTION SYSTEM AND SIGNALLING AND TELECOMMUNICATIONS AT THE SWEDISH RAILWAYS
When 16 2/3 Hz electric traction systems were developed in the twenties, comprehensive research was undertaken concerning the interference produced in telecommunication circuits. To solve the problem, modifications were made to both the traction system and the telecommunication lines. With the introduction in 1967 of thyristor controlled locomotives and motor coaches, extensive investigations were made of disturbances in signaling and telecommunication circuits. During 1971-1972, a prototype static frequency converter for transforming utility-supplied three-phase 50 Hz power to single-phase 16 2/3 Hz power was tested to investigate harmonic disturbances and to determine ways of reducing the disturbance. Finally, techniques have been developed for reducing interference of railway telecommunication and signaling circuits resulting from exposure to induction and earth potentials from power lines and plants.

INTERFERENCE TO TELECOMMUNICATION INSTALLATIONS BY RAPID TRANSIT SYSTEMS
Power conversion by means of semiconductor elements, i. e. the use of thyristors in traction systems operating with dc or ac has resulted in new electromagnetic compatibility problems. While it has hitherto been possible to control the interference to telecommunication installations caused by the fundamental frequency and harmonics of the traction current without great difficulties, the growing number of harmonics may call for special measures to be taken. In addition, traction currents are also increasing due to the demand for higher acceleration and speed of trains, particularly of rapid transit systems in densely populated areas-a demand which can particularly be met by the thyristor technique. This paper examines the electromagnetic compatibility problem from both the viewpoint of the Railways and the telecommunication authorities. Moreover, measures for keeping the interference within tolerable limits are indicated.

SELF-COMMUTATED RECTIFIER TO IMPROVE LINE CONDITIONS
When thyristor rectifiers are used for electric drives, reactive power is produced with fundamental and harmonic frequencies. Especially in single-phase traction lines, with their low short-circuit power, a technical solution of this problem, applicable mainly to thyristor-driven rail cars and locomotives, had to be found. In this paper, the sector-control system of a self-commutated unsymmetrical bridge is described. In the unsymmetrical half-controlled bridge connection, the two thyristors can be quenched by adding a self-commutating device. This attachment (supplement) can be applied to the single bridge or to two bridges in series (sector control). By using this self-commutating attachment, it is possible to shift the fundamental of the current to a leading angle with respect to the voltage.

SYSTEMS OF COMMUNICATION BETWEEN TRACK AND TRAINS ON PARIS SUBWAYS [LES SYSTEMES DE TRANSMISSION ENTRE LA VOIE ET LES TRAINS DU METRO DE PARIS]
The first transmission devices used in the past to transmit signals between the tracks and the trains are briefly recalled. With a view to increasing the traffic and improving the control and ease of train driving, new transmission systems have been introduced. In the case of the Paris Metro network, 14 transmission systems are currently in use. They are briefly described. [French]

REQUIREMENT AND IMPLEMENTATION OF REGENERATIVE TRAIN CONTROL
Advances beyond the state of the art are desired for car performance, reliability of scheduled service and passenger comfort. The train propulsion and control system constitutes a major element affecting such requirements as car configuration, acceleration and braking, jerk rate, efficiency, maintainability, initial and operating cost, etc. This paper discusses the requirements imposed on an optimized propulsion system for this type of service. These requirements are then implemented by utilizing an advanced concept regenerative drive coupled to a dc shunt or series motor. A generalized approach is evolved. It is shown that close analogy exists between ac and dc systems intended to fulfill the same requirements. The paper thus projects the philosophy that advanced concepts and improved performance are not synonymous, as is often assumed, with the exercise of varying the method of implementation. It concludes by showing that the stress should be on the mating of the system elements to the source of supply and the car and on the method and techniques of exploiting their inherent characteristics advantageously. The discussions and arguments are supported by suitable signal flow diagrams, block diagrams and schematics.

LOW SENSITIVITY DESIGN OF OPTIMAL FEEDBACK SYSTEMS FOR LONGITUDINAL CONTROL OF AUTOMATED TRANSIT VEHICLES
Many new urban transportation systems involve the use of automatically controlled vehicles. Some new systems, such as personal rapid transit (PRT) and dual mode, are characterized by small automated transit vehicles traveling on exclusive guideways. The number of passengers per vehicles is small, and short headways are necessary for high capacity. A versatile, efficient, and safe control system is needed to maintain proper spacing between vehicles without causing passenger discomfort. The report is devoted to the design of a longitudinal control system using modern control technology. A detailed mathematical model of the longitudinal motion of automated transit vehicles in an external-reference system is presented.

ON THE REGENERATIVE BRAKING OF DC MOTORS WITH AC SUPPLY
A new method is described in which the DC motor may regenerate power effectively to AC supply. The principle is similar to that with a DC chopper for regeneration of the power from DC motor to DC supply. In this new method, however, thyristor switches synchronizing to the AC supply are used instead of a DC chopper. The principle and the power calculations as well as experimental results are presented. From theoretical and experimental considerations it is clarified that there exist suitable trigger angles in the thyristor of the synchronizing switches.

SYSTEMS PARAMETERS AND THEIR AFFECT ON AUTOMATIC TRAIN CONTROL SYSTEM DEVELOPMENT
In order for an Automatic Train Control System to function within the total complex of a rapid transit system, the ATC designer must be aware of and make adjustment and allowance for the various other elements of the system which can place restrictions on the ATC design and operation. These and other system parameters take on many shapes and forms and in many cases are not as apparent as some of the parameters. Changing any of the critical systems characteristics can have far reaching effects on the total system.

OCCUPANCY DETECTION TECHNIQUES FOR TRANSIT SYSTEMS
Occupancy detection in a transit system which does not use a pair of rails for shunting can be accomplished by a continual "check-in/check-out" process for each train as it moves about the system. With this process, each train in the system indicates track occupancy by transmitting signals to wayside antennas which extend the length of each block. Once received for a particular block, this occupancy signal sets a latched, positively reset relay or solid-state memory, which will provide an occupancy indication for that block until the train establishes occupancy in the next block. The occupancy information for each track is processed through a series of vital safety checks. These checks monitor possible emergency conditions and provide the appropriate alarms to the speed encoding subsystem and other subsystems. By using the appropriate hardware to implement these principles, this

subsystem has been made failsafe. The failsafe operation of this subsystem depends upon the specific hardware component choices such as vital relays, failsafe and gate, etc., and on proper system-level design criteria. In addition, this type of logic can be used in a system which does employ shunting of the rails for occupancy detection in order to provide redundancy for increasing the margin of safety.

B8 072559
SAFETY AND AUTOMATIC TRAIN CONTROL FOR RAIL RAPID TRANSIT SYSTEMS

The anticipated construction and expansion of rail rapid transit systems in the United States over the next 10-15 years implies major capital expenditures. A significant level of automation in train control is likely to be central to these systems. The potential safety problems associated with various implementation alternatives, several possible levels of automation, and uncertainty in the corresponding proper role of the human operator raise issues requiring timely resolution. This report describes the state-of-the-art in rail rapid transit system automatic train control, assesses the safety related interrelations between the train control system, functions of the human operator and other portions of the total system, and makes recommendations, based on current experience, to aid the process of planning, funding approval, design, implementation, test, safety certification and operation of new systems or modifications of existing systems. The Study suggests that the Federal Government develop safety criteria by which to evaluate future proposals and establish guidelines for safety certification procedures. It also concludes that knowledgeable application of system engineering skills and advanced development program techniques together as a process, are probably more important to achieving a successful new rail rapid transit system than are individual design decisions or application of advanced technology.

A SURVEY OF RAILWAY SIGNALING AND CONTROL

Railway signaling originated from the basic needs of safety, but its development has permitted the exploitation of wider facilities, in the form of considerable economics and increased efficiency, coupled with the attainment of higher speeds and improved control. It is closely supported by telecommunications techniques, both in ancillary functions and in characteristic railway communication networks, using land and radio transmission media. Signaling is based on the principle of "fail-safe" and complete reliability; at first it was effected by mechanical means, but subsequently supported and replaced by electrical means, the latter method proving itself by means of specialized application and method, to be the most suitable for the very exacting performance demanded. The introduction and improvement of electronics is now playing an increasing part in the operation of railways, and holds much promise for greater application in the future, having under its wing not only control and peripheral installations as they are known today, but also new capabilities in the form of revenue collection, data handling, and streamlined administration. The recent trend is toward automation, to which railway systems are particularly adaptable, but there are still many unsolved problems. In signaling and communications, managements have not only the best possible insurance policy, but an indispensable tool for commercial viability; these two assets will play a large and vital role in the imminent transport explosion of the future.

TRANSPORTATION NETWORK ANALYSIS-SYSTEM AND TERMINAL

Eleven addresses, followed by discussions, given at the meeting, held in April, 1969, of the RSMA, on the general subject of the application of systems analysis, the theory of graphs, and the computerisation theory of communications, to transport problems. The above brochure contains a list of the 50 previous publications of the RSMA which appeared between 1955 and 1969. The following are some of the most characteristic of the subjects dealt with:--W.P. Allmann. Foreword. The fundamental transport problem: way and works, rolling stock, methods of operating, its importance, methods of study--mathematical models, simulation, adaptation of the problem to the possibilities of computers.--A. Dooharian. Communication and control in an operational analysis. Connections between a national defence strategy and the transport problem.--W.H. Turner. Economics of the configurations of chain systems and the problem of point-to-point communications. A parallel

between the the problem of the telephone system and that of the transport system.--R.S. Farnsworth. Optimised system of land and sea transport. Linear programming of the transport of a product to the ports in the United States, and from there to destinations inside the country. Study of the breaking down of a problem which is too large to be dealt with as a whole.--G.J. Ahrenholz. Systems analysis applied to operations in a sea port. Details of the TRANSIM model and application in a military port to the enbarkment of an infantry division.--D.J. Collins. The individual control of wagons, the basis for the efficient operation of a railway system. Details of the model used on the Canadian National.--E.C. Dwyer. Relations between the running of marshalling yards and headquarters. Elaboration of a complete railway operating system.--H.N. Shycon. The distribution system. Research into an optimum distribution strategy, taking into account marketing, selling points and the geographical situation of the producers, by means of computer simulation.

A NEW BRAKE-REVERSING TRANSMISSION FOR SHUNTING WORK
Locomotives used in shunting operations require 1) power acceleration with smooth stepless development of tractive effort, 2) steady change of load and speed, 3) rapid reversing, 4) uniformly high braking effort without wearing parts, 5) easy control and operation, and 6) simple and rugged design to ensure trouble-free running. AEG (Allegemeine Electricitaers Gesellschaft) has developed the Ser 311-Fottinger transmission. Characteristics include: power up to 280 HP; compact design; high turbine moment is obtained when starting; the torque converter gives smooth acceleration, adjusting automatically to the load; friction-disc reversing clutches are made of non-wearing sinter-bronze and steel; and most importantly, it can be reversed while the locomotive is still moving. In fact, it is possible to reverse at speeds of up to half maximum. The Sar 320 has also been developed by AEG for use on multiple-unit stock for medium and long distance services, consisting of up to 6 or 8 cars. It uses force locking reverse clutches. The arrangement is advantageous on extensive railway systems with long intervals between stations. It permits the use of very simple transmissions with a minimum of control equipment.

BIT ERROR RATE AND CROSSTALK DISTURBANCE IN TRANSMISSION OF BASEBAND SIGNAL CODES
First, a structure of occurring error codes caused by pulsive noises in transmission of baseband signal codes is analyzed theoretically, and then confirmed by experiments using various noise patterns, as regard several parameters affecting the error rates. Examples of the rates measured in J.N.R.'s lines are shown, and a predicting method for the rates as well as application to practical lines are illustrated. Next, as for crosstalk disturbances, formulae derived analytically from the step response function of the line are presented, expressing spectra of the crosstalk wave. Applying this to comparatively short lines, the disturbances in lines practically used, such as low speed telegraph and the C.T.C. system's 2400 bauds are evaluated, and for the future, sending power levels of high speed lines are discussed relating with the error rates.

RELIABILITY EVALUATION OF A BRAKE PIPE FLOW INDICATOR FOR USE WITH REMOTE CONTROL LOCOMOTIVE EQUIPMENT
The test data presented in this report show that the Type "B" Brake Pipe Flow Indicator is mechanically capable of operating one million cycles under laboratory conditions without failure or loss of sensitivity. Under prolonged exposure to high temperatures the diaphragm showed some effects of heat aging which is to be expected with molded rubber products not specifically synthesized to withstand high temperature environments. The apparatus developed for the cycling tests was realistic in terms of simulating a number of significant operating parameters of a flow meter used on locomotives in service. It appears therefore that the flow rater as used for a control function in remote-controlled locomotives is functionally adequate and no special precautions need be considered in relation to normally testing and maintaining this part.

DETECTION OF TRACK GUIDED GROUND VEHICLES USING THE TRACK AS AN ELECTROMAGNETIC SURFACE WAVEGUIDE
The importance of vehicle detection and communication in mass transportation systems is discussed along with the advantages of track guided systems and the use of automation. Present and proposed methods of tracked vehicle detection are reviewed. An innovative method is proposed for detecting or communicating with tracked vehicles in which the track is used as an open waveguide. The characteristics of a rail as a communication channel are determined and suggestions for analyzing other parts of the system are discussed. A method of analyzing wavelengths of arbitrary shape and consisting of glossy materials was required. The problem of distinguishing the desired modes from non-physical spurious and other modes is discussed and the complete set of programs is listed and described. History, definitions, and applications of electromagnetic surface waves are reviewed and behavior of two types of surface waves are presented.

LIMIT CAPABILITIES OF COMBINED BRAKING SYSTEMS [Leistungsgrenzen Kombinierter Bremssysteme]
The article deals with brake systems of high-speed trains, the main attention focussing on braking to complete stop. Assuming low axle drive masses, it is shown that safe braking from speeds up to 350 km/hr, is possible by means of different combined brake systems. In this connection, the eddy-current brake is of particular importance for attaining short stopping distances. [German]

MOPAC CONTROL SYSTEM SPEEDS INVENTORY AND MOVEMENT
The Transportation Control System project of the Missouri Pacific is now controlling car, train and terminal operations with computer-based techniques. Data on inventories and movements of cars on the entire system are maintained in the computer at MP's St. Louis headquaters. At the yard level, MP has developed a standardized Yard and Terminal Subsystem (YATS) which ties in with the overall TCS network. YATS has produced substantial improvement in yards, more than enough to offset the cost of computerizing car information and processing at the individual yard level. Some data is processed on minicomputer subsystems at individual yards.

MEASUREMENTS OF LEAKY COAXIAL CABLES AND POSSIBLE APPLICATIONS TO TRAIN COMMUNICATION
The electrical and radiation properties of the Radiax have been measured. The main results are: i) the surface wave exists, ii) the radial radiation follows $1/r^2$ relation for frequency below 190 MHz and $1/r$ relation for frequency near 400 MHz, iii) the transverse radiation pattern is nearly omnidirectional, iv) the coherent band-width is on the order of 3 MHz and the operating frequency range is several hundred megahertz; and v) better coupling efficiency is observed at lower frequency. Possible applications for railroad communication are discussed.

OPERATION OF HIGH SPEED PASSENGER TRAINS IN RAIL FREIGHT CORRIDORS
A preliminary examination of the problems associated with mixed-traffic operations-conventional freight and high speed passenger trains-is presented. Approaches based upon a modest upgrading of existing signal systems are described. Potential costs to the operating railroads, impact on railroad efficiency, and safety of passengers and train crews are considered. Special attention is given to analysis of stopping distance for various conditions and rolling stock. Basic conclusions are that speeds above 125 MPH are likely to require substantial signal system modification and that freight service capacity will be severely degraded by large numbers of HSPT's; further analysis is required to determine well-founded control-system guidelines.

HOT SPOT HEATING BY COMPOSITION SHOES
It is generally understood that uneven heating of the tread of a wheel during braking is possible. A method has been devised to measure the intensity and frequency of hot spots on the wheel tread surface. After a description of the measurement apparatus and technique, results of a study of hot spots during constant speed brake applications with single composition shoes are presented. Possible lowering of the hot spot level by increasing the conformability of the brake shoe is studied by cutting one slot across each pad of a brake shoe. This method of hot spot study may be useful for future analysis and improvement of brake shoes.

REMOTE CONTROL AND TRANSMISSION OF DATA BY RADIO [Funkferasteuerung mit Datenuebertragung]
This appliance makes possible the remote control of 10 shunting locomotives through one radio channel. The device operates on a selective call system and the transmission data on a simplex channel in the 160 or 460 MHz frequency bands, with a data transmission speed of 2,400 Bands. A self-check code ensures correct transmission from the transmitter to the vehicle. Repetition by the vehicle is unnecessary because of the inherent safety of the system. The radius of action of the installation is 600 m. In the case of breakdown in the transmitter or the vehicle device, as well as in the case of a severance of communication, the "emergency stop" process will be triggered off, and this can only be cancelled by special instruction.

TELECOMMUNICATION FOR BRITISH RAIL
The principal object of the National Telecommunications Plan (NTP), a railway-owned and maintained telecommunication network, is to provide an automatic extension-to-extension trunk-dialing telephone network between all business centers on the railway, as well as a good base for data-transmission services. The trunk cable network connecting the business centers is installed in lineside routes. It has sufficient bandwidth capacity to serve all telephone traffic as well as for an automatic switched teleprinter network. It also provides for all the expected requirements for low-,medium-and high-speed data transmission for purposes like the total operations processing system (TOPS) and seat reservation systems, etc.

THE LIMITATIONS OF THE BRAKING POWER OF COMBINED BRAKE SYSTEMS [Leistungsgrenzen kombinierter bremssysteme]
The author explains the brake systems of high speed trains and describes braking to a stop in detail. He then discusses the limitations of the braking power of brakes and explains the problem of the coefficient of adhesion, as well as suitable combinations of brakes. Providing that each bogie is loaded at 12 tonnes per axle, various combined brake systems can be used for speeds of up to 350 km/h. Electromagnetic eddy-current brakes are very important for braking over short distances. [German]

DYNAMIC BRAKING
The kinetic energy of rapid transit trains that is normally dissipated as heat during braking can be converted to potential energy. The use of a flywheel energy storage system is an old idea that has recently been revived. A competitive idea being advanced is the thyristor inverter-recuperative system. While extensive operational experience is not yet available for either, both are currently being tested. The flywheel system is being tested on the New York Transit Authority and the regenerative system on the Sao Paulo, Brazil, Metro. It appears that the regenerative system is more efficient and requires less maintenance, thereby justifying the additional capital investment.

TELE-INFORMATION TECHNIQUES FOR AN INTEGRATED DATA TRANSMISSION NETWORK OF THE EUROPEAN RAILWAYS
Particular importance must be attached to the continually progressing advance of automation. Railway operation calls for the processing of frequently recurring data which must be exchanged and processed within a short period of time. For this purpose, modern electronic data processing plants with their rapid and reliable processing methods provide an optimum solution for the continuing process of introducing cybernetics into railway operation. Within the framework of the ever closer European co-operation, the need for the co-ordination of all these systems into a single integrated international system has become more amd more evident. The international network stems from the integration of the different national systems; this gives a brief description of their characteristics.

ELECTRIC BRAKING IS ESSENTIAL: HISTORY AND ADVANTAGES OF ELECTRIC BRAKING: TECHNOLOGY AND PERFORMANCE
In the first article, the author, who is Rolling Stock Manager of the SNCF, explains the functioning of electric braking, its development and how it is employed. He lists its various advantages and states that electric brakes are essential for speeds above 180 km/h. High-speed running experiments have therefore produced a new technology in this field. The author refers to the economic benefits of this braking system and concludes by describing the developments which, by employing electronic power-control systems, have led to present applications. In the second article, the author, who is Head of the Electronics Division at the SNCF Rolling Department, gives details of the SNCF electric motive power fleet fitted with electric brakes, which are essential for high-speed running. The characteristics and operation of electric braking equipment are described on the most modern direct-current, single-phase and dual-current locomotives (CC 6500, BB 7200 BB 15000 and BB 22200 series), as well as on the experimental high-speed Z 7100 railcar. The locomotives have two different electric brake systems (one for normal braking, the other for emergency braking); the railcar is provided with an eddy-current linear brake system. [French]

TRAIN CONTROL, STRESS AND VIGILANCE
Modern railway operation, due to the control exerted on the man-machine-pathway combination is the safest form of transportation available. The vehicle pathway is continuously monitored and both front and rear end protection is provided to prevent collisions. Man although extremely versatile is known to be the weak link in the man machine system. Consequently, his duties need to be arranged to match his capabilities. An examination is made of human factor research, levels of arousal, driving efficiency and driver stress, fatigue, diurnal bodily rhythm and vigilance. Accident rates have been progressively reduced by various safeguards instituted to guard against human failure. Measurements of driver stress under various conditions of high speed train operation have been carried out and changes in stress in accordance with train speed, hours of duty, periods of rest, and day and night operation determined. There are a series of railway signalling and vigilance control devices which successively reduce the effect of the human element. These have further developed into semi-automatic and automatic train operation.

ELECTROMAGNETIC EDDY CURRENT BRAKE (SNCF TRIALS)
In order to avoid the dependence of braking effect on the adhesion of the wheels to the rails, experiments have been carried out by the SNCF (French National Railways) on two designs of electromagnetic brakes acting by inducing eddy currents in the rail. The tests were made on an experimental high-speed vehicle drawn by a locomotive at speeds up to 250 km/hr. Fitted to the frame of a long- wheelbase truck, each "shoe" is approximately 2 m long and contains up to 9 poles. The mean air gap is 7 mm, and the pole faces are 78 mm wide, which is 6 mm wider than the railhead of the U80 60 kg/m rail often used for high speeds as continuously welded rail, and 13 mm wider than the more common U36 50 kg/m rail. A retarding force of 1400 daN has been obtained with the new brake at an acceptable electric power demand. Tests indicated that switch points and rail joints did not present a hazard, and that heating of the rails was slight. Remaining problems to be investigated and directions of further research are indicated.

SWISS FEDERAL RAILWAYS NEW COMMUTER 15-KV MULTIPLE-UNIT PROTOTYPE SETS IN LIGHT ALLOY WITH THYRISTOR CONTROL
To obtain greater versatility, lightweight trainsets were selected for pre-production service evaluation. Two power cars were incorporated in three-or four-car sets to determine acceptable power demand consistent with

good acceleration. Thyristor controls are seen as having several advantages in suburban operation, but problems of electrical interference with communications and signal cables are special problems.

GREATER SAFETY THROUGH LINEAR CONTROL OF TRAINS
[Securite accrue par le controle lineaire des trains]
A short description of the integrated transmission system designed by the ORE. The tests were begun on the Lavorgo-Bodio (St-Gothard) line, with RE 4/4 II type locomotives. Further tests are planned on the Turgi-Coblenz section with one of the new RABDe 8/16 type suburban trainsets. The system as a whole will be thoroughly tested between now and 1977, so that large-scale production can be begun at that date. [French]

THE S.N.C.F. CENTRAL SIGNALLING AND TELECOMMUNICATIONS LABORATORY
The author, Head of Section at the S.N.C.F. Equipment Department, relates the history of this laboratory since it was built by the former Northern Railway. He describes its present arrangement and states its purpose which is not research but essentially the verification of equipment, tests, investigations. This work is in principle confined to S.N.C.F. signalling and telecommunications equipment. Activities have been grouped as a result of the reform of S.N.C.F. structures. The author then describes the laboratory equipment and its use as regards electronics, photometry, relays, track circuit testing with simulators (high speed, information), and the testing of telecommunications and electronic equipment, computer functioning, etc. He then gives facts about the laboratory's mobile equipment which enables readings to be taken at any point in the installations, in particular 10 testing coaches, a power coach taking current directly from the 1,500 V supply, and an experimental railcar. LIGHTNING AND ITS EFFECTS ON RAILROAD SIGNAL CIRCUITS
This study discusses the occurrence of lightning, its effects on railroad signal equipment, and protection of such equipment from lightning damage, with special attention to known protective techniques which are employed in a variety of situations in the power, communications, and railroad industries. A brief review is offered of the causes of lightning and other surges, followed by an extensive treatment of the means by which lightning and power-line transients induce surges and over-voltages in signalling circuits. Specific topics include the effects of the direct stroke current, the collapsing electric field when the stroke occurs, inductive coupling, and the effects of ground

currents in the earth. A survey of protective devices and techniques currently in use for specific types of equipment is presented, including categorization of arrestors by type and application. Preferred lightning protection practices in railroad signalling are examined and related to practices in other fields. The problem of lightning protection is addressed from an overall systems viewpoint, encompassing development and testing of protective systems and design of systems, so that they can more easily be protected. Recommendations for future research are made.

THE INFLUENCE OF TRACK CIRCUIT PARAMETER VARIATION ON MAXIMUM PERMISSIBLE LENGTH
In an article published in Rail International in June 1974. this author described a method for determining the maximum length and optimum terminal impedance for track circuits which are compatible with the system and the parameters defined in that paper. These parameters were assumed to be constant. This second article is a study of the influence of parameter variations on the maximum permissible length of circuits. The author discusses line resistance, line inductivity and terminal resistance to signals.

MEASURING DEVICES OF TESTING CAR FOR SIGNAL APPARATUS
The measuring devices used for testing the wayside signal equipment of Japanese National Railways are described. All these are mounted on the high-speed inspection cars used on the New Tokaido line and on the conventional network. The functions checked are the ground coil for the automatic train stop device, the detector circuits used for grade crossing protection devices, and the regular track circuits. An elapsed distance system is also used for correlating measurements on the digital output tape. A computerized system is under study.

IMPROVED INSPECTION, DETECTION, AND TESTING RESEARCH

Research in the Improved Inspection, Detection, and Testing Research Division is conducted under four program areas: (a) track inspection and testing operations, (b) automated track inspection, (c) vehicle inspection, and (d) safety life-cycle testing.

The track inspection and testing operations program provides the services (personnel and equipment) and basic technical support for several FRA research and safety related programs. The automated track inspection program (ATIP) provides the FRA Office of Safety with track monitoring capabilities, such as the track inspection vehicles and their associated equipment. The program also assists the railroad industry in establishing track maintenance priorities and in developing new maintenance procedures. In the automated track inspection research and development, both track inspection and data acquisition technology and equipment are developed and refined. Research is conducted to improve speed, sensitivity, and accuracy of rail flaw detection and track geometry systems and to extend the mobile inspection capabilities to include assessements such as rail wear, track impedance, and crosstie condition.

In the vehicle inspection program, systems are being tested for an effective on-board monitoring capability for individual cars and for wayside surveillance stations to detect abnormal car behavior in trains.

Under the safety life-cycle program, the methodology to test the safe performance of rail systems during their entire life spans is being developed. The Facility for Accelerated Service Testing (FAST) at Pueblo, Colorado, provides an ideal environment for component life-cycle evaluation.

INTEGRAL TYPE MEASURING EQUIPMENT FOR SUPERELEVATION
In measuring superelevation with track inspection car a gyrostabilizer is generally used. The gyrostabilizer is considerably expensive and needs electric power source. So, for a simple mechanical type track inspection car, it is difficult to mount a measuring equipment for superelevation using a gyrostabilizer. A new mechanical integral type measuring equipment which enables measuring the superelevation from twist of track has been made. The equipment needs no source of electric power. The frequency characteristics of the equipment is fairy good for ordinary superelevation, the accuray of mechanical parts being about 10 percent.

QUALITY OF RAILS AND MEANS OF GUARANTEEING IT; EXAMINATION OF THOMAS STEEL RAILS OF THE THIRD SERIES OF TESTS BY MEANS OF THE RALUS ULTRASONIC PROCEDURE; DOCUMENTARY REPORTS OF IRSID AND BAM
The investigation of the quality of steel rails and the means of guaranteeing it has been entrusted to the D 45 Specialists Committee at the request of the 7th UIC Commission. Two series of tests have already been made within the scope of this work. A third series of tests was then carried out on rails having shown a 'good' performance in the track and on those having shown a 'bad' performance, these performances being defined beforehand according to some accurate criteria. The definition tests and the special tests on the Thomas steel rails of this series have been dealt with in Interim Report No. 9. As many as possible of the Thomas steel rail samples of the third series of test have been examined by means of the RALUS ultrasonic equipment, developed by IRSID and designed for the automatic industrial ultrasonic inspection of the rail head. The results of this examination have been dealt with in this report (RP 10), which also contains a documentary report by

IRSID on the RALUS method and one by BAM on the investigation of rails for non-metallic inclusions.

Restrictions on the use of this document are contained in the explanatory material.

ON THE ULTRASONIC RAIL INSPECTION CAR

Seventy percent of rail failures are located in the joint areas starting from the bolt hole, but these defects could not be found out by the electro-magnetic method. The new ultrasonic rail flaw detector car was designed and manufactured by the Railway Technical Research Institute, Japanese National Railways. Results of the tests are summarized as follows: (1) up to a test speed of 35 km/h records are satisfactory, (2) at a higher speed than that the recording of joint areas becomes unreliable, (3) jumping tendency of probe was avoided by elongation of shoes and water supply devices, (4) a revolving type searching unit has been manufactured and a test is now continuously being carried out.

RELATION BETWEEN SUPERELEVATION AND CAR ROLLING

Springs and links between car body and axles can be thought as a mechanical filter to isolate the car body from axle motion (except axle revolution). Then the problem to know the relation between track irregularity and car vibration is the problem to know the characteristics of this filter. there are three methods to study the characteristics. The first method is to calculate the characteristics theoretically from the parts constants. The second method is to know the characteristics by measuring the output of filter for special input. The third method is to determine the characteristics by analyzing the input-output relations for normal operation. No special equipment except measuring instruments is needed. Second, the effect of random noise can be cancelled out by statistical treatment of data. An application of this method is described.

NEW SHAPE OF TRANSITION CURVE IN HIGH-SPEED RAILWAY TRACK AND ITS ALIGNING

The quantity called "Track Irregularities" is usually used as basic data and technical inferences are made from it. From the view-point of safety and comfort of traveling, we are requested to decrease the track irregularity especially with regard to high speed railway track. Must first of all grasp the essential meaning of "Track Irregularity" and consequently the next two quantities clearly: (i) difference between geometrically practicable shape and the actual shape of railway track. (ii) difference between physically rational shape and geometrically practicable shape of railway track. These two items are almost self-evident for the straight railway track, but for the curved railway track, especially transition curve, there are many problems yet to be solved.

ACCOUSTIC EMISSION TECHNIQUE FOR THE DETECTION OF FLAWS IN RAIL WELDS
An acoustic emission technique of testing for flaws in welded rail was conducted in June and July of 1969 at the Bellevue, Ohio, rail welding plant and at the Roanoke, Va., gas welding plant. Several welds by thermite, gas and electric welding processes were prepared for these tests under controlled conditions, with several samples of each process having artificially induced or included defects. This technique is entirely non-destructive and is accomplished immediately after welding so authoritative corrective action can be taken. Correlation was found between poor welds and high AE activity and good welds and lower AE activity. It appears that innovations and refinements will be required to obtain a practical "black box" of this type suitable for use on the railroads.

SEVENTH PROGRESS REPORT OF THE JOINT INVESTIGATION OF FISSURES IN RAILROAD RAILS
The development of detector cars made possible the detection of many fissures before rail fracture had occurred, but it did not touch the problem of prevention of fissures. A "rolling-load" testing machine was designed and built which subjected a specimen of rail to repeated cycles of wheel load and bending moment. Before testing in this machine an etch test to detect the presence of shatter cracks was made on the rail from which the specimen was cut. Rolling-load tests showed the following results: Only shatter-cracked rails developed fissures, but not all shatter-cracked rails developed fissures. It is the complex stresses directly under a wheel load which cause cracks to develop into fissures. Bending moment tends to cause fissures to take a transverse direction, and accelerates their spread. No greater wheel load was required to start a fissure in a heavy rail than in a lighter rail. The minimum wheel load which started a fissure in the rolling-load tests was 40,000 lb. The wheel load necessary to start a fissure, the theoretical shearing stress in the zone where shatter cracks are located, the fatigue strength of rail steel, and the weakening effect of minute cracks (shown by fatigue tests of specimens) form a coherent picture of the mechanism of fissure formation and spread. The solution of the problem of preventing shatter cracks in rails was attacked by making tests of specimens from rails cooled in air and also controlled cooled. A large amount of study has been given to the problem of finding a nondestructive test which could be used to detect shatter cracks in new rails. Shatter cracks are so minute that changes, due to these shatter cracks, in properties or structure of metal around them, are masked by other variations in the metal. Unfinished work of the investigation relating to fissures includes formulation of proposed standards for control cooling of rails and for bend tests for acceptance of rails. Numerous photographs detail rail defects of the type described.

THE "RALUS" METHOD FOR RAIL INSPECTION BY MEANS OF ULTRASONIC PROBE
Shrinkage of a rail is not due to vertical wear but to diverse cause divided into two main categories:--Defects in rail fabrication;--Shrinkage due to use, for example the lateral wear at chamfer, or damage to the surface by slipping. Though the diminution of shrinkages in the second category is the affair of the user, the first category concerns the rail makers and the S.N.C.F. jointly. The study and development of the RALUS method provide an efficient means of checking the metallurgical quality of rails. A tool which will enable it to follow up the quality of production and to detect any anomalies before rails are laid on the track.

DATA HANDLING OF HIGH-SPEED TRACK INSPECTION CAR
Measurement records made from the high-speed track inspection car are for two purposes, one of them is to defect and locate large track irregularities for preparation of the data necessary for spot maintenance. The other purpose is to give an overall information on the track irregularities found within a certain distance, as this helps service and maintenance planning. For the second purpose, however, records must be sorted, classified and processed statistically. The machine operation shows more stability than that of manual work and this is because the machine has no personal error. The machine has been employed officially since April 1961 and the inspection data over 40,000 km throughout Japan has been already handled. Therefore savings of man-power, cost and time to date have been very large.

MECHANIZED MAINTENANCE OF TRACK ON THE JNR
The Japanese National Railways are making continuous efforts to mechanize track maintenance work in line with the policy towards general modernization of operation. Emphasis is laid on the wider employment of small-sized equipment which will allow a train to pass or which can easily be taken out of the track when a train is coming. So-called overall track renewal using heavy equipment is carried out where an interval of 3 or 4 hours is available between midnight and 4 o'clock in the morning as in the case of the electric multiple unit train lines in and around Tokyo and Osaka. This method is also used on some trunk lines, such as the Tokaido Line in cases where sufficient work time is available by blocking one side of the double track. Outlined are the principal kinds of maintenance work in which such equipment is used, and the measuring devices.

DEFORMATION OF RAILWAY TRACK UNDER HIGH-SPEED TRAIN--MEASUREMENTS ON THE TEST-RUN SECTION OF THE NEW TOKAIDO LINE
In designing the new Tokaido line, many tests through actual operations of trains at high speed were conducted in parallel with model experiments, laboratory tests and theoretical analyses. Major items of measurement on the ground were rail deflections, rail stress, stress on fastening device, track vibration acceleration and sleeper stress. Major measured items on the car were wheel side thrust, wheel load, bogie stress, car body vibration, axle box vibration and similar forces.

TESTS ON THE TRACK ON THE RIDING STABILITY AND THE GUIDING QUALITY OF VEHICLES BY MEANS OF A SPECIAL VEHICLE-RESULTS OF THE FIRST TRACK TESTS
The report gives an account of the results of the tests made with the experimental bogie described in a previous report. The first part of the report supplies data relating to four series of tests during which the various parameters of the bogie (lateral play between axle-box and axle, axle load) and also the riding speed were successively varied. These tests have made it possible to establish conclusions relating to the wave-length of the hunting movement, the amplitude of the transverse movements of the bogie and the maximum transverse forces occurring between bogie and axles. The second part of the report supplies data relating to the tests during which the wheelbase of the test bogie was varied. The data obtained have permitted the establishment of some conclusions relating to the wave-length of the hunting movement, the transverse displacement of the bogie frame, the maximum angle of rotation of the bogie and the transverse forces. The third part of the report contains an account of the results obtained during the tests, the object of which was to study the same magntiudes as those prevailing during the previous tests, the wheel tyres of the test bogie having however been machined in accordance with the wear profile "Muller No. 2". All the tests were made on one and the same section, this being in an excellent state of repair and having a relatively constant gauge and chiefly consisting of straight track.

Restrictions on the use of this document are contained in the explanatory material.

MEMORANDUM DESCRIPTION OF DERAILMENT
A memorandum discussing a derailment includes the vehicles involved (4 diesel locomotives, 112 loaded and unloaded freight cars) and the probable causes of the derailment. The scene of the accident is described, list of possible causes, with each discussed in detail. Causes are not clearcut, but probably the rolling of an empty car, the wheel of one track on that car hitting a rail joint on the outer rail of a curve, the upward force from car roll, the bad joint caused the wheel to run over the rail causing the derailment. It is suggested that differences in rail height at joints be limited to 1/16 in. and rail wear be limited so that wheel flanges will not be raised by joint bars when hit by wheels with worn treads.

TRACK TEST EQUIPMENT FOR EVALUATION OF ROAD BED IRREGULARITIES
The Norfolk and Western Railway Company has been investigating various methods of evaluation of track irregularities. The R-S Three Way Ride Recorder records accelerations in 2 or 3 directions as required, such as vertical and lateral accelerations, whereby riding qualities of cars may be compared to evaluate the track structure. The Tracon system for track analysis is an electronic track inspection system which measures and digitalizes the dynamic cross level variations of a track structure. There are three possible multiples of cross level variations that may be measured. This system can be applied to any car and is designed to operate at any speed above 35 mph. In addition, consideration has also been given to a computerized method road bed evaluation through measurements and simulation of "rock and roll" of a car. This problem is continuing under study.

TRACK GEOMETRY AND DESIGN OF THE PERMANENT WAY OF HIGH-SPEED LINES
The increase in maximum speed envisaged by many railway administrations makes exacting demands on the permanent way. In the following, the resulting problems associated with the railway track are discussed mainly on the basis of theoretical considerations and on the strength of the results of experimental research carried out by the German Federal Railway (D.B.) at speeds of 200 km/h. The resulting conclusions are also applied to even higher speeds. Comparisons are made with similar developments abroad.

RAIL FAILURE DETECTION IN THE UNITED STATES
The major components of inductance, residual magnetic, and ultrasonic instruments for detection of flaws in rails are described. The Association of American Railroads report for 1964 correlated the drastic reduction in service failures due to transverse defects with the success in controlled cooling of the rails during manufacture, although the number of failures detected using the above NDT methods remained fairly constant. It was concluded that the $400,000 cost of the flaw detection services was well worth while in the USA, but could not be justified in the United Kingdom due to the use of different steel for the rails.

ULTRASONIC CAR WORKS AT 25 MPH
British Rail's detector car uses ultrasonic methods to detect and record hidden rail flaws while running at speeds up to 25 mph. The train can test up to 100 miles a shift--means that entire main routes can be ultrasonically tested in a matter of a few days. The train's rail scanning probes are carried on a trolley mounted between the running wheels of the equipment car. For scanning the rails the trolley is lowered to run on its own wheels, allowing the probes to slide along the surface of the running rails on a thin film of water. Using the principle of reflection of high frequency sound, the probes inspect the running rails for minute cracks and internal flaws Signals from the probes are relayed to monitoring devices on the train and then recorded on film. At the end of each day's testing, the film is sent to an evaluation center near Paddington station, London, where a team of evaluators examines it and reports any signals that indicate a possible rail deflect.

PURPOSES AND REQUIREMENTS OF TRACK INSPECTION AND MEASUREMENT
This is the first part of a two-part study prompted by recent interest in automated inspection devices and systems. This first portion, deals with the general questions about inspection such as why is track inspected, what is being looked for, when and how often inspection should be done rather than how it should be done. The first is as a fundamental guide to procedures and purposes of inspection, and for an examination of what may or may not be wrong about the way inspection is now being performed. The track materials inspection should include: the load bearing function of the track; the effects of loading on deformation and rupture and wear and abrasion, and on fatigue; and the environmental effects. The present inspection methods are given for rail, cross ties, switches, turnouts, crossings, and ballast.

ULTRASONIC RAIL TESTING AT THE ROLLING MILL

Studies have shown that fatigue defects which appear in rails in the track can always be traced back to segregations in the metal, inclusions or micro-cracks. Metallographic tests which show up these defects are lengthy, costly and must inevitably be restricted in scope because they involve destruction of the specimen tested. Consequently, it was necessary to find a non-destructive method of detecting these defects by sounding the whole length of the rail head. The ultrasonic method using echoes was chosen by SNCF and ORE. The Ralus equipment was designed to detect heteorogeneities which are particularly harmful to the performance of the rail in the track: non-metallic inclusions and flakes located in the critical zone of the rail-head where most fatigue defects originate. Studies have shown that the Ralus testing method does give a reasonable indication as to the quality of the rails.

SERIAL MEASUREMENTS ON RAIL TO DETERMINE WHEEL LATERAL FORCES

The rail-head bending procedure is described for measuring the loading on the rail due to the lateral forces of the wheels of motive power and freight cars for various conditions of track curvature and speed ranges up to 200 km/h. Comparisons are given for the lateral and vertical loads imposed by the different wheel and axle arrangements of this equipment at various speeds and of the stress effects on the rail. Charts show these relations, and the relations of the lateral forces to the curve radii. The side wear or abrasion of the rails is also shown in mm(super 2) per million gross tons rolling over the rail in relation to the curve radii.

C1 037598
LATERAL RAIL FORCES DUE TO VARIOUS LOCOMOTIVE AND TRAIN CONSISTS

A series of tests was performed to determine the lateral forces developed by various types of locomotives and train consists. Analysis of the data indicates that no excessive lateral forces were developed by any of the test consists. The maximum average force, 7,400 pounds was developed by the T.P.F.C. freight. The effect of roadway irregularities on lateral forces generated by normal consists remains largely unknown. Based on the results of this test series, it is concluded that light locomotive, passenger and freght consists generate relatively low lateral force on good roadway. There is a slight reduction in maximum lateral forces as training tonnage is increased. A study of the available research literature on the forces required to overturn rail shows that the maximum pressures measured were about 30% of the forces theoretically needed.

CAR ROLL AND WHEEL LIFT TESTS ON SIMULATED SERVICE TRACK: TEST CONDITIONS AND RESULTS AT PRR ALTOONA TEST SITE
The class H-43, 100-ton hopper car began derailing at increasing rates beginning in the Spring of 1964 as more and more of these cars were placed in service. It was decided to set up a test track to simulate the rock-off phenomena and determine what modifications could be made to the car to reduce wheel lift and car roll. All cars were tested first on a tangent track with rails shimmed 3/4" to produce an 1-1/2" total change in cross level at each 39-ft. joint over a distance of ten rail lengths at speeds in the range of ten miles per hour to 22 miles per hour at approximately one mile per hour increments or until the critical speed was exceeded. The cars were then tested on a 3 degree curve having a 4-1/2" super-elevation with an 1-1/2" change in cross level superimposed at each joint over a distance of six rail lengths. Speeds on the 3 degree curve did not exceed 15 miles per hour. After testing, it was decided to adopt the following truck modifications:--1. Replace the 2-1/2" travel springs with 3-11/16" travel springs. 2. Add two friction snubbers to each spring group to absorb energy input into the spring group: 3. Move the side bearings in from 50" centers to 46" centers. 4. Machine the bolster gibs to permit more bolster lateral freedom. Even though a truck modification eliminate wheel lift on the test track, it was not certain just how close the wheel is to becoming unloaded.

RAILWAY ENGINEERING AND RADIOGRAPHY
When X-rays penetrate a substance opaque to visible light they are partly transmitted, partly absorbed, and partly reflected or scattered, the amount of each depends on the substance and its thickness. Substances of high density and atomic weight usually absorb X-rays to a much greater extent than those of light weight, for the latter tend to scatter the rays rather than absorb them. An outline arrangement for taking a radiograph is shown. In welds, unsoundness of the weld metal, imperfect penetration of the weld head and cracks in both bead and parent plate may be sought for. In castings, any such defects as porosity, draws and hot tears are likely to be revealed. Radiographs are shown of various welded and cast specimens.

OVERHEAD LINE EQUIPMENT INSPECTION VEHICLE
A diesel-driven vehicle for overhead line inspection is described. Of steel construction, the interior provides space for eight men and necessary working equipment. Drive is from either end with speed options of 1.5, 5.6, 9.8, 14.8, and 23.1 mph. A hydraulically operated tower is housed in a well in the vehicle body. Windows are set at 45 degrees to permit inspection from inside the vehicle. Accessory lighting is provided by two separate battery-operated 24 volt circuits.

INSPECTION CARS AND GANG TROLLIES
The wide range of motor inspection cars and gang trollies manufactured by D. Wickham and Co., Ltd., are described. Nine models are pictured. One out of four variations of the type 40, 6 to 9 person car is shown, as is the new type 30. Also shown are the flyweight, one-man trolley; the one-man, light-weight type 8B; the type 18A gang trolley; the heavy-duty type 18A; the 5-ton loader version of the type 18A; the covered version of the type 18A; and the medium-duty type 17A gang trolley. The power unit in each type of vehicle is described.

TRACK INSPECTION ON THE L.N.E.R.
A system of assessing numerically the condition of track is briefly described. Track is evaluated for 10 different characteristics and awarded a maximum of 100 points for each. A perfect score is 1000--average scores on the L.N.E.R range from 650 to 950. Uniformity of assessment is essential: to this end the judgment of individuals of considerable experience of the system was pooled and a small nucleus was formed which trained others, who again became apostles to spread over a widening field the level of uniform discrimination.

TRACK TESTS ON THE ILLINOIS CENTRAL RR
This article describes a number of tests conducted on the Illinois Central. One test was conducted to determine whether the removal of the mill scale from the rail ends and fishing surfaces of the plates would reduce the initial rate of bolt tension loss or have beneficial effects on fishplate wear. Insulated joints were also tested. Tests were also carried out with various types of bearing plates in an attempt to eliminate the cutting of soft wooden sleepers by such plates. To prevent creep, 14 rail anchors of different types were fitted per rail length, and in addition 12 rail clips to the rail length were used. Eight different arrangements of the anchors were installed. Various kinds of sleepers and ballast were also tested.

RAILROAD RESEARCH FIELD TESTING PROGRAM
The primary purpose of this project is to assist in defining the operational characteristics and constraints of conventional rail systems at speeds of the order of 150 miles per hour. Four electric, multiple-unit commuter-type cars, modified to facilitate instrumentation and to achieve full-power balancing

speed in excess of 150 miles per hour, were built and heavily instrumented. High-speed tests are being conducted on an improved 21 mile section of the Penn-Central Railroad between Trenton and New Brunswick, New Jersey, and track geometry measurements reflecting track conditions are being made between Washington, D. C., and Boston. Of particular interest are the evaluation of ride quality, truck and suspension performance and vibration, track geometry measurements, pantograph performance, catenary profile and dynamic response, track-roadbed characteristics, and interaction between trains. An initial part of the original contract was the formulation of a general purpose mathematical model of car motion suitable for evaluating the performance of new or proposed vehicles or vehicle components in response to rail excitation at high speeds. The parameters and characteristics of the research cars and statistics of track geometry are being used to validate the mathematical model with actual measurements. This dynamic railcar simulation program will be the subject of a separate comprehensive report. The purpose of this report is to present in summary form the progress achieved thus far on this program.

STUDIES FOR RAIL VEHICLE TRACK STRUCTURES
Conventional (tie-type) and non-conventional rail vehicle track structures were studied, with the restriction that standard gauge and rail-head contour be used. Computer programs were developed and used to analyze track response to both static and dynamic vehicle loading. The models of conventional track were validated by track, and on the Penn-Central high-speed track near Bowie, Maryland. The DOT research cars were used to obtain a series of controlled-speed passes at speeds up to 125 mph. Track response under Metroliner and regular freight traffic was also recorded, both at a joint and away from a joint. The measurements showed the lack of consistency of track characteristics at different locations and at different times, and indicated the computer results to be as accurate as the degree to which track parameters could be defined. The predicted presence of individual pressure pulses for individual axles on trucks with wheelbases exceeding 6' was verified by measured subgrade pressures 3' beneath the tie base, at speeds up to 125 mph. A major philosophy in the development of improved track structures was to reduce the magnitude and number of pressure cycles transmitted into the roadbed, with the number of cycles reduced by using beam and slab type rail supports having substantial longitudinal bending stiffness. Following the analysis, performance specifications were written for rail fasteners and three types of reinforced concrete structures recommended for further evaluation in field tests: cast-in-place slab, cast-in-place twin beams, and precast twin beams. CIVIL ENGINEERING MAINTENANCE WORK
Regular examination is the basis of railway civil engineering maintenance work, ranging from daily examination of passenger-carrying lines to underwater examination of the piers or abutments of a bridge at 20-year or longer intervals. The Matisa track-recording self-propelling trolley unit, introduced during the last two years, enables reliable records of cross level, track curvature and track gauge to be obtained at a running speed of about 20 mph. Examination of rails with manually-applied ultrasonic-type flaw probes was introduced in 1954. A special rail-mounted adaption of the principals and mechanism of the Simon hoist has been developed to provide better means of regular examination of high masonry vaiducts. At the end of 1958, only two major equipment developments were being pursued. First, a prototype "on track" self-propelling machine was under construction. This is designed to excavate track ballast from outside the ends of sleepers, and screen it, and replace the clean ballast. Secondly, a design of a type of low-loading lorry with both pneumatic-tired road wheels and steel flanged tired wheels is being developed.

RAIL-END DEFECTS
Of all steel rail defects, probably the most difficult to detect are those which occur at the rail-ends and are concealed by the fishplates. The major cause is the pounding and vibration to which rail-ends are subject because of the gap between the rails over which the rolling load must pass. This may encourage the development of corrosion fatigue cracks from any sharp edges, such as those of the fishbold holes or in the fishing angles of the rails, which stresses are concentrated. In the course of ordinary inspection, the only way to discover whether or not a rail is cracked at the end is to take off the fishplates but this is a costly operation from the labour point of view. In the United States certain railways are now supplementing the regular patrolling of their tracks with Sperry or other detector cars by supersonic testing of rail-ends. One of the problems arising from such inspections has been to decide at what stage of development a crack becomes sufficiently serious to demand the removal of the rail from the track. To remove all rails in which small cracks are found would appear to be an unjustifiable costly proceeding. The present practice of classifying the cracks and removing from the track only rails that have cracks of over a certain length, would appear to be reasonably safe, and far less costly than the indiscriminate removal of all rails show ing the slightest sign of cracking.

A NEW FATIGUE DEFECT IN RAILS
The shelling defect has been most commonly encountered in the 131-lb standard flat-bottom section, though it has been reported in some degree in all sections from 100 lb. upwards. The first manifestation of the trouble is the appearance, on the running surface of the rail near the running edge of dark spots, which indicate the presence of horizontal planes of separation of the steel within the rail-head; these may occur at a number of different levels in the same rail. The shelling is the result of wheel action on the rail causing failure of the metal, either by direct stress exceeding the elastic limit, or by loss of ductility which is the outcome of constant reversals of stress. Factors which may influence the relative severity of the shelling are the inclination of the rail, the superelevation, the bearing pressure exerted by the wheels, the radius connecting the flanges and the treads of the wheels, and the radius of the gauge corner of the railhead.

RAIL WEB FAILURES
Out of 30,881 failures of new rails in U.S.A. tracks in 1942-51, and removed during that period because of defects, 13,554, or 44 percent, were web failures. The great majority of the latter were failures within the area of the rail joint. Laboratory and track tests showed that many web failures could be explained by corrosion-fatigue but not by corrosion alone. Various factors increase the web stresses at rail ends. One is poor or irregular fit of fishplates; loose or worn fishplates or loose fishbolts have a bad effect, as they are liable to cause greater impacts to develop under the rolling load. Excessive gaps at the rail-joints or battered rail ends similarly tend to increased impacts.

GP-7 LOCOMOTIVE WHEEL TO RAIL LATERAL LOADING TEST ON ILLINOIS CENTRAL RAILROAD
The report is based upon testing conducted by EMD to determine causes of derailments which involved GP-9 locomotives. The EMD Test Car was used to determine wheel loading levels for the GP-9 locomotive to determine wheel loading at the derailment sites. The test train from which data for this report was obtained represented a typical freight train operating in normal service through the areas where previous derailments occurred. The loads measured between wheel and rail during the testing were substantially below levels which are normally considered necessary to cause derailment by wheel climbing rail, rail turn-over, or shift of entire track structure. The maximum steady state net lateral load measured on the guiding wheel was 13,200 lbs. which represents 41.2% of the nominal wheel vertical load. Accompanying this load was a 5,400 lb. axle lateral load which represented 8.5% of the nominal axle vertical load. The above loads were measured in a 6-1/2 inch curve. Threshold tendency of wheel climbing rail is generally expected when net lateral force on guiding wheel is 90 to 100% wheel vertical load. Rail turnover demands that total lateral load compared to total vertical load on an entire rail length unsupported, or practically unsupported, by adjacent lengths gives a ratio great enough to cause the load resultant to fall outside of the base of the rail. Dynamic instanteous peak loads which are of very short duration resulting from sudden rail irregularities (joints) are not believed to affect wheel climbing rail or rail turn-over. Train speed did not significantly change steady state forces in a particular curve. However, increased speed did significantly change the level of dynamic loading as much as 200%.

PENNSYLVANIA RAILROAD CLEARANCE CAR
The Pennsylvania Railroad has introduced a specially designed car for the measurement of track clearnace. It is usually made up into a short train consisting of a locomotive, the clearance car, and a crew coach. The car has now been in service for three years. Aluminum rods, 3 ft. long, and steel tipped, project from the sides and roof of the car in the form of an arch. As the train moves slowly towards a structure to be measured the rods are brushed backwards by contact to conform to the contours of the structure. The rods, 126 in number, are each capable of giving readings to 1/8 in. Graphs show the profile and clearance of the structure measured. The clearance car can cover an average of 100 miles of track each day. The time taken for measurement is about five minutes for a bridge and 30 minutes for a tunnel a mile long.

TRACK TESTS AT WOOD GREEN
This appendix taken from an unidentified report, describes a test conducted between London and Edinburgh on a section of track which was causing maintenance problems due to soil instability. The following measurements were taken through the use of pressure transducers: (1) transverse distribution of vertical stress beneath a test sleeper, (2) vertical stresses on the rail to sleeper reaction axis beneath both rails of the adjacent sleepers, (3) transverse horizontal stresses beneath the test sleepers, and (4) longitudinal horizontal stresses acting across the rail to sleeper axis. As a supplement to the stresses, induced by traffic, the in situ changes in the density and moisture content of the track foundation was determined by means of radioactive probes. This was done to check the behavior of the individual layers of the ballast, the blanketing layer just down and the formation under traffic loads. Findings are presented graphically.

TRACK SURFACE AND CAR DERAILMENTS
Tests under laboratory conditions to determine the effect of warped track surface as a cause of derailment of freight cars and the flange pressure required to turn the trucks under freight cars have led to certain conclusions contrary to the accepted beliefs of many competent engineers and railroad officers. Among the definite conclusions indicated by these tests may be mentioned the following: That a rigid and a flexible track are equally effective in resisting a tendency to derailment caused by warped track surface; that center-plate resistance plays little part in the total resistance

which must be overcome in turning trucks on curves, and that grease lubrication of center plates has no appreciable effect on truck turning resistance. It is interesting to note that, in general derailment occurred with less depression than super elevation of the outer rail. In general, it is evident that side-bearing clearance is the most important single factor, so far as the car is concerned, affecting derailments caused by warped track surface, and it is evident that flexibility of car structures plays no small part in keeping cars on the track where side-bearing clearance is small or altogether absent.

INVESTIGATION TO DETERMINE THE CAUSE OF "SUDDEN" WIDE GAGE ON THE DELAWARE AND HUDSON RAILROAD

The purpose of this investigation was to determine the cause of this "sudden" gage widening. It would appear that this gage widening would most probably be caused by a jackknifing condition. This investigation measured the jackknifing forces developed under heavy pushing. The first part of the investigation was made on a 3 deg curve. A special test train was used consisting of a number of diesel units in dynamic braking and 15 loaded hopper cars, including one 100 ton car, to provide the pushing resistance at one end, an 89 ft. TTX flat car and short hopper in the middle and the pushing diesel units under test at the other end. Four special ties and eight roller bearing tie plates were installed near the middle of the 3 deg curve to measure and record the lateral forces exerted by the equipment on both inner and outer rails. Strain gages were placed on the rail webs to measure the vertical wheel loads. The lateral displacement between the first and second diesel units and the total locomoitve drawbar force were also measured. The investigation did not result in finding any clear cut and specific answer as to the cause of the occurrences of "sudden" wide gage. However, it appears most likely that the occurrences were due to lateral forces exerted against the outer rail as a result of locomotive jackknifing under dynamic braking.

COMPUTERIZED DATA PROCESSING OF TRACK GEOMETRY RECORDING

The British Railways system of automatic assessment of the records produced by track-condition recording cars is described. The mechanical movements of the pens of the recording trolley are converted to electric pulses, which are measured on a floating datum in the case of the versines and twist. All measurement and evaluation is electronic and in no way impairs the production of the standard track-record graph. All the information on the print-out and the date of the recording are reproduced on a punched tape which is subsequently processed by a central computer to produce future work programmes for tamping and lining machines. This is done by extrapolating the trend of deterioration revealed by the fault counts to predict the content and order of priority of future maintenance work loads on the tracks.

DYNAMICS OF RAIL FAILURES IN THE TRACK

The propagation conditions of the following defects were studied: transverse cracks in the head; horizontal cracks in the head; and starcracking at fish-bolt holes. The main object was to attempt to determine the length of time after the appearance of detection of the failures during which the rails could be left in the track before dangerous failure became imminent. Laboratory tests failed to determine this time factor. Field test results from the Paris suburban railway are briefly described for the three types of defects. Laboratory measurement of transverse defects showed the electric method gave more accurate results than the ultrasonic method using pulse echoes.

DIGITAL PROCESSING OF TRACK GEOMETRY DATA FOR MAINTENANCE PLANNING

The concepts for data processing described in this paper and the resulting preferred formats for the presentation of track geometry data resulted from discussions with knowledgeable people within the railroad industry. Data on 450 miles of track geometry are recorded by the test cars in less than 8 hours. The analog chart data is then scrutinized and edited. Within 48 hours after the test run, the digital gage printout and the annotated charts are ready for review by the maintenance engineer. By use of digital computer processing, a vast amount of track data can be collected and reduced into meaningful form quickly and efficiently. The Gage Data Reduction Program is a tool actively providing maintenance engineers and key management personnel with information to direct the planning of maintenance-of-way activities. The crosslevel program, presently under development, will be providing information on another key track parameter.

ENGINEERING TRACK RECORDER CAR

The Canadian National Railways have developed a track recorder car which measures and records condition of track. Track measuring and recording equipment has been installed in a converted passenger car which is equipped with two six-wheel trucks. This car is capable of testing track when operated

within the speed range of 20 mph to 100 mph. This car is equipped to measure and record the surface conditions of each rail, cross level and gauge. Photographs show the instrument panel and the equipment installation. Sample output is illustrated.

STUDY OF RAIL FAULTS IN THE TRACK--STANDARD RAIL FAILURE STATISTICS 1965 RAIL FRACTURES CAUSING DERAILMENTS

This report provides an account of rail failures for 1965 compiled by nineteen Administrations. The report also includes a study on broken rails having caused derailments. A primary distribution of the failures bases on their location is failures at rail-ends, failures away from rail-ends, and butt-weld failures. The principle rail defects classified according to their cause are failures attributable to manufacturing defects, failures attributable to service, failures which may be attributed either to manufacturing defects or to service, and failures due to butt-welding or thermit-welding and rebuilding of surfaces.

Restrictions on the use of this document are contained in the explanatory material.

INSTRUCTION GOVERNING THE SUPERELEVATION OF OUTER RAIL AND THE SPEED OF TRAINS ON CURVES

This specification for operations practice provides four superelevation tables: Table A gives the equilibrium elevation for various speeds on curves at which the overturning forces are balanced by the superelevation. Table B gives the speed at which conventional passenger equipment will ride comfortably around a curve. Three additional inches of superelevation would be required for balance of overturning forces. Table C gives a modified speed which may be authorized for freight trains. The superelevation is between equilibrium and comfortable. Table D gives a maximum theoretically safe speed assuming a center of gravity at 98 inches above the rails. This table is not to be used for elevating track. It is for information only. Change in superelevation will follow the alignment spiral where possible. The rate of change of superelevation should not exceed 1/2" in 31' for speeds up to 50 mph or 3/8" in 31' for speeds over 50 mph.

BATTER TEST OF 151 LB. R.E. RAIL

This report covers a test of 151 lb. R.E. rail in which the base and lower portion of the web at the rail ends is cut square while the head and upper portion of the web is mitred, the change in angle of cut taking place about the center of height of web. The mitre makes an angle of 60 degrees with the line of track. For the purpose of test the above rails were laid on the Pittsburgh Division in No. 1 Eastward Freight Track east and west of Ardara on April 27, 1935. For comparison, 67, 131 lb. X-Rails with ordinary square ends were laid at same time adjacent and west of the mitred rails on the same track. After one night's traffic had passed over the rail initial measurements of rail and batter were taken. It was concluded that insofar as rail end batter there is no advantage in the use of mitred end rails over ordinary square cut end rails as determined by batter measurements over a period of one year and-1/2 months service in heavy tonnage freight track.

FINAL REPORT ON 131 LB., R.E. FERRO-TITANIUM RAIL TESTS NOS. 253 AND 300 CONDUCTED ON THE ALTONNA AND COLUMBUS DISTRICTS

It was the purpose of the tests to determine to what extent rail with ferro-titanium added would alleviate the presence of shatter cracks with ultimate formation of detail fractures or other kinds of failures. Also, to obtain information as to the service quality of the above rail by means of observations and measurements of wear and rail end batter. The ferro-titanium rail used in Tests Nos. 253 and 300 was rolled under standard specification C.E. 35-(b). It was concluded that there is no overall advantage, either in reduction of head wear or rail end batter, in the addition of ferro-titanium to rail steel. Shatter cracks have been eliminated in rail of normal composition by control cooling. There is no necessity for using rails of special composition for this purpose. While the reduction in flaking, often associated with the formation of shelly spots, was not marked, there may be justification in considering titanium along with higher silicon contact as an alloying element intended to reduce shelling. It is recommended that in the study of rail chemical composition intended to reduce shelling, consideration be given to titanium.

COMMENTS ON PENNSYLVANIA RAILROAD ELECTRIC LOCOMOTIVE TRACK TESTS CONDUCTED BETWEEN 1930 AND 1938

These are the first tests in which a section of track was equipped with special ties with means of measuring the maximum lateral force exerted outwardly on the rail by an electric locomotive on a test run. The tests were quite extensive with respect to instrumentation and also the number of run made with various types of locomotives. The section of test track consisted of steel ties spaced on 43 inch centers. The applied loads would be considerably different than on wood ties placed on 20 inch centers. A loaded profile of the right rail and left rail on the tangent track test section 440 ft. long including 128 test ties was intentionally made with variations in cross level in order to develop the performance of locomotives under unusually large variations in track cross level for very high speed running. The second phase of the tests included the use of weight bars equipped with magnetic strain gages to measure the lateral force exerted by the axle against the locomotive frame. These tests are of limited value to diesel locomotives and freight car equipment now in service.

TEST 431--RAIL MODIFICATION

The test comprised modified rails applied on high side of 6 deg 00' curve in heavy tonnage territory. For the test rails 131 lb. No. 1 quality, open hearth high carbon steel were furnished. Performance of the rails in track was followed during 2 years service by occasional inspections, measurements of rail wear, and rail end batter. Carnegie rails with 10" head radius were heavily flaked but no shelling was evident, whereas, the Bethlehem rails with 14" head radius were shelling.

STRESS CORROSION OF RAIL WEB STEEL (STATIC)

The test included six rail joint segments containing one bolt hole with a bolt inserted to make the joint. It also included twenty steel specimens taken

from rail steel which were subjected to static bending stresses. The twenty corrosion test specimens were tested after nearly twelve and one half years of exposure to the elements. The joint segments were tested approximately one month later. All of the test specimens were cleaned throughly and examined in the laboratory by Magnaflux and Magnaglow methods for the presence of corrosion cracks. While there was considerable pitting to be found, the laboratory examination disclosed no cracks in any of the specimens. This test shows that static stress combined with corrosion has little or no effect upon the development of cracks in rail web steel.

C1 040278
DETERMINATION OF PLASTIC FLOW IN RAIL HEAD
The purpose of the test was to determine the amount of plastic flow which takes place in the gauge corner of a rail on the high side of a curve under conditions which produce shelling. The rails were laid on the Bolivar Curve. At this location the track was laid with 140-lb., 1948 rail, which in August 1953, was showing flaking and light shelling. This is a 4-degree curve with 4-inches superelevation, authorized speed 45-mph, and carries moderate to heavy eastward freight traffic. Records kept in connection with another test indicate a tonnage of approximately 29,000,000 gross tons annually. The three test rails were installed August 17, 1953. Inspection September 12, 1955, showed light flaking on all three rails. On the high rail of curves there is a flow of metal at the top gauge corner of the rail toward the gauge side. This flow of metal extends to a depth of 1/4-inch to 3/8-inch below the rail surface. The magnitude of deformation is positive evidence of shear stresses well beyond the yield point of the steel.

C1 040279
RAIL WEB STRESSES IN HIGH SPEED TERRITORY
The purpose of the present test was to determine if possible the cause of frequent split web failures in the joint on 131-lb. RE rail on the Fort Wayne Division, and in 152-lb. PS rail on the New York Division. Web failures in 131-lb. and 152-lb. rail on the Fort Wayne and New York Divisions are adequately explained by the corrosion fatigue theory. The ocassional bolt hole failures in 133, 140, and 155-lb. rail are not readily explained. A 50% allowance for impact is justifiable based on measured wheel loads. Application of reformed bars changes stress distribution in the rail web and in many cases increases web stresses, accelerating rail web failure. Loose bolts and increase in rail end gaps increase rail web stress. The results of this test emphasize the need for protection of rail steel against corrosion, for maintaining standard bolt tension, a good fit between bars and rail, and good surface through joints.

C1 040281
ALLOY STEEL RAIL (CHROME-VANADIUM OR "CV")
The CV rail was laid in October 1953, in connection with regular rail renewals. The location was selected because it was one where moderate shelling had developed in the previous 131-lb. rail over a period of about 11 years. A total of 47 CV rails were laid--16 on the low side and 31 on the high side of the curve. Measurements of gauge superelevation, ordinates and rail head wear were made. A final inspection of CV rail was made on October 29, 1959, at which time 30 CV rails remained in track. There was no indication of shelling, although, some flaking was noted on the CV rail, and there was no indication of rail and defects. The results of this test have shown the CV alloy steel of the composition used to be unreliable. Its good wearing qualities and superior resistance to shelling are over-shadowed by its poor resistance to impact.

APPLICATION OF AMERICAN CURVE LINING CORPORATION CROSS LEVEL INDICATOR TO TRACK PATROL CAR
The cross level indicator is rectangular, eleven inches long, ten inches high and two inches deep. The dial opening is about ten inches long and four inches wide. The dial scale is graduated to read cross level in inches, from zero at the center of the dial to eight inches at the extreme ends of the dial. The indicator is geared to and actuated by a pendulum which is dampened with oil. The instrument had an accumulative error of 3/64 of an inch for every inch of superelevation reading on the dial. The indicator did not always return to zero when the instrument was returned to level. This unit is very sensitive to vibrations. To date the results of this test indicate that this unit is unsatisfactory. The present instrument should be retained for trial application to a separate unit to be propelled by hand or track car.

RELATIVE HAZARD INVOLVED IN WEB CRACKS OF VARYING LENGTH DETECTED BY AUDIGAGE
For testing, eight rails having web cracks from 0.25 to 9 inches in length along the centerline of the web were prepared by joining them with a pair of reformed joint bars, to a sound rail end of the same section, making a combined specimen somewhat over six feet in length with a joint at the center. These specimens were placed under the million pound machine with supports 60-inches apart, the joint at the center, and the load applied at the extreme end of the sound rail at the center of the joint. The loading was increased until ultimate failure in the rail end was obvious. Two rails with cracks through the bolt hole were also tested. On the first series of tests, except for one rail which had a nine inch crack, the load had to be carried beyond that which gives a bending moment corresponding to what can be expected in track. In the second set of tests rail loading caused the cracks to lengthen. It is still recommended that rails with cracks over 5 inch in length be removed as is required by Audigage testing procedure.

A METHOD FOR RELATING TEST TRACK DATA TO THE REAL WORLD
The purpose of this discussion is (a) to develop a method by which test track data can be related directly to any railroad's rock and roll problem, and (b) to provide a means for objectively evaluating the railroad's requirements for

100,000 in-lb to unload the wheels of a high cube car and create a potential derailment condition. The rate of energy buildup on the number of joints required to unload the wheels defines the car's susceptability to derailment. The rate of energy buildup also allows test track data to be related to the real world. By determining the distribution of low joints in the curved territory over which the equipment must operate, and the relative probability of derailment thus generated, the test track data can be used to objectively evaluate the needs of any railroad for rock and roll devices.

MEASUREMENTS OF VERTICAL AND LATERAL FORCES ON BOTH RAILS OF A SIX-DEGREE REVERSE CURVE UNDER DIFFERENT TYPES OF SIX-AXLE AND FOUR-AXLE DIESEL LOCOMOTIVES
An investigation was conducted on a 6 deg. reversed curve with 150 ft. spirals and practically no tangent between them. The track was instrumented at two locations, one on each of the spirals near the juncture with the 6 deg. curve. Vertical and lateral wheel loads were measured for each passing wheel of the locomotives on both rails. Four classes of locomotive were included in the tests having six wheel trucks as well as locomotives having four wheel trucks. The lateral force exerted against the high rail increases with speed; is relatively low for the freight diesel locomotives with four axles and the passenger diesel locomotives with six axles; and is appreciably higher for the two types of freight locomotives with the trimount trucks.

DYNAMIC MEASUREMENT OF RAIL PROFILE AND RELATED LOCOMOTIVE TRUCK MOTIONS
The profile of the railroad track on which a railway vehicle operates represents an input into the vehicle. This input is due to vertical and lateral rail irregularities and can cause dynamic loads that result in excessive damage or wear and tear on vehicle components and on the track itself. In order to study the dynamic operation of rail vehicles, it is necessary to know the profile of the track on which they operate. Since the unloaded profile of the rail can vary significantly from the loaded condition, it is the loaded-rail profile that must be known. This paper presents a method developed by the authors' company for the rapid measurement of the loaded-rail profile and includes some typical rail profiles and related truck motions resulting from these profiles. The instrumentation resulting from this work appears to have immediate application in day-to-day railroad operation and in high-speed rail transportation studies.

HIGH-SPEED RESEARCH TRAIN INSTRUMENTATION
The material presented in this paper will describe the basic instrumentation packages currently used in high-speed rail research. The instrumentation for the test and research program was subdivided into four separate packages, viz., body suspension (or ride quality), catenary-pantograph, track geometry, and track and roadbed dynamics. The task was to provide the necessary instrumentation for measurements, tests, and studies into the behavior and dynamic performances of rail vehicles, catenary, and supporting track structures at speeds up to 160 mph. The program was to be composed of four distinct but interrelated parts: (1) instrumentation, (2) computer programming, (3) data collection, reduction and interpretation, and (4) analysis and simulation. This presentation is concerned primarily with instrumentation. As a result of this program track geometry can now be determined at speeds in excess of 150 mph. Cross level, gauge, profile, alignment, warp, and rate of change of gauge can be measured at high speeds by using non-contract sensors.

QUALITY OF RAILS AND MEANS OF GUARANTEEING IT--FALLING WEIGHT TESTS AND DEFINITION TESTS (1ST AND 2ND SERIES OF TESTS)
The main object of these tests--was to define and to standardize the conditions of use of the falling weight tests laid-down in UIC Leaflets 860-1-0 and 860-2-0, for the acceptance of rails of current quality and rails of nontreated steel of a quality resistant to wear. It was concluded that a falling weight test, irrespective of its type, is not representative of the fatigue behavior of rails in the track, but it was considered advisable to retain for the time being, such a test on complete pieces of rail, to make it possible to detect and eliminate brittle rails with a large degree of probable success and to maintain each rail production within a truly characteristic and correct scatter range.

PROBLEMS OF INTERACTION OF VEHICLES AND TRACK--WORN PROFILES OF RAIL HEADS AND WHEEL TYRES

As a result of a large number of tests it has been proved that service wear on wheel tires and rail heads leads to definite profiles. These worn profiles are to a large degree independent of the initial profiles of tires and rail heads. In the worn condition the profiles maintain their form and are not subject to any further change. The worn profiles are characterized by good mutual conformity and thus by little increase in wear. The worn profile of tires results in a shortening of the wave length of the periodical wheel set motions (hunting) in the track clearance. It was concluded that to wear new profiles of rail heads and tires should be adapted as much as possible to the worn profile. The use of special wheel tire profiles promise no lasting influence on the riding quality of vehicles. Therefore other design measures on the vehicles should be preferred to control the hunting motion.

ROLLING-LOAD AND SLOW-BEND TEST RESULTS OF BUTT-WELDED RAIL JOINTS

In the period from October 1, 1965, to October 1,1966, sixteen rolling load tests and six slow bend tests were conducted on butt-welded rail joints at the Association of American Railroads Research Center. The joints were made by the thermite (Thermex Metallurgical, Exomet and Orgotherm), submerged-arc and oxyacetylene pressure-butt-welding process. The rolling-load tests were made on a 12-in-stroke rolling-load machine. Welded specimens were tested for various reasons including: (1) to determine the quality of the submerged-arc-welded rail joints, (2) to evaluate 115-lb thermite welded rail joints made by the Exomet process, (3) to determine the seriousness of making butt welds from rails with hairline cracks of (pipe) in the web. (4) to investigate the possible detrimental effects of a collar that was not removed from an Orgotherm thermite welded rail joint. The slow bend tests were made with the rail resting on supports 4 ft. apart and loaded at 2 points, one on each side of and 6 in. from the weld. These tests were made with the rail base down, thereby subjecting the head to a compressive stress and the base to a tension stress. For satisfactory service performance a minimum of 1.5 in. of deflection and 140,000 psi modulus of rupture are being used as tentative criteria for oxyacetylene and electric-flash pressure butt welds. A summary of the slow bend test results is provided.

C1 040431
METALLURGICAL EXAMINATION OF FOUR ELECTRIC-FLASH BUTT WELD SERVICE FAILURES SUBMITTED BY THE FLORIDA EAST COAST RAILWAY

An investigation was made to determine the cause of four electric-flash butt welded rail joint service failures. These four failures are representative of a group of 13 or more failures that occurred in a short period after laying. From the results of this investigation it is believed that these failures are not related to the quality of the rails or the soundness of the welds. It was later disclosed that the rail ends were cropped with a petrogen torch prior to welding. Information was also received that the time between cutting and welding could range from a few days to several weeks. It is possible that incipient cracks formed during cropping of rail ends. Once these incipient cracks have formed, further development of the crack can occur on reheating, such as during the welding operation. A second possible cause for these failures is that the amount of rail cropped from the ends of these secondhand rails was insufficient to remove bolt-hole cracks that extend back into the web. From this investigation it is believed that these failures can be attributed to (1) cutting the rail ends with a petrogen torch, (2) incomplete removal of existing bolt-hole cracks, or a combination of both these factors.

SHELLY RAIL INVESTIGATION, ROLLING-LOAD AND SLOW-BEND TEST RESULTS

Two methods presently employed for improving shelling resistance is the addition of alloying elements and the heat treating of rail. The rolling-load tests in a cradle-type machine are designed to evaluate these methods of improving the resistance to shelling. Rolling-load test results obtained from these cradle-type machines for the period between October 1, 1965, and October 1, 1966, are shown. The S-13 series were initiated to compare the effects of welding prior to flame hardening and flame hardening prior to welding. The electric-flash butt welds were made from secondhand 132-lb HF rail and flame hardened by the Hammon process. Specimens S-13A and S-13C failed after being subjected to 389,800 and 656,900 cycles, respectively. As a result of this performance, rolling-load tests were conducted on welded joints made from 132-lb HF secondhand rail having no flame hardening applied. These joints, S-13E and S-13J, shelled after being subjected to 1,088,000 and 1,163,000 cycles, respectively. Rails flame hardened by the Linde process developed shells after being subjected to 1,254,400 and 844,900 cycles in the cradle-type rolling-load machine. During this period there were no slow-bend tests.

DERAILMENT OF A PASSENGER TRAIN CONSISTING OF A DIESEL LOCOMOTIVE WITH SIX-WHEEL TRUCKS, A BAGGAGE CAR, AND A COACH

Three letters discuss the derailment of June 7, 1968. A sketch of the derailment area and photographs of sections of the track involved are included. This derailment is characteristic of a number of derailments that have occurred on curves at or near permissible speed of passenger trains having locomotives with six-wheel trucks, derailment apparently occurring

first of the rear truck of the locomotive unit or the lead truck of the baggage car following. In each case the high rail of the curve was overturned. A high ratio of L/V is required to overtrun a rail and it is unlikely that this high a L/V ratio would be developed in track unless there is some unusual condition such as a jack-knifing of couplers between cars, an unloading of the lead wheel of the truck on the high rail, or some severe wedging action of the truck between rails due to a malfunction of the truck components.

TEST TO DETERMINE VERTICAL AND LATERAL FORCES IMPARTED TO THE RAIL BY A TYPE U28CG GENERAL ELECTRIC LOCOMOTIVE, SANTA FE CLASS 350
The test runs were made using a train consisting of two lightweight chair cars and three baggage cars and a locomotive of two units, one having the instrumented truck. Tests were run at speeds up to 90 mph on dry rail and moderate temperature. The test results show lateral forces of substantial magnitude being exerted on the rails, an occasional one having a finite duration of ten feet. They also show vertical wheel loads of low value in some locations. The test results indicate it is possible for these two conditions to occur simultaneously on two or three adjacent wheels of a truck and produce an effective L/V ratio of sufficient magnitude to overturn the rail.

DERAILMENT DATA
A series of derailments are discussed. The majority of the derailments involve a loaded car connected at one or both ends with a cushion underframe car. A test plan is suggested to simulate the derailments by using a loaded hopper car and an adjoining box car with cushioned underframe containing instruments trucks. The instruments would measure lateral and vertical forces exerted on curves similar to the derailment sites.

DERAILMENT ON REVERSE CURVE
Four data sheets concern derailments on reverse curves and turnouts. The derailment on the reverse curve involved a hopper car, loaded with bulk clay, which climbed the high rail at 15 mph. The Santa Fe rules for laying and maintaining turnouts are given. One derailment at a No. 8 turnout involved splitting a switch by entering the turnout at 18 mph, proscribed speed was 10 mph. Crosslevel information is given for a derailment at the point of a frog.

RESULTS OF ROLLING-LOAD TESTS OF BUTT WELDED RAIL JOINTS
Between October 1, 1967 and September 30, 1968 fifteen butt welded rail joints were tested on the rolling-load machines at the AAR. The rails were tested to a maximum of 2,000,000 cycles, or to failure, of repeated loading. The rolling-load tests are tabulated. For the failed rails the damage points are shown.

RESULTS OF ROLLING-LOAD AND SLOW-BEND TESTS OF BUTT WELDED RAIL JOINTS
In the period between October 1, 1966 and October 1, 1967, 22 rolling-load tests were conducted on butt welded rail joints but no slow-bend tests were conducted. These butt welded rail joints were made by the oxyacetylene and electric flash butt welding process. The rolling-load tests were made on a 12-in-stroke rolling-load machine. Investigation 214 (samples A through F) was conducted to determine the seriousness of hairline cracks (segregation and pipe) on oxyacetylene pressure butt weld quality. Five of the six joints with stood 2,000,000 cycles of repeated loadings without failure, which is considered a run-out, and one joint (214E) failed after 897,100 cycles. A macroscopic examination made on transverse sections cut from the end of each rail prior to welding indicates that this failure originated from a fishtail. Investigation 220 (samples A through F) is a continuation of the problem presented in investigation 214 but was conducted to determine the effects of hairline cracks on joints from rails of heavier sections. It was found that fatigue of the failed specimens originated in the fillet between the head and web and can be attributed to a shear drag introduced while removing the weld upset. Investigation 226 (samples A and B) was conducted to evaluate two electric flash butt welded joints from which the upset metal had been ground from the top and sides of the head and bottom and sides of the base but not removed from the web. An examination of the fracture surface to determine the fracture mechanics indicates that this failure originated in the fillets between the web and upset metal. Investigation 230 (samples A and B) was conduced to evaluate oxyacetylene pressure butt welded joints made with a new type of welding head. Joint 230A failed after 33,500 cycles of repeated loading and joint 230B withstood the 2,000,000 cycle minimum requirement without failure. This failure can be attributed to the lack of fusion at the weld interface.

INVESTIGATION OF FAILURES IN CONTROL-COOLED RAIL
In the period between October 1, 1966 and October 1, 1967 there were seven failures in control-cooled rail, three service and four detected, investigated by the metallurgical laboratory of the AAR. Investigations 132-10A and B involved two rail specimens both having a detected transverse discontinuity in the head. These transverse discontinuities were detected by a detector car. Rail specimen 132-10A was identified as a 100-lb RE. This failure should be classified as a transverse fissure from hot torn steel. Rail specimen 132-10B was identified as a 132-lb RE. This failure should be classified as a detailed fracture from a shell. Investigations 132-12A and B involved two

rail specimens both having a detected internal imperfection in the web. These internal imperfections were detected by a detector car and a hand test. Both rail specimens were identified as 132-lb RE. It was noted that both these rails have a pipe, and a non-metallic entrapment (slag) commonly associated with pipe, in the web. Investigation 135-16 involved a rail that failed in service. This rail was identified as a 112-lb RE. A photograph of the fractured faces showed a fatigue ring development. This fatigue ring development (detail fracture) started from a longitudinal separation close to the running surface of the rail head, then turned downward to form a transverse separation at a right angle to the running surface. This failure should be classified as a detail fracture from a shell. Investigation 135-28 involved a service failure that resulted from a derailment. This rail was identified as a 112-lb RE. This failure was caused by an impact force of unusually high magnitude that is believed to have been the result of a derailment. Investigation 135-29 involved a rail that failed in service. This rail was identified as a 115-lb RE. This failure was attributed to the presence of a base seam in conjunction with a high impact loading at subzero temperatures.

ULTRASONIC TESTING OF RAILWAY COMPONENTS

Ultrasonic testing has expanded to the stage where it is a vitally important inspection method for two major railway components, axles and rails. It is likely that the use of the method will extend in many other fields. The success with which ultrasonic testing is now practiced is dependent upon three factors. They are: a thorough understanding of the type and position of flaws likely to occur in the component and the significance of flaw size; a sound knowledge of the principles underlying the use of ultrasonics for this purpose; and, a testing organization which can put sound techniques, well-trained men, and well-maintained instruments of the right type to work.

TWO-VIBRATOR TYPE SEARCHING UNIT AND ITS APPLICATION TO ULTRASONIC FLAW DETECTOR

In order to detect flaws located closely near surface in a metal material using a ultrasonic flaw detector, a two-vibrator type searching unit was invented. One of the two vibrators is a transmitter and the other a receiver. This unit can be used to inspect Thermit welded part of rails. Two-vibrator type searching unit is applied to an audigauge type flaw detector for use in rails. The unit can detect big flaws if they exist more than 1 to 5 mm apart from surface. In case of small flaws, they can be detected if their distances from surface are more than 5 mm.

REPEATED SHOCK TEST OF RAILWAY TRACK

By means of a repeated shock tester for track, the dynamic properties are studied of the test track. Test tracks were selected one on a wooden tie section and the other on a concrete tie section. There were laid 50 kg PS rails, wooden ties without tie-plates or pre-stressed concrete ties with a spacing of 60 cm. Ballast was crushed stone with a depth of 25 cm and a shoulder width of 35 cm. Before every test the ballast was tamped. To know the pressure on rails, bending stress was measured. Displacement of rail depression was calculated on the data of measurements by the velocity vibrometer. Dynamic force upon rails was calculated on the data of rail bending stress. This force exceeds the centrifugal force under 1400 to 1900 rpm and this is considered to be caused through resonance.

TESTS TO DETERMINE THE EFFECT OF REMOVING THE BULGE FROM THE BOTTOM OF THE RAIL BASE ON THE STRENGTH OF ACETYLENE PRESSURE BUTT WELDS

Eight specimens were welded from 3-ft lengths sawed from two 115 RE Inland rails, and welded in the normal fashion. On four of the specimens the bulge was left on the base and on four of the specimens the bulge was ground off. A ninth specimen was cut from a 78-ft length from a previous welding run leaving the bulge on the base. Slow bend tests were made. There was considerable variation in the maximum load before fracture and especially in the energy for fracture. Observation of the fractured surfaces showed smooth areas predominately in the base and web indicating that full fusion had not been obtained in the welding process. The results obtained in the drop tests showed the same lack of complete fusion in the appearance of the fractured area. It is concluded that there is no significant difference in the strength of the weld whether or not the bulge on the base of acetylene pressure welds is removed by grinding or left on as has been the past practice.

ROLLING-LOAD-TEST RESULTS OF WELDED ENGINE-WHEEL BURNS ON RAIL SUPPLIED BY THE SEABOARD AIR LINE RAILROAD

The oxyacetylene-welding method is the standard procedure for repairing wheel burns. Two welds of this type were prepared as controls. Eight engine-wheel burns were then welded by means of the electric-arc method. The first six welds were made on 115-lb RE rail and the last four welds were made on 132-lb RE rail. In this type of test 2,000,000 cycles without failure are considered a run-out. All of the welds were checked ultrasonically for defects. The oxyacetylene welds had the best results, in that one ran to 2,000,000 cycles without a failure and the other ran to 589,000 cycles, failing from a detected inclusion. The electric-arc welds failed prematurely at 49,000 to 159,000 cycles. The microscipic examination of fractures revealed taht a sharp line of demarcation between the weld metal and rail metal existed as well as very fine porosity on the interface. This porosity in all of the electric-arc welds was the cause of the failure. The microsocpic porosity in the interface could not be detected ultrasonically whereas the indication of the inclusion was very definite.

REPORT ON PENNSYLVANIA RAILROAD M. OF W. TEST NO. 591, DETERMINATION OF PLASTIC FLOW IN RAIL HEAD

On the high rail of curves there is a flow of metal at the top gauge corner of the rail toward the gauge side. This flow of metal extends to a depth of 1/4 in. to 3/8 in. below the rail surface. The flow of metal toward the gate side extends back to the edge of the center arc and beyond, probably to the center of the rail head. The magnitude of deformation is positive evidence of shear stresses well beyond the yield point of the steel. This condition was demonstrated on the high rail of a 4-deg curve under moderately heavy freight traffic after 75,000,000 gross tons. This was at a location of moderate shelling on previous rail. Only light flaking had developed in the test rail at the time of removal.

TESTS OF ELECTRIC FLASH BUTT-WELDED RAILS

This paper describes rolling-load tests and physical tests of specimens of 131 and 130-lb electric flash butt-welded rails which were undertaken to determine if stress relief treatment would be necessary. The 131-lb. rail was set up for rolling-load tests of weld 73 in. in a 33-in. stroke rolling-load machine. The second rolling-load test was made on weld 52 in the 131-lb. rail, which was supplied with all the flash metal ground off except under the rail base. 1. The first two-rolling load tests that failed at a bolt hole and stress raiser on the rail webs emphasize the damaging effects of such conditions. 2. The rolling-load tests which ran over 2,000,000 cycles with 60,000-lb. wheel load without failure, are considered very satisfactory for welded rails. 3. The bend tests of 132-lb rails gave higher tests than unwelded 131-lb. rails, and as high as any previously tested rail welds. 4. Some of the physical tests indicate that the welds which were not stress relieved were slightly stronger than the stress relieved welds. However, the difference is negligible and no conclusions on this subject should be based on tests of only two welds.

TRACK ANALYSIS

In the present paper an attempt has been made to create the physical based for an objective assessment of the quality of railway track. For this purpose, the damage occasioned by faults in the geometric position of the track has been reduced to the universally applicable notion of 'detrimental energy' which is, in its turn, based on the detrimental integral exclusively derived from the geometry of the track. The definition of these novel notions is made possible by classifying the faults as subcritical, critical or super-critical depending on the period length of the oscillations caused by them. This leads to a coherent evaluation system which is largely founded on physical facts, lends itself to automation by means of modern computers, and furnishes directly applicable data not only for short-term maintenance programmes (marking of danger spots) but also for long-term renewal programmes (quality assessment of entire sections of track). The necessary computing techniques are outlined in their logical set-up.

MEASUREMENT AND ANALYSIS OF WHEEL-RAIL FORCES

Described is a method used to continuously measure, record, and analyze the lateral and vertical forces between wheels and rails of several types of railroad freight cars under a variety of car and track conditions. The method, using analog-to-digital conversion and computerized data handling, has produced results relating to a multitude of car and track behavior subject areas. Especially important is the definition, development, and verification of performance "signatures" which are generated in a unique and characteristic manner by each car in negotiating a given curve. The finding of such "signatures" to be completely reproducible and yet sensitive enough to change with relatively minor track or car component variations, i.e., modifications, supports the belief that these techniques can be applied beyond pure experimental scopes into routine (a) trackside inspection of cars in passing trains; (b) mechanized track inspection; and (c) truck design evaluation.

This paper was presented at the ASME Winter Annual Meeting, November 28-December 2, 1971. The notification of this paper appeared in Mechanical Engineering.

A RAIL REVIEWAL PROBLEM

Two alternative solutions are proposed for an unexpected rail trouble: laying a new track or reducing speed and intensifying inspection over the present one. The problem must be solved quickly because of material and service ordering. Cash inflows and outflows are analyzed and compared; and the figures favor a new rail. Next, a negotiating process takes place between financing people and engineering and operating people. The new rail is agreed upon and the decision is executed immediately.

MAINTENANCE OF WAY AND THE INFORMATION EXPLOSION
Maintenance of way activities have traditionally been subjected to budget restrictions, in part because it has been difficult to document and quantify the real cost of deferred track maintenance. Southern is using the computer to produce studies and reports on maintenance of way programs. The key elements are a group of data bases or master files containing essential information. Probably the most important is the Track Characteristic Master. Southern's Research C r R-1 provides key information on track conditions. A second file contains all pertinent details on derailments. Correlation of the derailment file with the track characteristic master produced a sensitivity index of defect types as a predictor of derailments. Southern is completing a System-wide anchor and double spiking program with standards based on traffic density, degree of curvature, and grade. The best way to determine when rail should be relaid and when track should be retied and surfaced is by measuring rail and track condition. R-1 car findings cause adjustment in maintenance schedules. Southern is pursuing an equally aggressive role with respect to rail defects and rail failures. The most recent addition to the data bases is the bridge file. Track programs have been correlated for efficiency.

TECHNICAL STUDIES TO EVALUATE THE INFLUENCE OF OPERATIONAL FACTORS ON TRACK LOADING
This paper describes briefly theoretical and physical investigations which have recently been performed by Canadian National Railways. The objective of investigations has been to establish means of reducing the probability of train derailment. While the scope of the derailment study is indicated, two efforts have been singled out for more detailed description. The first effort was directed to determine through computer simulation and analysis programs the lateral loading on curved track which can result from longitudinal train action forces. The second effort to be reviewed was directed to determine, through field measurement, actual lateral tieplate loads on curved track imposed by various vehicle types.

MECHANIZED TRACK INSPECTION: WHERE IT IS TODAY, WHERE IS IT HEADING?
Technology is available for mechanizing track inspection, but traditional methods are waging a stubborn battle against the new techniques which have been accepted in varying degrees on some roads but rejected on others. However, a significant point is the fact that no railroad after having acquired a track recorder, ever abandoned the idea later. The C&O/B&O, the Southern, the Canadian National, the Chicago and North Western, the Louisville and Nashville have track inspection cars which are described in this article. At least two track-measuring cars of European origin are now commercially available, the Matisa (Tamper) Trackfax car and the latest, the Plasser EM-50 Track Recording Car which has been in operaton on the Union Pacific. The technology of track-measurement and data processing has been brought to a high level of sophistication in the track-recording cars developed for the Department of Transportation. Known as "Rail Research Track and Vehicle Response Measuring Cars", these are self-propelled cars designed for operation in electrified territory, but operated also on portions of a number of roads and in more or less regular use for track-measurement in the Northeast Corridor.

C1 046362
DETECTING THE PROPAGATION OF KIDNEY-SHAPED FATIGUE FLAWS IN RAIL HEADS ON THE LINES OF THE HUNGARIAN STATE RAILWAYS
The author discusses the cause and propagation of kidney-shaped fatigue flaws in the rail head as well as the measures designed to prevent fractures. The main purpose is the description of the functional relationship between the propagation of the fatigue flaw and the traffic load. The formation of flakes in the rail material, the hardness of the rail head and the notch effect set up in the rail head by internal flaws are discussed. It is found that the propagation of the flaws is jointly caused by a number of processes such as microinclusions, oscillatory movements of dislocations, high stresses in the rail head, etc. The positions of the initial centres have been investigated by examining and measuring several fractures. Methods for calculating the height of the fissure and its inclination towards the vertical are developed. An analysis is made of the development of fatigue flaws as a function of the traffic load, and the existing relationship is established by an equation. In determining the effective cross-sectional area of the rail, the wear of the rail is also taken into account and added to the area of the fatigue flaw. After an analysis of the permissible threshold values, certain specifications are suggested, and the size of the flaw area in percent of the total cross-sectional area of the rail head is indicated with the aid of nomographs. In addition to the manual examinations, the introduction of ultrasonic high-speed testing vehicles is urgently recommended. In modern railway operation, ultrasonic testing is the most suitable method of detecting dangerous flaws; but the influence of human subjectivity in evaluating the results must be eliminated by using modern computers.

DYNAMIC BEHAVIOR OF SHIN-KANSEN SLAB TRACK--TESTING RESULTS OF 951 MODEL TEST CAR
Slab track has been carried on research since 1965 by the Railway Technical Research Institute, JNR. This slab track is laid for test in many places and to be fully used for the future Shinkansen, Okayama-Hakata, Tokyo-Mori-oka and other railway tracks. This present report shows test results of dynamic behavior of Shinkansen slab track under high speed, max. 260 km/h. The test results confirmed that slab track has sufficient efficiency and is also safe.

C & NW IS NOW ABLE TO TELL MORE ABOUT TRACK AND CAR RIDE
The Chicago & North Western and Gulton Industries have jointly developed an electronic system called a Dynamic Track Analyzer. The system measures track deviations in cross level and alignment and then relates their combined effect upon the car's rock and roll action. It consists of rate gyroscopes to give measurements, a solid state analog computer along with a digital computer and a data processor to analyze the information, plus a printer to record all the pertinent data. The dynamic Track Analyzer has a pick-up device that is mounted on one of the axles of the car's rear truck. It includes two gyroscopes, one sensitive to the roll axis and the other to the turn axis. Tranducers convert the gyro measurements to signals. The analyzer system's speedometer pick-up is mounted on a different axle of the same truck and on the same side as the transducer housing. Another gyroscope within the computer cabinet measures spirals and curbes. The track geometry defects that are detected are divided into three classes; minimums, subcritical defects, and critical defects. The analyzer has proved to be an invaluable aid in picking out track areas that may be conductive to rock and roll derailments of a covered hopper car.

TECHNICAL STUDIES TO EVALUATE THE INFLUENCE OF OPERATIONAL FACTORS ON TRACK LOADING
This paper describes briefly theoretical and physical investigations which have recently been performed by Canadian National Railways. The objective of investigations has been to establish means of reducing the probability of train derailment. While the scope of the derailment study is indicated, two efforts have been singled out for more detailed description. The first effort was directed to determine through computer simulation and analysis programs the lateral loading on curved track which can result from longitudinal train action forces. The second effort to be reviewed was directed to determine, through field measurement, actual lateral tieplate loads on curved track imposed by various vehicle types.

EFFECT OF FLAT WHEELS ON TRACK AND EQUIPMENT
Although old, this work is generally considered to be an excellent reference on this subject. The report describes the Test Apparatus and the Tests, presents the results of the tests, and presents some conclusions from the tests. The conclusions cover the effect of train speed, the effect of flat spot length, the effect of wheel load, and the impact force of a flat spot; and recommend guidelines for removing wheels from service and for running cars with flat wheels to terminals for service.

C & NW PINPOINTS ITS DERAILMENT PROBLEMS
Chicago & North Western is taking an electronic approach to the prevention of derailments by determining the precise locations where track conditions are conducive to rock-and-roll wheel uplift. The system measures track deviations in cross level and alignment and relates their combined effect in producing rock-and-roll action that will cause a car's wheels to lift from the rail at a critical speed. Pick-up device includes two gyroscopes, one sensitive to the roll axis of the axle and the other to the turn axis. Both are in fixed position with respect to the axle.

A TRACK CURVATURE MEASURING SYSTEM AND ITS APPLICATION
A track curvature measuring system has been designed and installed in the Department of Transportation's rail test car by ENSCO, Inc. The system employs an inertial rate-of-turn gyroscope to measure the yaw rate of the car, an axle-driven tachometer to measure speed, and velocity transducers to measure the relative motions between the car and the trucks. An analog circuit receives these inputs and performs the curvature computation. The system is capable of making continuous curvature measurement at any speed greater than 3 mph at either direction of travel. The system performance and various applications of the data are demonstrated. Schemes for detecting undesirable superelevation and curvature mismatches are discussed.

C1 051536
APPLICATION OF GUIDEWAY ROUGHNESS POWER SPECTRAL DENSITY AS A MANAGEMENT TOOL
Ground surface vehicles such as trucks or railway cars can be considered as mechanical systems suspended on vibrating wheels. The source of vibrational energy is the roughness in the roadway or the guideway. A portion of the vibrational energy is transmitted through the vehicle suspension system and to the passengers or lading inside the vehicle. The magnitude of the transmitted energy and its frequency content depend on the roughness of the surface, the speed of the vehicle, and the mechanical characteristics of the suspension system. If the roads and guideways are categorized by the Power Spectral Density (PSD) of their surface roughness, the amount of vibrational energy can be predicted if the speed and the characteristics of the vehicle suspension system are known. Conversely, if a safe limit of the vibration has been established for a particular lading, management can render a cost effective decision on guideway maintenance, speed practices, and vehicle design from knowledge of the PSD characteristics of a proposed route.

JOINT BARS-DESIGN SPECIFICATIONS AND SERVICE TESTS INCLUDING INSULATED JOINTS AND COMPROMISE JOINTS
Various tests and application procedures of joints are discussed. Insulated joints, glued joints, web-contact joint bars, Huck fasteners, and joints with structural adhesives are studied in service tests, both in the laboratory and in field installations. The field installations are varied in location. Static stresses in rail and dynamic stresses in rail joint are studied in connection with field installations Huck fasteners. Among the conclusions are: 1)service tests of redesigned vulcabond insulated joints showed much chipping and flaking off; 2) Huck fasteners on polyurethane insulated joints were in satisfactory condition after two to twelve months installation; 3) Huck fasteners in standard head-free toeless angle bars would not satisfactorily restrain rail movement.

RESULTS OF ROLLING LOAD AND SLOW-BEND TESTS OF BUTT-WELDED RAIL JOINTS
Results of 13 rolling-load and 13 slow-bend tests of butt-welded rail joints are described. The butt welded rail joints are made by the thermit (Exomet and Orgotherm process), the electric-flash and the oxyacetylene pressure butt-welding processes, and are submitted for testing to evaluate the various welding methods. Rolling-load tests are made on either use 12 in. or the 33 in. stroke rolling-load machine; slow-bend tests are made on supports 4 ft. apart with a two-point loading 6 in. on each side of the weld. Results of rolling load tests indicate that with the thermit weld orgotherm process and the thermit weld type from Exomet, Inc. a rail broke, but otherwise no failures occurred in butt-welded rail joints. Results of slow-bend tests indicate that a rail broke in each test situation, but that there was good structure in Southern Railroad's Thermit Weld (Orgotherm) specimen.

C1 052287
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail are explored and methods for their prevention are presented. Heat-treated-rail and alloy rail service test installations are inspected on curves with shelly histories, and laboratory investigations of shelly rail involving rolling-load and slow-bend tests are also made. Service test installations on the Great Northern Railway of rails rolled from continuously cast blooms, fully heat-treated rails, Columbium-treated rail, and Curve-master rail, were inspected, and contour tracings of the rail inspected were made. Service test installations on curves are designed to study both resistance to wear and flow and resistance to shelling. Two methods presently employed in improving these properties are the addition of alloying elements and heat treating. The addition of certain alloying elements improves resistance to wear and flow but does not necessarily improve resistance to shelling. The use of other alloying elements may improve both of these properties. It is shown that rail if properly heat treated, will be improved in both of these properties. If improperly heat treated, the results are detrimental rather than beneficial.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail are determined, and methods for their prevention are discussed. Two phases of the investigation include the inspection of heat treated and alloy rail service test installations on curves with shelly histories and the laboratory investigations of shelly rail involving rolling-load and slow-bend tests. The usual service test inspections are made of the fully heat-treated and alloy rail installations to corroborate the observations of previous years. Investigations featured include the service test installation of induction-hardened rail on the Great Northern Railway and on the Norfolk and Western Railway and the test installation to compare high-carbon rail with blue-end rail on the Pennsylvania Railroad. New developments in induction and flame hardening of rails to increase their resistance to shelling are also reported.

RAIL SLIPPAGE TESTS-CONCRETE TIES
Tests are conducted to determine rail slippage for concrete ties, using the fastenings to check the slippage resistance anticipated in the design calculations. Test procedure is described and results are presented. It is noted that the values of rail slippage resistance for the AAR design clips for the Type E tie are generally more than the 2000 lb minimum for 5000 lb bolt tension, except those with vibration, which are only about 1000 lb. It is concluded that the measurements of rail slippage resistance obtained agrees reasonably well with those anticipated in the design of the fastening for the AAR Type E prestressed concrete tie. It is believed that a range of bolt tension between 10,000 and 5000 lb should be maintained with AAR clips until such time as service experience indicates that a change in these limits is warranted.

RAIL WEAR TESTS ON THE ST. LOUIS-SAN FRANCISCO RAILWAY
Two curves on the St. Louis-San Francisco Railway were selected for rail wear tests. The section having a slightly lower rate of wear in past service was not lubricated. The other curve had a "Meco" single rail lubrication using graphite grease at the far end of its two curves. The effectiveness of the lubrication was gaged by taking rail profiles at various intervals of time. These profiles show the amount of steel worn from the heads of the rail gage. Elevation and curvature of the high rail were measured at each point where a profile was taken. Seven sets of profiles were taken of the rails undergoing the tests. The profiles show significantly less wear on the curve with the track lubricator than on the curve with no lubrication. The effectiveness of molybdenum-disulphide was tested as a rail lubricant. Its application showed less wear rate. These service tests definitely show that track lubricators are effective and can double the life of the outer rail in the presence of heavy sanding.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL: METHODS FOR THEIR PREVENTION
This report is presented in two appendices. Appendix 8-a covers the inspection of service tests of fully heat-treated and alloy rail installations. There are five tests of fully heat-treated rail, three of high-silicon rail, one of chrome-vanadium, and one of columbium-treated rail. The heat treatment in some locations has shown considerable value in extending rail life under shelly conditions and in resisting head flow on the low side of curves. The high silicon and low-alloy rails show a resistance to wear and shelling. The chrome-vanadium rail shows excellent performance. Appendix 8-b covers 1) rolling-load tests to produce shelling in high-silicon chrome-vanadium rail, columbium-treated rails, basic-oxygen standard carbon rails and flame-hardened rails; and 2) end-quench hardenability curves determining the quenching characteristics of some of the low-alloy rail steels. High-silicon chrome-vanadium rails rated high in rolling-load tests. End-quench hardenability curves are given for four rail steels to furnish information on the quenching characteristics of low-alloy rail steels.

C1 052333
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
This informational progress report is contained in two appendices. Appendix 8-a covers inspections of service tests of heat-treated and alloy-rail installations at 11 locations. There were five tests of heat-treated rail, three of high-silicon rail, and three of chrome-vanadium alloy rail. Heat-treated rail continues to show decided increased life over standard rail. Use of heat-treated rail on the low side of curves has increased life of rail 5 to 8 times, and on high sides 1 1/2 to 4 times. High-silicon rails have shown greater resistance to the detrimental effects of heavy wheel loads on the low

side of curves than standard rails. Chrome-vanadium alloy rails show greater resistance to wear than standard rails. However, in this test the chrome-vanadium alloy steel of the composition used was unreliable. Appendix 8-b covers rolling-load tests to produce shelling in 136-lb high-silicon vanadium rails, failed shelly rails from service, and rolling-load tests to produce detail fractures from shelling. Results of tests of 115-lb columbian rail and tests of 133-lb rail single flame hardened by the Union Pacific Railroad are also reported.

C1 052352
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Most of the information in this report on causes of shelly spots and head checks in rail is contained in the two appendices. Appendix 8a covers inspections of service test of heat-treated and alloy steel rail installations at five locations. There are three tests of heat-treated rail and two of high-silicon rail. Heat-treated rail in tests on the Norfolk & Western Railway continues to show increased life over standard rail. High-silicon have shown greater resistance to the detrimental effects of heavy wheel loads in the low side of curves than standard rails. Appendix 8b contains studies done at the University of Illinois. Three rolling-load tests to produce shelling in high-silicon rails, standard carbon-steel rails and 50-kg rails induction hardened in Japan are presented and discussed. Two rolling-load tests on a high-silicon rail ran 1,944,400 and 1,480,000 cycles. A standard-carbon-steel rail gave unusually long tests of 4,347,000 and 4,371,000 cycles. These specimens deformed considerably before the shelling cracks were visible on the side of the headrail. Two induction-hardened 50-kg rails from Japan gave rolling-load tests of 577,400 and 718,300 cycles.

C1 052398
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS OF THEIR PREVENTION
Causes of shelly spots and head checks in rail are discussed, and methods for their prevention are recommended. Research conducted by the research staff of the Engineering Division of AAR and by the University of Illinois is reported. Inspections of service tests of heat-treated and alloy rail are made at nine locations, including five tests of heat-treated rail, two of chrome vanadium alloy, and two of high-silicon rail. The final report of heat-treated rails on the Norfolk & Western Railway reveals a very definite advantage of heat-treated rail over standard control-cooled rail, with rail life increased by 2 1/2 times in the case of shelling. Economic advantage of heat-treated rail involves a rail life 4 1/2 times that of standard rail. University of Illinois reports results of mechanical and rolling-load tests to produce shelling failure and details fractures and tests of six rails which developed detail fractures in service.

C1 052403
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL METHODS FOR THEIR PREVENTION
Continuing investigations confirmed that heat-treated or alloy rails were effective in extending the service interval before gage corner shelling occurs in track. A description and summary of eight test installations of heat-treated and alloy rails in areas of high shelling was presented. Appendix 8-a presented the progress of shelly rail studies. Rolling-load tests of high-silicon rails and one chrome-vanadium rail were performed. Shelly rail failures from service were examined and rolling-load tests to produce detail fractures in the laboratory were performed. Detail fractures from shelling in European rails were discussed. High-silicon rails gave rolling-load tests 50 to 100 percent better than standard carbon-steel rails before developing shelling failures. Three tests of a chrome-vanadium alloy rail gave two tests over 5,000,000 cycles and one test of 1,846,000 cycles. Rolling-load tests of high-silicon rails to develop detail fractures from shelling produce failures similar to those produced in track.

C1 052406
CURVE WEAR WITH DIESEL LOCOMOTIVES ON THE BESSEMER AND LAKE ERIE RAILROAD
A series of test runs were made to obtain definite information on the amount of rail curve wear produced by diesel locomotives relative to that produced by the remainder of the train. A second series of tests was made for the purpose of relating the effectiveness of flange oilers on the locomotive and rail lubricators in the track in controlling the amount of curve wear. Instrumentation consisted of a box to catch metal abraided by diesel units from the track and a motion picture camera to photograph the passing wheel flange on the high rail. The tests show that although the rate of rail and wheel wear with a diesel unit is greater than for a heavily loaded freight car, the greater amount of rail wear is due to the train rather than the diesel units. Rail and wheel flange wear on curved track can be practically eliminated by lubrication with either flange oilers on the diesel units or rail lubricators in track, or a combination of the two.

C1 052410
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Progress in the continuing study of the causes of shelly spots and head checks was reported. The performances of various installations of heat-treated and alloy-steel rail have been tabulated. Appendix 8-a presented rolling-load tests of heat-treated chrome-vanadium rail, high-silicon rails, and 140-lb. chrome-vanadium alloy rail. Examination of shelly rails from service and rolling-load tests to produce detail fractures in the laboratory were discussed. One specimen of chrome-vanadium rail, heat-treated to 490 Brinell hardness, ran 21 million cycles in a rolling-load test. Ten specimens of high-silicon rails averaged 2,307,000 cycles in rolling-load tests. Two specimens of 140-lb. chrome-vanadium alloy rail averaged 3,625,000 rolling-load cycles. Photographs of one shelling crack in a service rail indicate the crack started at a segregation streak in the rail. All rolling-load tests to produce shelling indicate that rails with higher hardness, with corresponding increase in mechanical strength, give longer laboratory rolling-load tests.

C1 052418
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Five service tests of rail are discussed. There are four of heat-treated rail and one of alloy rail. In the progressive study of shelly rail rolling-load tests of flame-hardened rails, high-silicon rails, and electric furnace steel rails were performed. Examination of shelly rails from service was performed. Rolling-load tests to produce detail fractures were done. The rolling-load tests indicate that stronger rail steel should give longer life before shelling develops in service. Study and testing on simulated rails indicated that plastic deformation is the major factor in shelly failure. Design changes and metallurgical changes to limit plastic deformation would improve rail life. Use of lower wheel loads, larger wheels and higher strength material is indicated. A photoelastic study of the stresses in a model of a railhead utilizing developments in three dimensional photoelasticity for a better understanding of rail shelling was presented. Plastic models of the prototype were thinly sliced and the data obtained were subjected to a field of polarized light. Processing the data was done by the shear difference method. Principal stresses and maximum shears were studied through loading tests. Principal stresses and maximum shears were found in the transverse section of the rail under the center of the wheel.

C1 052426
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
A summary of the performance of heat-treated rail at five installations is presented. Results of rolling-load tests for each installation was presented. The progress on shelly rail studies was presented. Rolling-load rests on heat-treated rail, three experimentally flame-hardened rails and commercially flame-hardened rails were performed. Rolling-load tests to develop detail fractures and stress relaxation tests were made. The tests of the experimentally flame-hardened rails did not compare favorably with tests of heat-treated or alloy rail. Progress in the studies of stress relaxation in rail steel and deformational behavior of rails is reported. Bending fatigue tests of rail steel specimens were run to investigate whether a subcritical thermal treatment might heal progressive fatigue damage. No beneficial effect was noted. The mechanisms involved in rolling-load failures were then studied by work with low-carbon steels sensitive to the Fry "strain-etch" technique and with silver chloride which has optical properties and metal-like mechanical behavior. More work will be done with these two materials.

C1 052434
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
A summary of the performance of five test installations of heat-treated rail was presented. Appendix 9-a presented the progress of shelly rail studies at the University of Illinois. Repeat cradle type rolling-load tests on two specimens of manganese chrome, vanadium alloy rail indicated that these rails may be several times as good as standard carbon steel rails. A test of 115-lb heat-treated standard carbon rail indicated that this type was as good as the manganese, chrome, vanadium alloy steel of the heat-treated standard carbon steel rails. An electron micrograph of nickel alloy steel showed detail in fine pearlite structure which was not revealed by a light microscope. Appendix 9-b presented a summary of progress on the investigation of stress relaxation in rail steel. The work was in two areas: 1) Relaxation of stresses in small bar specimens was studied as a function of time and temperature, and 2) rolling-load fatigue tests on small systems. Specimens cut from the top section of the rail were tested and results indicated possibly larger values of relaxation in percent of applied stress than for other specimens. Rolling-load fatigue tests produced failures that require further investigation of the effect of alleviation of damage by stress relaxing heat-treatment.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
A summary of the performance of heat-treated rail in two test installations was presented. Progress on shelly rail studies at the University of Illinois was presented in appendix 10-a. Rolling-load tests of heat-treated rails, flame-hardened rails, alloy rails and headfree rails were performed. Laboratory examination of detail fractures from shelling was performed. Design and construction of a new cradle-type rolling machine was discussed. A description of the technique used to produce electron micrographs at 35,000X magnification was given. Rolling load tests continued on 132-lb heat-treated rail revealed that yield strength was increased 65 percent, tensile strength 31 percent, elongation 18 percent, reduction of area 100 percent, and endurance limit 40 percent. Results of rolling-load tests on seven rails flame-hardened different amounts on the rail treads showed four specimens failed by head and web separation cracks, and three failed by shelling. Rolling-load and physical tests on two specimens of alloy rail steel showed that these rails have physical properties which compare closely with those of heat-treated rails. Examinations of seven detail fractures from shelling revealed that the shelling cracks started longitudinally in the steel and then turned into transverse detailed fractures.

C1 052447
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Progress on the continuous study of shelly spots and head checks in rail was presented. Heat-treated rail tests indicate that its use extended the life of a rail before gage corner shelling occured. Appendix 10-a described studies at the University of Illinois where examinations of shelly rails from service and laboratory tests to produce shelling were performed. It was observed that the black shelly spots developed by two processes. Two rolling-load test on an alloy rail were high. Examination of the failed specimen revealed non-metallic inclusions. Rolling-load tests on heat-treated rail specimens of standard chemical analysis compared with non-heat-treated companions revealed that heat-treated specimens gave 3 to 4 times the performance of the non-heat-treated specimens. Appendix 10-b presented a summary report on the examination of rails containing detail fractures found by detector cars. The purpose was to determine if the chemistry, mechanical properties, or structures of detail fracture rails varied from those of random rails. The average chemical analyses and mechanical properties of 44 rails having detail fractures and 26 random rails were so nearly the same that no distinction between the two groups was possible. The mechanical tests included hardness, tensile properties, and impact properties. Examination of deep etched structures and microstructures of detail fracture rails indicated that the steel used was of relatively good quality.

TEST RESULTS ON RELATION OF IMPACT TO SPEED
Test results on relation of impact to speed are reported to support the proposed Article 107 of the Rules for Rating Existing Iron and Steel Bridges. It is noted that a study of short span steel bridges 20 to 40 ft. long and deck plate girder spans 40 to 130 ft. long subjected to live loads with or without hammer blow indicates that the reduction of impact as a result of speed should occur at 40 mph or less, rather than synchronous speed or less as was proposed in 1947 for spans longer than 50 ft. The value of 40 mph was selected as the maximum practical speed where allowable reduction in impact might be permitted since rolling equipment without hammer blow has no synchronous speed. It is noted that some values of total impact on truss spans approximately 120-150 ft. long, subjected to equipment with hammer blow, receive more impact than is provided by Article 206 of the Specifications for Steel Railway Bridges. The character of the reduction equation for truss spans subjected to rolling equipment with hammer blow is consistent with the data.

C1 052460
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-MEASURES FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail are reported and measures for their prevention are recommended. Reports of four study groups are presented. It is noted that no definite relationships or trends exist in the relationship between chemistry and shelling, or curvature, elevations, speeds, and grades. It is found that transposing shelly high rails to the low rail, if done in time, is worthwhile. Rail slow-cold worked under traffic in nonshelling locations and relaid in shelling locations possesses very little, if any, greater resistance to shelling than ordinary rail. Studies of high carbon rail indicate that it will retard but not eliminate shelling and that it has a tendency to head check and this in turn causes gage corner flaking or minute shelling. A seven-year summary report of shelly rail investigation at the University of Illinois is presented. Also presented is a summary report on the examination of 300 shelled spots selected from the track of 11 major roads, indicating that the shelled spots were predominantly of surface origin.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL SURFACES-DEVELOP MEASURES FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail surfaces are investigated, and preventative measures are recommended. It is found that no definite relationship exists between chemistry and shelling, and no definite trend regarding curvature, elevations, speeds and grades. Transposing shelly high rails to the low rail, if done in time, is worthwhile. Rail slow-cold worked under traffic in non-shelling locations and relaid in shelling locations possesses little resistance to shelling compared to ordinary rail. It is also found that high carbon rail does not eliminate shelling but retards it more than ordinary carbon rail; however, the high carbon rail tends to head check and in turn cause gage corner flaking or minute shelling. Reports are submitted by the Norfolk & Western, Pennsylvania, Duluth, Missabe & Iron Range, and Chesapeake & Ohio Railroads.

INVESTIGATE CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL SURFACES FOR THE PURPOSE OF DEVELOPING MEASURES FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail surfaces are investigated, and preventative measures are presented. Topics discussed include mill chemistry records; curvature tabulation, elevation, speeds, and grades; effect of rail lubricators, transposing rails, slow cold rolling; field tests of special rails; experience of roads having these defects; radius of gage corners of rail, tread of wheels, radius between flange and tread of wheels; relationship between wear of rail and wheel; bearing pressure of wheel on rail; cant of rail; superelevation of rail on curves; examination of service rail failures caused by these defects; rolling-load tests to produce these effects under laboratory conditions; resistance of rail steel of various composition to the development of these defects under laboratory conditions; resistance of different heat treatments of rails to the development of these defects under laboratory conditions. Progress is made but no definite solution has been found.

INVESTIGATE CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL SURFACES FOR THE PURPOSE OF DEVELOPING MEASURES FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail surfaces are investigated to develop measures for their prevention. Topics discussed include study of rail steel compositions, heat treatments, wheel and rail contacts and pressures, mill practices, and consideration of larger diameter wheels or lighter loads on the wheels. It is cautioned that new chemistry or heat treatment may induce other types of defects or excessive expense. Study of shelling reveals no definite trend or definite conclusions. It is noted that the control cooled process will not prevent shelling. Rolling load machines and tests are discussed.

C1 052472
INVESTIGATE CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL SURFACES FOR THE PURPOSE OF DEVELOPING MEASURES FOR THEIR PREVENTION
The investigation into the causes of shelly spots and head checks in rail surfaces was presented. A definition and description of shelly spots, the most serious type of rail damage, was presented. The division of the work of this subcommittee was described. Appendix A presented the shelly rail studies conducted at the University of Illinois. Laboratory studies of failed shelly rails concluded that shelling appears to be the result of cold working of the rail steel by "line contact" with car wheels. The presence of imperfections accelerated the formation of cracks. Laboratory rolling-load tests to produce shelling were performed. Different rail steel compositions were studied through rolling-load tests. The Brinell hardness of the wheel path after rolling was measured. Full sections specimens of heat-treated carbon rail were tested under rolling-load. No conclusions were reached.

C1 052473
NINTH PROGRESS REPORT OF THE JOINT INVESTIGATION OF FISSURES IN RAILROAD RAILS
The information in this report of the joint investigation of fissures in rails was contained in five sections. Field tests for batter of end-hardened rails in service on the Chesapeake and Ohio Railway were performed. The summary of the batter values was tabulated. Rail ends with large cracks had approximately three times the batter of uncracked ends. Examination of end-hardened rails from the C and O test track in Carey, Ohio revealed that most damage, weeping cracks and flow of the metal over the ends and sideways, produced batter and drooping of the rail ends. Tests of mill cooling containers for rails were discussed. Examination of control-cooled and Brunorized rails which failed in service revealed that none of the control-cooled rails contained shatter cracks, but did have transverse fissures from blow holes and welded spots, horizontal split heads, detailed fractures from engine wheel burn, fatigue failures starting in the web, and detailed fractures from shelly spots. The Brunorized rails had developed transverse fissures from shatter cracks as nuclei. A comparison of drop and bend tests was summarized.

Conducted by the Engineering Experiment Station, University of Illinois in cooperation with the Association of American Railroads and the Rail Manufacturers' Technical Committee.

STATISTICAL CHARACTERIZATIONS OF RAILWAY TRACK BEHAVIOR

Absolute space curve data of railway track, representing the vertical and lateral perturbations of both running rails, was collected and analyzed. A variety of track is studied, including high speed versus yard, bolted versus continuous welded rail (CWR), and old versus new construction. Analytical techniques include Signal Averaging, Analysis of Variances, and Correlation analysis. As a result, it is concluded that railway track is characterized by a pure Markovian process, a periodic process, and a periodically modulated random process.

INERTIAL PROFILOMETER AS A RAIL SURFACE MEASURING INSTRUMENT

A pair of profilometers, modified from the original design of the Electro-Motive Division of General Motors, has been built and installed on the Department of Transportation rail test car by ENSCO, Inc. The inertial profilometer system is capable of accurately measuring variations in rail surfaces of both short wavelength (a few feet) and long wavelength (a few hundred feet). In addition to its application in vehicle-dynamic simulation, the measured inertial profile can be used as a data base for extracting mid-chord (or other types of relative profile measurement) at any selected chord length. Field and laboratory tests have been conducted to evaluate the performance of the profilometers. The laboratory tests consisted of shake table tests to measure the amplitude and phase response within the frequency range of interest. These results correspond closely to the theoretical frequency response. Extensive field tests were performed on tangent, spiral, and curved track. Both manual stringline and DOT mid-chord system measurements were made on the same sections of track. The results show good agreement between the profilometer data and the accurate stringline measurements.

IMPROVEMENTS OF MAINTENANCE CRITERIA COVERING THE RUNNING GEAR OF SHIN-KANSEN RAILCARS BY MEASURING THE TRANSVERSAL ACCELERATIONS OF THE BODY [SHIN-KANSEN DENSHA SOKO KANRI SHIRYO SEIDO UO KOJO NI KANSURU KENKYU]

Osaka engine shed officials measure, under 200 km/h on line conditions, the body accelerations of Shin-Kansen railcars each time the wheels are re-profiled (every 70,000 km). Following these measurements, an index is calculated in accordance with an empirical formula that is a linear combination of the acceleration occurrence frequencies classified by section (linear combination of the values of the acceleration distribution analysis). Bogie overhaul is scheduled in accordance with the value of this index. In applying this method, the JNR encountered difficulties due to the effect of 3 factors on transversal accelerations: the state of the track, the speed (the index is very sensitive to speed variations of only a few km/h), weather conditions (transversal stability is distinctly improved in rainy weather). The article describes how corrective laws were worked out to eliminate the effect of the first 2 factors. For the 3rd factor, it was decided to limit measurements to periods of wet weather. RAILROAD ACCIDENTS AND NONDESTRUCTIVE INSPECTION
Railroad accident data published annually by the Office of Safety in the Federal Railroad Administration are analyzed to indicate the most severe causes of railroad accidents. The severity is judged by viewing both the frequency of accidents and the dollar damage per accident. Most of the components or conditions in the groups found to be severe accident causes are amenable to non-destructive inspection. An analysis shows the maximum benefits of an extensive non-destructive inspection program to appear in the wheel and axle category followed in order by track geometric and dynamic conditions and rails and joints. A review is provided for non-destructive inspection methods in current railroad use and potentially useful for the future.

SUMMARY OF HEAT-TREATED AND ALLOY RAIL SERVICE TEST INSTALLATIONS ON CURVES WITH SHELLY HISTORIES--1972
The AAR, in its program of Rail Research, has a project of field inspection and analysis of those rails that continue in service which show some potential for improvement in performance. The field inspections are carried out as a cooperative effort of the American Railway Engineering Association (AREA) Rail Committee, the American Iron and Steel Institute (AISI), and the AAR Research and Test Department. This report is a summary of results of the August and September 1972 inspections of seven field test installations of High-Silicon, Curvemaster, Fully Heat-Treated and Columbium Treated Rails.
An RPI-AAR Cooperative Project.

TRAIN HANDLING AND OVERTURNED RAIL
The Canadian Pacific Railway recently used the EMD's dynamometer car to explore the problem of harmonic roll and over-turned rail. The problem is particularly bad in the Rockies. The tests indicated several methods by which train handling procedures could be improved to reduce the chance of a derailment.

NW EMPHASIZES STRONG TRACK, WELL MAINTAINED
Norfolk & Western is committed to a policy of having strong track handled by a well-equipped maintenance organization which is adequately supplied with replacement materials. This article discusses various facets of the road's track programs and the maintenance groups which do the work. There has been great emphasis on mechanization. One result is a maintenance expense per thousand gross ton miles which is among the lowest in the U.S.

COMPUTERIZED SUPERVISION OF TRACK MAINTENANCE
Japanese National Railways has computerized the planning of the maintenance of its 26,000 km of main lines, 13,000 km of sidings, and 70,000 switches. JNR has programmed the replacement of 2,000 km of rail yearly. For each individual turnout, data is stored on the parts involved, on the results of annual inspections, and on the speed and volume of movements. Initially tie condition has involved the almost 38 million wood ties on JNR but the growing number of prestressed concrete ties are to be included in the future. Seven high-speed track inspection cars are being fitted to provide input for a maintenance planning system. While problems remain, computerization of maintenance equipment control, track improvement planning and track work estimates are being made.

TRACK GEOMETRY MEASUREMENTS AND DATA PROCESSING DEVELOPMENTS IN THE RAIL RESEARCH PROGRAM
This report summarizes the FRA-sponsored Rail Research Program, and outlines many of the problems presently encountered by the railroad industry in providing safe, high-speed transportation; and illustrates the vital role of cost-effective maintenance planning. This report was originally presented at the IEEE/ASME Joint Railroad Conference in St. Louis, Missouri, in April 1973. The FRA Test Cars are described, with emphasis placed on the ability of the cars to measure all parameters of track geometry at high speed. Examples are included of the various types of computer-generated reports which are designed specifically for personnel who are responsible for maintenance planning and operations. The information in this report is intended for use by a general audience who desires a comprehensive nontechnical summary of the operation and application of the FRA Test Cars, related instrumentation and data processing operations.
This project is sponsored by the Federal Railroad Administration, Department of Transportation.

DEVELOPMENT OF AN INERTIAL PROFILOMETER
The information in this report covers the design, fabrication and testing of an inertial profilometer system, developed for use on the FRA Test Cars. The profilometer is used to measure rail profile at high speeds, relative to an inertial reference. Design details and analysis of the profilometer are covered, and comparisons are made between profilometer measurements, mid-chord measurements, and manual measurements made with stringline and roll-ordinator devices, to show the relative accuracy of the profilometer measurements. The inertial profilometer offers several advantages over the currently-used mid-chord syystem. Accuracy of the profilometer has proven to be quite good. Operation of the profilometer is not degraded by inclement weather, and system components are not subject to damage by protruding objects in close proximity to the rail being measured.

ACQUISITION AND USE OF TRACK GEOMETRY DATA IN MAINTENANCE-OF-WAY PLANNING
The report describes data acquisition by the FRA Measurement Cars and subsequent use of the collected track geometry data by the Bessemer and Lake Erie (B and LE) and the Denver and Rio Grande Western (D and RGW) Railroads. These two railroads, in conjunction with ENSCO, Inc., have prepared the report for the Federal Railroad Administration. The major emphasis of the report is placed on use of the track geometry data by B and LE and D and RGW for immediate maintenance and maintenance planning. Also provided are descriptions of data processing reports, system and measurement repeatability data, and the Track Geometry Measurement System onboard the FRA Measurement Cars.

The information herein is intended for use by maintenance- of-way personnel who are concerned with the utilization of track geometry data collected by track measurement cars and by management personnel who are involved in maintenance planning. This report was sponsored by the Federal Railroad Administration.

A NON-DESTRUCTIVE METHOD OF MEASURING INTERNAL RAIL FORCE
Stability of continuously welded rail (cwr) can be monitored by determining the longitudinal force that exists at all times in the rail. British Rail Scientists have developed a rail-force transducer which permits rapid simple accurate measurements to be made of stress changes unaccompanied by changes of length. Using the results, the stress-free temperature of the rail is easily calculated. Transducers are cylindrical in shape and are installed by gluing in holes of the standard fishbolt size drilled in the rail's neutral axis. Readings from the transducers are taken at any time by using a portable measuring instrument.

C1 095414
ANALYSIS OF TRACK PARAMETER HETEROGENEITY AS A COMPLEMENT TO GEOMETRICAL METHODS OF TRACK CONDITION RATING
The condition of a track may be defined by track rating indices (W indices at the PKP) taken from recordings by a track inspection car, or obtained by geometrical measurements (longitudinal dip and cross-sectional irregularities, without load or with a moving load, lateral displacement, etc.). By track heterogeneity, the writer means the differences that such indices reveal on lengths of line with identical make-up, similar age, and used by the same traffic. These heterogeneities, which may be caused by the laying or maintenance of the track, or by constructional features with different characteristics, are also likely to result in great differences in the rapidity with which these lengths of line deteriorate, necessitating earlier continuous track renewal. The article proposes methods of assessing these heterogeneities by tests based on classic statistics laws. Numerical examples thus deal with: heterogeneities in the W index, by the X to the 2nd power test; heterogeneities in the track gauge by a method called the "ZM test" taken from an American book referred to in the bibliography; correlations between rail dip and lateral displacement under a moving load, by an analysis of sequential correlation. These complex analyses are not used as a basis of routine maintenance decisions, but in investigations for the purpose of explaining abnormal phenomena.

SURVEYING AND CALCULATION OF CURVED TRACK, USING ANGLE CONFIGURATION CO-ORDINATES
The method described for surveying and calculation of curved track with the aid of angle configuration coordinates is not inferior to values calculated on the strength of normal coordinates and has the following advantages: Less mathematical effort compared with polar marking and surveyings; work can be carried out with instruments currently available (measuring tapes and theodolites); application of calculators with the well known angle- Configuration method. The formulas which apparently are complicated can be derived without major effort from the calculation sketch for each individual case.

FIELD INVESTIGATION OF LONGITUDINAL FORCES IN A SANTA FE RAILWAY CONCRETE TRESTLE

This report contains a description and analysis of data obtained on a 660 ft long concrete trestle. The trestle contains 20 spans of 33 ft prestressed concrete box beams on reinforced concrete caps and columns. The height, base of rail to ground line, was uniform throughout at 26 ft. The purpose of this investigation was to determine the effect on the trestle of braking and traction as developed by a 278 ft long test train. Direct and bending stresses were obtained in the bents and axial stresses obtained in the rails at each abutment. Runs were made with both tight and loosened rail joints. In addition to the braking and traction runs, normal speed runs were made to determine stresses in the box beams and columns. On the basis of tests on this structure it may be concluded that: 1) The maximum longitudinal bent force measured was from braking and was 23 percent of the force computed on the basis of 15 percent of the test train bent reaction. 2) With tight rail joints the percentage range of total longitudinal braking force resisted by the bents was 41 to 56 percent, by the rails was 20 to 46 percent and by the backwalls apparently was 5 to 30 percent. 3) That portion of the longitudinal braking force transmitted to the bents was resisted by all bents of the bridge, acting as cantilevers, including those which carried no vertical live load. The distribution of longitudinal force was not uniform throughout the length of the bridge, but was highest for bents under the test train and gradually decreased with increase in distance from the test train. Loosening the rail joints at the ends of the bridge increased the longitudinal force resisted by the bents. 4) The maximum longitudinal force resulting from braking was 158 kips, which was 12 percent of the weight of the train. 5) The maximum longitudinal force resulting from traction of the locomotives was 76 kips, which was 15 percent of the weight on drivers. 6) Bending stresses were lower than those resulting from longitudinal forces. Also, bending stresses due to eccentricity were highest near the tops of the bents, while the stresses due to longitudinal forces were highest near the ground line. 7) For the test span, the arrangement of transverse tie rods, and the shear keys used was effective in producing a very nearly uniform distribution of the live load to each of the box beams comprising the span. 8) For the test span, the ratio of recorded to calculated strains due to bending, ranged from 0.83 to 0.94.

ACOUSTIC EMISSION MONITORING OF SHOP AND FIELD WELDS OF RAIL

A short program was conducted utilizing state-of-the-art acoustic emission instrumentation to monitor both thermite cast welding and electric flash butt welding of rail. The primary objective of the program was to investigate the applicability of acoustic emission techniques for establishing the quality of the weld. Welds on continuous rail strings were monitored during electric flash butt welding, weld cool-down and weld anneal. The specimen welds were fabricated to represent a variety of good and poor conditions. Piped rail sections, for example, were joined to good rail and electrode burns were purposely made, as were good welds. The acoustic emission data, both location and number have been correlated with mechanical properties established by physical tests of the welds. Fractographs of the rail sections are shown. The acoustic emission data gathered during the weld anneal cycle shows a tentative relationship with the strength of the weld. A total of seven welds were monitored where acoustic emission data was obtained. Thermite cast welding, as used in the field joining of rail, was also monitored with the same acoustic emission instruments. Variations in the weld procedure were used to produce good and poor quality welds during this portion of the program. The acoustic emission data was obtained both during the pour and subsequent weld cool-down. A total of three welds were monitored. The instruments, techniques and test results present a clear description of the ease of performing acoustic emission monitoring. Due to the limited number of thermite welds monitored, the data by itself is inconclusive, however, analysis of the weld sections provides some rationale which tends to support the creditability of the technique. The data obtained during the electric flash butt welding shows a good to excellent possiblity of usefulness as a quality control monitor.

RAIL FAILURE SYSTEM

File name is ENRF. Computer program. The "Rail Failure" application is designed to compile statistics of all types of rail failures. The system employes two highly regimented input forms entitled "Rail Removal Order" and "Rail Insertion Report" which also serve to cause the appropriate physical action to take place. The system is modular and as such contains over twenty (20) separate programs re: data validity edits, maintenance and print routines which can provide monthly, year-to-date and yearly statistics, e.g.: (a) "Audigage and Reflectoscope; Detector Car; and Service Rail Failure Statement": a three part statement, i.e., a separate report for each potential input source, giving a complete description by Division and District of type of track, location of rail, position, grade, weight, mill, etc. of all failures reported. (b) "Rail Insertion Report Statement Covering Service and Detected Rail Removal Orders"; this statement lists all rail that has had a defect and that has been replaced by a new rail, angle bar repaired or taken out of service. (c) "Annual Report of Rail Failures, Service and

Detected, in Rail of All Ages and Sections". (d) "Rail Removal Orders not Covered by Insertion Reports on the Eastern, Western and Coast Lines". Report will flag any removal order over 30 days old for which as insertion report has not been issued. (e) The "Transverse Fissure Rail Heat Statement": This statement provides listing of all transverse fissure heat failures over the system. The statement is written out in mill order and year rolled plus pertinent detail data. (f) The "Thermite and Butt Welded Joint Failure Statement"; This statement lists all thermite and butt welded rail failures by division, district, mile post, type track, weight or rail, mill and year rolled. Each report is year to date.

RAIL AND TRACK CHARACTERISTICS PICKER PROGRAM
File name is Track Characteristics Master, Rail Defect Master, Derailment Master. Computer Program. The purpose of the rail and track characteristics picker program is to provide the information with which to develop the relationships between various rail and track characteristics and their correlation with rail failures, rail defects, and derailment frequency. The Track Characteristics Master contains rail type (jointed versus welded, kind of steel) weight, rail rolled and laid dates, history of surfacing dates, rail and track inspection and test data, grades, curves, load limits, and traffic density (tons per year) for all system track. Locations of rail failures, rail defects, and exceptions to track geometry standards found by testing and inspection are contained in the rail defect master. The derailment master contains pertinent data on all derailments. The rail and track characteristics picker program selects and prints out track locations from the track characteristics master with user-defined selection criteria; these can be minimums and/or maximum for any combination of the characteristics listed above. Up to 50 different combinations, i.e., cells in a matrix can be requested at one time. For each cell or specific request, the number of miles of track and the number of ton-miles is printed out. In addition for each cell, the progrm gives the types and numbers of rail defects and derailments reported over a time period selected by the user. Once relationships have been established, the program can be used for developing rail laying and timbering and surfacing programs, anchor and double spiking programs, problem area identification, budgeting, and other applications.

COMPUTERS GO "ON TRACK"
This is a report of an IBM seminar on computerized management of track maintenance. Discussions centered on the use of a data base in which the computer can sort, store, combine and compute information and run simulations of maintenance strategies. The experience of several railroads was reported, along with the use of computer studies of track problems confronting the United States Railroad Association in its restructuring of the Northeast railroads. It is noted that the computer input has frequently been gathered and compiled manually by railroads, but only the barest use of such information could be made. Computer technology is changing all this.

BLUEPRINT FOR TRACK REHABILITATION?
The Iowa Department of Transportation has been authorized by the legislature, concerned about track conditions in the state, to take several steps. A program of rehabilitation of branch lines has seen work started on ten segments involving expenditure of $8.7 million. Condition of all trackage in the state is to be monitored annually by a new track-measuring car. Development of a numerical "sufficiency rating" for all trackage in the state will rate ability of the lines to perform in accordance with accepted standards. Steps will be taken to assure sufficient supplies of materials and machines and enough manpower to meet any crash program of railroad rehabilitation which might be initiated at the federal level. So far state, local and railroad funding is involved.

PRINCIPLES AND CRITERIA FOR THE DESIGN OF A RAILROAD TRACK TEST FACILITY
This paper discusses principles and criteria for design of a track test facility such as will be built by the Federal Railroad Administration to support various track research programs aimed at improving design and maintenance procedures. It is suggested the facility be as versatile as possible so that tests can include determination of stresses in rails due to vertical and horizontal loads, study of axial rail forces induced by moving trains and track buckling caused by temperature stresses and moving trains. Construction of permanent structures such as concrete piers should be avoided whenever mechanically possible.

CLASSIFYING TRACK BY POWER SPECTRAL DENSITY
Historically, the Power Spectral Density (PSD) has been used as a diagnostic tool and as a classifier in many disciplines. This paper illustrates how this valuable tool can be applied to railway track geometry data to assist in the understanding and management of the permanent way. The PSD can be used to diagnose random and periodic behavior in the track surface (profile). Three parameters are developed that are capable of describing this behavior. Furthermore, the PSD can be used to classify the track. Two of these parameters have a strong impact on the deviations of a 19-m (62-ft) midchord offset. Within prescribed confidence limits, these can be tied to the Federal Railroad Administration's track safety standards. This permits the assignment of the speed class at which the track may be economically maintained without major overhauling.

This paper was presented at the Winter Annual Meeting of ASME, Houston, Texas, Nov 30-Dec 5, 1975 and is from ASME Mechanics of Transportation Systems, RRIS 02 128605.

AN INVESTIGATION OF FACTORS CONTRIBUTING TO WIDE GAGE ON TANGENT RAILROAD TRACK
Wide gage--a fatigue failure of the track to maintain the nominal lateral distance between rail heads--is one of several modes of track failure on which the AAR-FRA-RPI-TDA Track Train Dynamics Program has focused attention. To investigate the generation of wide gage on tangent track, experiments were conducted to measure track dynamic response and long-term fatigue life of track sections on the Union Pacific Railroad in Idaho. Results of these experiments have defined the important factors in this mode of track fatigue.

This paper was contributed by the Rail Transportation Division of the ASME for presentation at the Winter Annual Meeting, Houston, Texas, November 30-December 5, 1975.

CLOSE-UP OF SOUTHERN POLICIES AND PRACTICES
In a four-part feature, the Southern Railway policies in track maintenance are examined. Southern started early in mechanizing m/w operations and has achieved a high degree of efficiency in manpower use. It has always emphasized rail and tie renewals. In Part 1, The Strategy Behind the Progress, the development of a five-year plan, the acceptance of a high m/w ratio, and use of a track geometry car and rigid quality control are discussed. Part 2, Dual Method of Laying Highlights Rail Practices, tells how a 54-man gang lays eight welded rail strings in a day and discusses welding, heat-treated rail and hardening of frogs. Part 3, Top Efficiency Is Goal in T&S Operations, tells how highly mechanized system gangs are organized around machines, including those which remove ties for possible reuse. Part 4, Innovations Feature Prefabrication of Turnouts, Track Panels, tells how turnouts are produced for rail relay programs and new industrial tracks. Track panels are used in building sidings and industry tracks and for reconstructing tracks damaged during derailments.

A REVIEW OF MEASUREMENT TECHNIQUES, REQUIREMENTS, AND AVAILABLE DATA ON THE DYNAMIC COMPLIANCE OF RAILROAD TRACK
The need for increasing train speeds and operating safety while, reducing track maintenance is responsible for much of the current research on track structues, vehicle dynamics, and vehicle/track interaction. This report covers Phase I of a 3-phase program to design and fabricate equipment for measuring track dynamic characteristics. It is generally recognized that the available data and measurement techniques for obtaining this type of data for U.S. track and inadequate. This Phase I report includes a review of previous measurement techniques, a compilation of available data on track dynamic characteristics, an evaluation of data requirements, and the development of concepts for measuring track dynamic compolance.

This project was sponsored by the Federal Railroad Administration, DOT.

ARE FRA RAIL STANDARDS RESTRICTING RAIL-FLAW DETECTION
Since the FRA Track Safety Standards were implemented the number of defective rails has decreased, but the number of accidents due to rail failures has increased. The article tries to explain this discrepancy. A 10% increase in the availability of test equipment has resulted in only 6% increase in test mileage. In fact, Railway Companies lack the means of applying regulations concerning defective rails and this could lead them, in some cases, to put off inspection. Moreover, there is no flexibility in existing standards in so far as the priority removal of potentially hazardous defects known to be in the rail is concerned. The article discusses the need to tighten regulations or make them more flexible.

USE OF THE MAGNETIC ANISTROPIC METHOD TO ASSESS THE STRESSES OF TEMPERED RAILS [O vozmoznosti ispolzovanija metoda magnitnoj anizotropii dlja ocenki ostatocnogo naprjazennogo sostojanija zakalennyh relsov]
The most practical method of determining residual stresses without damaging the rail is by magnetic anisotropy which makes it possible to obtain information rapidly and without difficulty. A special device called "Pion" was built in the Soviet Union for application of this method. It is made up of a magnetic core in the form of a cross with a coil which generates a magnetic field in the centre and measurement coils (2 to 5) on the sides making up the arm of the bridge. The article gives the results of tests on certain types of rail in the Soviet Union using this device. [Russian]

DOT TEST TRAIN PROGRAM SYSTEM INSTRUMENTATION MANUAL-SIXTH EDITION
This manual describes track measuring instrumentation which has been developed during the report period and covers all instrumentation currently installed aboard the FRA test cars. The major emphasis of this report deals with the operation and calibration of the track geometry measurement system installed aboard test car T-3. Ancillary systems as well as equipment aboard test cars T-1, T-2, and T-4 are also summarized. New track measurement subsystems such as the alignometer, compensated accelerometer, grade, and magnetic gage systems are described briefly in this report. These systems are scheduled for prototype testing on the FRA test cars during the coming year, and will be fully documented in subsequent reports.

THE ROLE OF PULSE-ECHO ULTRASONIC TESTING IN THE MODERN RAILWAY CIVIL ENGINEERING ORGANISATION
Since the Hither Green disaster of 1967 there has occurred on the Chief Civil Engineers Department a drastic re-organization of the methods by which defects in rail are detected. Prior to 1967 the method of flaw detection used was the 'AUDIGAGE', which although a form of ultrasonic testing was without doubt a very inefficient method measured in modern terms. The methods used since 1967 are those which employ the 'PULSE-ECHO' method of ultrasonic testing and which are highly suited to the problem of rail defect detection in a modern railway system. The article was written with a view to bringing to the notice of the Permanent Way Sections of the Chief Civil Engineer's Department the impact that the introduction of 'Pulse-Echo' ultrasonic testing has had to date. The content was deliberately kept non-technical in order that the people concerned would not get 'Bogged down' with technical jargon, but to be informed as to what is going on and why.

EFFECT OF HEAVY AXLE LOADS ON RAIL AND TIES
The Quebec North Shore and Labrador Railway was built in 1953 to handle iron ore from mines 350 miles north of the St. Lawrence River. Trains of up to 280 cars with five locomotive units are operated. This presentation reports the maintenance experience on track which carries up to 50 million net tons annually, and has handled almost 700 million gross tons since opening. Among the findings: line, surface and gauge must be maintained even on tangent track; corrugated rail develops quickly on grades and curves and must be countered promptly; joint bars must be kept tight and rail ends restored; oilers are all-important on curves.

INTEGRAL TYPE MEASURING EQUIPMENT FOR SUPERELEVATION
In measuring superelevation with track inspection car a gyrostabilizer is generally used. The gyrostabilizer is considerably expensive and needs electric power source. So, for a simple mechanical type track inspection car, it is difficult to mount a measuring equipment for superelevation using a gyrostabilizer. A new mechanical integral type measuring equipment which enables measuring the superelevation from twist of track has been made. The equipment needs no source of electric power. The frequency characteristics of the equipment is fairy good for ordinary superelevation, the accuray of mechanical parts being about 10 percent.

C2 033421
DATA HANDLING OF HIGH-SPEED TRACK INSPECTION CAR

Measurement records made from the high-speed track inspection car are for two purposes, one of them is to defect and locate large track irregularities for preparation of the data necessary for spot maintenance. The other purpose is to give an overall information on the track irregularities found within a certain distance, as this helps service and maintenance planning. For the second purpose, however, records must be sorted, classified and processed statistically. The machine operation shows more stability than that of manual work and this is because the machine has no personal error. The machine has been employed officially since April 1961 and the inspection data over 40,000 km throughout Japan has been already handled. Therefore savings of man-power, cost and time to date have been very large.

MECHANIZED MAINTENANCE OF TRACK ON THE JNR

The Japanese National Railways are making continuous efforts to mechanize track maintenance work in line with the policy towards general modernization of operation. Emphasis is laid on the wider employment of small-sized equipment which will allow a train to pass or which can easily be taken out of the track when a train is coming. So-called overall track renewal using heavy equipment is carried out where an interval of 3 or 4 hours is available between midnight and 4 o'clock in the morning as in the case of the electric multiple unit train lines in and around Tokyo and Osaka. This method is also used on some trunk lines, such as the Tokaido Line in cases where sufficient work time is available by blocking one side of the double track. Outlined are the principal kinds of maintenance work in which such equipment is used, and the measuring devices.

TRACK TEST EQUIPMENT FOR EVALUATION OF ROAD BED IRREGULARITIES

The Norfolk and Western Railway Company has been investigating various methods of evaluation of track irregularities. The R-S Three Way Ride Recorder records accelerations in 2 or 3 directions as required, such as vertical and lateral accelerations, whereby riding qualities of cars may be compared to evaluate the track structure. The Tracon system for track analysis is an electronic track inspection system which measures and digitalizes the dynamic cross level variations of a track structure. There are three possible multiples of cross level variations that may be measured. This system can be applied to any car and is designed to operate at any speed above 35 mph. In addition, consideration has also been given to a

computerized method road bed evaluation through measurements and simulation of "rock and roll" of a car. This problem is continuing under study.

ULTRASONIC CAR WORKS AT 25 MPH
British Rail's detector car uses ultrasonic methods to detect and record hidden rail flaws while running at speeds up to 25 mph. The train can test up to 100 miles a shift--means that entire main routes can be ultrasonically tested in a matter of a few days. The train's rail scanning probes are carried on a trolley mounted between the running wheels of the equipment car. For scanning the rails the trolley is lowered to run on its own wheels, allowing the probes to slide along the surface of the running rails on a thin film of water. Using the principle of reflection of high frequency sound, the probes inspect the running rails for minute cracks and internal flaws Signals from the probes are relayed to monitoring devices on the train and then recorded on film. At the end of each day's testing, the film is sent to an evaluation center near Paddington station, London, where a team of evaluators examines it and reports any signals that indicate a possible rail deflect.

C2 037420
PURPOSES AND REQUIREMENTS OF TRACK INSPECTION AND MEASUREMENT
This is the first part of a two-part study prompted by recent interest in automated inspection devices and systems. This first portion, deals with the general questions about inspection such as why is track inspected, what is being looked for, when and how often inspection should be done rather than how it should be done. The first is as a fundamental guide to procedures and purposes of inspection, and for an examination of what may or may not be wrong about the way inspection is now being performed. The track materials inspection should include: the load bearing function of the track; the effects of loading on deformation and rupture and wear and abrasion, and on fatigue; and the environmental effects. The present inspection methods are given for rail, cross ties, switches, turnouts, crossings, and ballast.

DETECTION OF RAIL FAULTS ON SNCF
French National Railways methods of magnetic examination of rails in service are so successful that 95 percent of all rails lifted in 1967 for transverse cracks were as a result of inspections made on only one-sixth of the main lines. The development of transverse cracks in the rail head generally follow an exponential law related to the traffic carried. A transverse crack increases by 10 percent of the section of the rail head and with an initial detection at 55 percent by the electromagnetic process, the risk of breakage is reached when about 15,000 tons have passed over the track.

RAIL DEFECT TESTING IN THE UNITED STATES
Over 130,000 miles of track are tested annually in USA by the Sperry fleet of 25 self-propelled test cars. A new and highly efficient ultrasonic detection system was developed which is capable of finding most cracks and flaws in the joint area. Details are reported. As part of its service Sperry Rail Service has compiled and published a comprehensive manual of rail defects, covering subjects from history and methods of rail manufacture to causes of rail defects and classifications of every known rail defect. This Rail Defect Manual is furnished free to any railway.

SELF-PROPELLED TRACK RECORDER
A track recording trolley, is being used by the civil engineering department, Eastern Region, for detecting and recording track irregularities. It is self-propelled, weighs some eight tons, and is powered by a 65-hp petrol engine. As the vehicle travels along the track a series of probes and wheel flanges in contact with the rail surfaces communicate any irregularities to the recording table by means of wire cables and mechanical linkage. Records obtained include gauge variation, superelevation, and alignment. Speeds during recording are up to 20 mph, but up to 50 mph can be attained when not recording. A crew of five is carried.

THE NEW C AND O TRACK INSPECTION CAR
The design of the new car allows accurate measurements to be made at all speeds through 100 mph. The overall system of the RI-2 includes means for measurement of such track characteristics as curvature, cross level or superelevation of rails, surface, and joint condition. These measurements are continuously recorded on tape along with landmarks and other notes indicating location, as well as speed of the car. The recording and control

facilities are compactly located near the center of the car. Facilities are provided for unobstructed visual observation of the railroad through an observation deck seating 31 persons. The car is placed as the last car in a train with the observation end towards the rear. At the other end of the car are kitchen, office, conference, sleeping and toilet facilities. Two men can operate all the measuring and recording facilities. The operation and facilities of the RI-2 are illustrated.

CROSS-SECTIONS BY PHOTOGRAMMETRY
When exceptional loads have to be conveyed by rail, measurements must be made along the route to determine by how much the normal loading gauge may be infringed. The Swiss Federal Railways has devised a method based on stereoscopic photography and has built a special measuring vehicle that houses the appropriate equipment. Stereo photographs coupled with a special viewing attachment permit the recording of continuous profiles as a cross-sectional diagram. The vehicle is equipped with a dark room to provide immediate on site inspection of exposures. An electric tractor is used to take the vehicle to site and also provides a 220V supply for the spotlight, heating, and charging of the car-lighting batteries. In transit speeds up to 56 mph are permitted. While operating, the speed is limited to 18 mph.

AUTOMATED TRACK INSPECTION INFORMATION AND ITS USE
The paper describes the type of track inspection information provided by the Department of Transportation test cars (railroad) and the way it is to be used. The D.O.T. track inspection car program and a computer program from which gage data is produced are discussed. The basic principle discussed apply to all track parameters. The concepts for data processing described and the resulting preferred formats for the presentation of track geometry data resulted from discussions with knowledgable people within the railroad industry. In particular track maintenance personnel were consulted regarding their preferred form for data presentation from the viewpoint of track maintenance. (Author)

TEST CAR PROGRAM SECOND PROGRESS REPORT
Developments such as a new signal conditioner for the gage sensors, a magnetic pulser for improved speed and distance measurement, and new sensor configurations were aimed at increasing the accuracy and reliability of track measurements. Improvements in overall system performance results from the development of special-purpose calibration devices, modifications to existing electronic circuitry, a more extensive use of selective filtering, and use of accelerometers which withstood the rough environment. Data processing techniques and displays were also modified to make better use of the data being collected and to present it in a convenient form for operating personnel. The design and development of an onboard digital data acquisition system is a distinct technological innovation with the ultimate purpose of improving the performance of the existing track geometry measurement system. Research during this period was conducted to provide data as input to other independent studies. These included data-collection runs to support the joint D.O.T./C&O-B&O RR Program, validation runs to verify the General Electric Pantograph-catenary simulation model and the Melpar rail car simulation model, track survey runs, ride quality studies, and Southern rail car roll oscillation studies.

RAIL FLAW DETECTION BY UNTRASONIC BEAM
The Audigage flaw detector, of Branson Instruments Inc. consists of a small-battery-operated ultrasonic frequency generator and receiver, carried in an 11-1/2-lb. pack on the operator's back, a crystal in a special holder on the end of a long handle, and a pair of headphones. The crystal is applied to the head of the rail and the presence of a crack indicated by a lowering of the continuous tone produced in the headphones by a perfect rail. In a cracked rail the wave is reflected by the flaw, and a change in tone--or loss of tone--is produced in the headphones. The nearer the crack to the head of the rail, the greater is the drop in frequency. The instrument has been in use by London Transport for about three weeks, during which time some 15 miles of rail have been inspected with it. Several minor defects which were not revealed by visual inspection were discovered in sections of rail covered by the fishplates.

MAUZIN TRACK INSPECTION CAR
This vehicle was designed to detect measure and record graphically all variations in true alignment, top and cross-level and curvature of the running rails under loaded conditions. The French National Railways have built three of these cars; two are in constant use in France and the third works regularly outside France. The equipment consists of a special eight-wheel bogie, situated midway between the normal running four-wheel bogies of the vehicle and sharing equally the weight of the vehicle. Thus a total of 16 wheels is available to form a reference plane and detect all vertical variation. Similarly, six disc-mounted feeler shoes which follow the contour of the running edge of the rail reveal any lateral displacement of the track. Vertical irregularities on each line of rails are detected by recording the difference between the height of one wheel and the average height of all eight wheels on that side of the vehicle. Alignment is determined from versines which are measured on each line of rails over a 10 m. chord by means of three disc-mounted feeler shoes bearing laterally against the rails. Gauge is measured by two disc feeler shoes bearing on opposite rails at two points on a line at right angles to the center line of the track. Variations are measured full scale.

PENNSYLVANIA RAILROAD CLEARANCE CAR
The Pennsylvania Railroad has introduced a specially designed car for the measurement of track clearnace. It is usually made up into a short train consisting of a locomotive, the clearance car, and a crew coach. The car has now been in service for three years. Aluminum rods, 3 ft. long, and steel tipped, project from the sides and roof of the car in the form of an arch. As the train moves slowly towards a structure to be measured the rods are brushed backwards by contact to conform to the contours of the structure. The rods, 126 in number, are each capable of giving readings to 1/8 in. Graphs show the profile and clearance of the structure measured. The clearance car can cover an average of 100 miles of track each day. The time taken for measurement is about five minutes for a bridge and 30 minutes for a tunnel a mile long.

RECENT EVOLUTION IN ON THE RAIL INSPECTION ON THE S.N.C.F.
Ultrasonic probing enables an operator, shifting a transductor over the surface of the railhead, to assess the extent of a crack. Rail inspection by ultrasonic apparatus employs two methods: vertical probing by a straight line transductor where the steel is subjected to a longitudinal beam of waves; and oblique probing by a transductor subjecting the steel to a refracted beam of transversal waves forming an angle of 65 degrees to 70 degrees with the vertical. The transversal fatigue cracks due to rail-head fatigue often causing railbreaks are detected by oblique probing. The present permissible speed at which the transductors are made to move along the rail is 12 km/h. The annual number of rail-breaks on the inspected lines which was about 1,100 has fallen to under 400, the majority of breaks being due to defects non-spottable by probing.

COMPUTERIZED DATA PROCESSING OF TRACK GEOMETRY RECORDING
The British Railways system of automatic assessment of the records produced by track-condition recording cars is described. The mechanical movements of the pens of the recording trolley are converted to electric pulses, which are measured on a floating datum in the case of the versines and twist. All measurement and evaluation is electronic and in no way impairs the production of the standard track-record graph. All the information on the print-out and the date of the recording are reproduced on a punched tape which is subsequently processed by a central computer to produce future work programmes for tamping and lining machines. This is done by extrapolating the trend of deterioration revealed by the fault c nts to predict the content and order of priority of future maintenance w k loads on the tracks.

DIGITAL PROCESSING OF TRACK GEOMETRY DATA FOR MAINTENANCE PLANNING
The concepts for data processing described in this paper and the resulting preferred formats for the presentation of track geometry data resulted from discussions with knowledgeable people within the railroad industry. Data on 450 miles of track geometry are recorded by the test cars in less than 8 hours. The analog chart data is then scrutinized and edited. Within 48 hours after the test run, the digital gage printout and the annotated charts are ready for review by the maintenance engineer. By use of digital computer processing, a vast amount of track data can be collected and reduced into meaningful form quickly and efficiently. The Gage Data Reduction Program is a tool actively providing maintenance engineers and key management personnel with information to direct the planning of maintenance-of-way activities. The crosslevel program, presently under development, will be providing information on another key track parameter.

HIGH-SPEED RESEARCH TRAIN INSTRUMENTATION
The material presented in this paper will describe the basic instrumentation packages currently used in high-speed rail research. The instrumentation for the test and research program was subdivided into four separate packages, viz., body suspension (or ride quality), catenary-pantograph, track geometry, and track and roadbed dynamics. The task was to provide the necessary instrumentation for measurements, tests, and studies into the behavior and dynamic performances of rail vehicles, catenary, and supporting track structures at speeds up to 160 mph. The program was to be composed of four distinct but interrelated parts: (1) instrumentation, (2) computer programming, (3) data collection, reduction and interpretation, and (4) analysis and simulation. This presentation is concerned primarily with instrumentation. As a result of this program track geometry can now be determined at speeds in excess of 150 mph. Cross level, gauge, profile, alignment, warp, and rate of change of gauge can be measured at high speeds by using non-contract sensors.

MEASUREMENT AND ANALYSIS OF WHEEL-RAIL FORCES
Described is a method used to continuously measure, record, and analyze the lateral and vertical forces between wheels and rails of several types of railroad freight cars under a variety of car and track conditions. The method, using analog-to-digital conversion and computerized data handling, has produced results relating to a multitude of car and track behavior subject areas. Especially important is the definition, development, and verification of performance "signatures" which are generated in a unique and characteristic manner by each car in negotiating a given curve. The finding of such "signatures" to be completely reproducible and yet sensitive enough to change with relatively minor track or car component variations, i.e., modifications, supports the belief that these techniques can be applied beyond pure experimental scopes into routine (a) trackside inspection of cars in passing trains; (b) mechanized track inspection; and (c) truck design evaluation.

This paper was presented at the ASME Winter Annual Meeting, November 28-December 2, 1971. The notification of this paper appeared in Mechanical Engineering.

AUTOMATED GAGE INSPECTION
The L&N Railroad has been inspecting track gage using a "high railer" outfitted with a mechanical feeler system. The high railer was able to inspect the track at moderate speeds and it carried a paint spray system to identify with colored stripes those portions of track that required maintenance attention. Because of the possible dynamic gage widening that could occur under a locomotive during certain train handling operations, the L&N Railroad suspected that the unloaded measurement provided by the high railer might not be indicative of the true dynamic gage. Therefore, the L&N undertook to outfit a locomotive with a measuring system which could measure gage in the vicinity of the wheels most likely to encounter dynamic gage widening. A non-contact gage measuring system was installed on an L&N locomotive by ENSCO, Inc. This system was very similar to the gage measuring system in use aboard the DOT test cars. The system employs capacitive proximity sensors. By mounting the sensors in the shadows of the wheel flanges, the sensors are well protected from damage and are in a location close to the very point of interest where dynamic widening is anticipated.

This paper was recommended by the IEEE Land Transportation Committee of the IEEE Industry Applications Society for presentation at the 1973 Joint ASME/IEEE Railroad Conference, St. Louis, Mo., April 11-12, 1973. The price is $1.35 for members.

AUTOMATIC RAILROAD TRACK INSPECTION
A technical survey of the automated stationary and mobile track test train systems to date is presented. The use and availability of sensors is also reviewed. A method of in-situ excitation in conjunction with a radio interrogation coupled to existing railway communication system is discussed. The automatic inspection system proposed here is limited to the track bed and the rails. The rails are tested for any fissures and flaws and not for the cross-over error and misalignment although these are invariably also caused by the settling of the track bed. The major features of this system are the real-time segment interrogation system and track sensors. The problem of selective random-spacing deployment to cover maximum optimum segment is also discussed. The need for the railroad industry to expand their efforts in the area of development of automatic track and track bed inspection is shown to be highly desirable as well as economical from an operational stand point.

This paper was recommended by the IEEE Land Transportation Committee of the IEEE Industry Applications Society for presentation at the 1973 Joint ASME/IEEE Railroad Conference, St. Louis, Mo., April 11-12, 1973. The price is $1.35 for members.

THE FRA TEST CARS--WHAT ARE THEY DESIGNED TO DO, HOW THEY ARE BEING USED, NEW CAPABILITIES IN THE OFFING
The Department of Transportation's Federal Railroad Administration is using automated Rail Research Track and Vehicle Response Measuring Cars for rapid and thorough track inspection and vehicle behavior evaluation. The DOT Track Geometry Measuring System on board the DOT Test Cars is one of the many innovations in progress or in the planning stage at FRA. Equipped with computers and electronic measuring devices, the test cars offer opportunity for on-site analysis of track conditions. At the request of the managements of several railroads scattered throughout the country, the cars have already been used extensively in a variety of track geometry and vehicle performance tests. The measuring system of car T2 is described along with a demonstration of a long-range program with the Bessemer and Lake Erie and Denver & Rio Grande Western and tests at the DOT High Speed Ground Test Center in Pueblo, Colorado.

This article was prepared exclusively for Railway Track and Structures by the Public Affairs Department of the Federal Railroad Administration.

MECHANIZED TRACK INSPECTION: WHERE IT IS TODAY, WHERE IS IT HEADING?
Technology is available for mechanizing track inspection, but traditional methods are waging a stubborn battle against the new techniques which have been accepted in varying degrees on some roads but rejected on others. However, a significant point is the fact that no railroad after having acquired a track recorder, ever abandoned the idea later. The C&O/B&O, the Southern, the Canadian National, the Chicago and North Western, the Louisville and Nashville have track inspection cars which are described in this article. At least two track-measuring cars of European origin are now commercially available, the Matisa (Tamper) Trackfax car and the latest, the Plasser EM-50 Track Recording Car which has been in operaton on the Union Pacific. The technology of track-measurement and data processing has been brought to a high level of sophistication in the track-recording cars developed for the Department of Transportation. Known as "Rail Research Track and Vehicle Response Measuring Cars", these are self-propelled cars designed for operation in electrified territory, but operated also on portions of a number of roads and in more or less regular use for track-measurement in the Northeast Corridor.

ELECTRONICALLY CONTROLLED MOTOR COACHES FOR WENGERNALPBAHN
A series of motor coaches equipped with electronic control systems, is described. The fully transistorized electronic control system cuts the grouping and notching contactors in or out according to signals from the master controller, operating on the digital principle. Using electronic equipment resulted in a considerable saving in space and weight. It has also eliminated wear and tear and reduced maintenance accordingly. As far as operation is concerned, the use of electronics is reflected in smooth starting and rapid acceleration. It simplifies the motorman's job of operating the train composition, allowing him to devote more attention to the line ahead.

AUTOMATIC PROCESSING OF RECORDINGS MADE BY THE CASTAN SOUNDING AND MEASURING APPARATUS [LE TRAITEMENT AUTOMATIQUE DES ENREGISTREMENTS DE L'APPAREIL PALPEUR-MESUREUR CASTAN]
The author recalls the problems involving gauge when train speeds are raised or special consignments are carried: calculation of the extreme distance between track centres, gauge problems resulting from obstructions (in particular structures, tunnels, overbridges); these problems, which were previously resolved manually, are now dealt with by computers. He explains in this article how the SNCF Calculating Centre processes automatically the data obtained on line by the Castan sounding and measuring apparatus used for determining the cross-section of tunnels and in track layout modification studies. Starting with a speed, a vehicle gauge and diagrams giving the outline of obstructions, the processing operations very quickly provide, for all sections perpendicular to the obstructions, in the form of figures and graphs, the clearance available between the wall and the vehicle, and subsequently the optimal positioning of the tracks. He concludes by giving some practical examples of application and referring to the possibilities opening in the future when a data bank is formed and information on fixed obstructions is stored in a data file. C & NW IS NOW ABLE TO TELL MORE ABOUT TRACK AND CAR RIDE
The Chicago & North Western and Gulton Industries have jointly developed an electronic system called a Dynamic Track Analyzer. The system measures track deviations in cross level and alignment and then relates their combined effect upon the car's rock and roll action. It consists of rate gyroscopes to give measurements, a solid state analog computer along with a digital computer and a data processor to analyze the information, plus a printer to record all the pertinent data. The dynamic Track Analyzer has a pick-up device that is mounted on one of the axles of the car's rear truck. It includes two gyroscopes, one sensitive to the roll axis and the other to the turn axis. Tranducers convert the gyro measurements to signals. The analyzer system's speedometer pick-up is mounted on a different axle of the same truck and on the same side as the transducer housing. Another gyroscope within the computer cabinet measures spirals and curbes. The track geometry defects that are detected are divided into three classes; minimums, subcritical defects, and critical defects. The analyzer has proved to be an invaluable aid in picking out track areas that may be conductive to rock and roll derailments of a covered hopper car.

RAILWAY TRACK MEASUREMENT USING LASER BEAM AS A REFERENCE LINE [SPARMATING MED LASERSTRALE SOM REFERENSLINJE]
At present a project aiming at improving calculation methods for studying interaction between track and traction bogies is being carried out by ASEA. For this project precise information on rail configuration is necessary. A method of measuring straight unloaded tracks is described in this article. The method uses a laser beam as a reference line approximately parallel to the rail. Along the rail is drawn a detector which can measure the distance between the laser beam and the centre of the light-sensitive detector surface. This makes it possible to determine the deviations of the rail from the straight line defined by the laser beam. [Swedish]

A TRACK CURVATURE MEASURING SYSTEM AND ITS APPLICATION
A track curvature measuring system has been designed and installed in the Department of Transportation's rail test car by ENSCO, Inc. The system employs an inertial rate-of-turn gyroscope to measure the yaw rate of the car, an axle-driven tachometer to measure speed, and velocity transducers to measure the relative motions between the car and the trucks. An analog circuit receives these inputs and performs the curvature computation. The system is capable of making continuous curvature measurement at any speed greater than 3 mph at either direction of travel. The system performance and various applications of the data are demonstrated. Schemes for detecting undesirable superelevation and curvature mismatches are discussed.

C2 051536
APPLICATION OF GUIDEWAY ROUGHNESS POWER SPECTRAL DENSITY AS A MANAGEMENT TOOL
Ground surface vehicles such as trucks or railway cars can be considered as mechanical systems suspended on vibrating wheels. The source of vibrational energy is the roughness in the roadway or the guideway. A portion of the vibrational energy is transmitted through the vehicle suspension system and to the passengers or lading inside the vehicle. The magnitude of the transmitted energy and its frequency content depend on the roughness of the surface, the speed of the vehicle, and the mechanical characteristics of the suspension system. If the roads and guideways are categorized by the Power Spectral Density (PSD) of their surface roughness, the amount of vibrational energy can be predicted if the speed and the characteristics of the vehicle suspension system are known. Conversely, if a safe limit of the vibration has been established for a particular lading, management can render a cost effective decision on guideway maintenance, speed practices, and vehicle design from knowledge of the PSD characteristics of a proposed route.

INTERACTION BETWEEN VEHICLES AND TRACK. POWER SPECTRAL DENSITY OF TRACK IRREGULARIES. PART 1-DEFINITIONS CONVENTIONS AND AVAILABLE DATA
The excitation of the track can be introduced into mathematical models in the form of "power spectral density of track irregularities" showing the relative importance of the various frequencies comprising the whole of the irregularities for a given section of track. A first stage for obtaining these spectra consists of recording the track irregularities by means of measuring vehicles, and a second stage consists of establishing these spectra by means of mathematical procedures (analogue and digital). The rules for the presentation of these spectra are laid-down and the spectra envelopes obtained by different Administrations are given. Numerous problems remain to be solved e.g. those relating to the stationarity of the records, to the influence of certain parameters (axle-load, measuring speed, wheel and rail profiles). For high speeds, it is also necessary to possess spectra in the low frequency field.

Restrictions on the use of this document are contained in the explanatory material.

INERTIAL PROFILOMETER AS A RAIL SURFACE MEASURING INSTRUMENT
A pair of profilometers, modified from the original design of the Electro-Motive Division of General Motors, has been built and installed on the Department of Transportation rail test car by ENSCO, Inc. The inertial profilometer system is capable of accurately measuring variations in rail surfaces of both short wavelength (a few feet) and long wavelength (a few hundred feet). In addition to its application in vehicle-dynamic simulation, the measured inertial profile can be used as a data base for extracting mid-chord (or other types of relative profile measurement) at any selected chord length. Field and laboratory tests have been conducted to evaluate the performance of the profilometers. The laboratory tests consisted of shake table tests to measure the amplitude and phase response within the frequency range of interest. These results correspond closely to the theoretical frequency response. Extensive field tests were performed on tangent, spiral, and curved track. Both manual stringline and DOT mid-chord system measurements were made on the same sections of track. The results show good agreement between the profilometer data and the accurate stringline measurements.

MODEL EMSE275 DYNAMIC TRACK ANALYZER
A Gulton Dynamic Track Analyzer is described. The Dynamic Track Analyzer performs three distinct functions. These are measurement of track dimensions, prediction of worst case roll amplitude of a selected type of car, and accumulation of a defect count (figure of merit) for each statute mile of track. All of these functions are performed in real time, giving immediate printed results. Train speed and distance traveled are measured and recorded. By operating the business car equipped with analyzer over a given stretch of track, it is possible to produce a chart showing the car roll for any desired type of car. A chart is attached showing the actual measured roll of a particular car over a section of track compared with the predicted roll determined from operating a business car equipped with the analyzer over the same track.

TRACK GEOMETRY MEASUREMENTS AND DATA PROCESSING DEVELOPMENTS IN THE RAIL RESEARCH PROGRAM
This report summarizes the FRA-sponsored Rail Research Program, and outlines many of the problems presently encountered by the railroad industry in providing safe, high-speed transportation; and illustrates the vital role of cost-effective maintenance planning. This report was originally presented at the IEEE/ASME Joint Railroad Conference in St. Louis, Missouri, in April 1973. The FRA Test Cars are described, with emphasis placed on the ability of the cars to measure all parameters of track geometry at high speed. Examples are included of the various types of computer-generated reports which are designed specifically for personnel who are responsible for maintenance planning and operations. The information in this report is intended for use by a general audience who desires a comprehensive nontechnical summary of the operation and application of the FRA Test Cars, related instrumentation and data processing operations.

This project is sponsored by the Federal Railroad Administration, Department of Transportation.

DEVELOPMENT OF AN INERTIAL PROFILOMETER
The information in this report covers the design, fabrication and testing of an inertial profilometer system, developed for use on the FRA Test Cars. The profilometer is used to measure rail profile at high speeds, relative to an inertial reference. Design details and analysis of the profilometer are covered, and comparisons are made between profilometer measurements, mid-chord measurements, and manual measurements made with stringline and roll-ordinator devices, to show the relative accuracy of the profilometer measurements. The inertial profilometer offers several advantages over the currently-used mid-chord syystem. Accuracy of the profilometer has proven to be quite good. Operation of the profilometer is not degraded by inclement weather, and system components are not subject to damage by protruding objects in close proximity to the rail being measured.

TRACK MEASUREMENT FOR TODAY'S RAILROAD SYSTEMS
This brochure describes the FRA Improved Track Inspection and Data Collection Technology Programs which utilize the Track Geometry Test Cars and Vehicle Dynamic Measurement Systems for the purpose of improving railroad safety, efficiency and economy. The data produced by the cars--through precise measurement of existing track structures--are used to plan effective track maintenance programs and to support the design of tomorrow's high-speed railroads.

ACQUISITION AND USE OF TRACK GEOMETRY DATA IN MAINTENANCE-OF-WAY PLANNING
The report describes data acquisition by the FRA Measurement Cars and subsequent use of the collected track geometry data by the Bessemer and Lake Erie (B and LE) and the Denver and Rio Grande Western (D and RGW) Railroads. These two railroads, in conjunction with ENSCO, Inc.,

have prepared the report for the Federal Railroad Administration. The major emphasis of the report is placed on use of the track geometry data by B and LE and D and RGW for immediate maintenance and maintenance planning. Also provided are descriptions of data processing reports, system and measurement repeatability data, and the Track Geometry Measurement System onboard the FRA Measurement Cars.

The information herein is intended for use by maintenance- of-way personnel who are concerned with the utilization of track geometry data collected by track measurement cars and by management personnel who are involved in maintenance planning. This report was sponsored by the Federal Railroad Administration.

C2 095414
ANALYSIS OF TRACK PARAMETER HETEROGENEITY AS A COMPLEMENT TO GEOMETRICAL METHODS OF TRACK CONDITION RATING
The condition of a track may be defined by track rating indices (W indices at the PKP) taken from recordings by a track inspection car, or obtained by geometrical measurements (longitudinal dip and cross-sectional irregularities, without load or with a moving load, lateral displacement, etc.). By track heterogeneity, the writer means the differences that such indices reveal on lengths of line with identical make-up, similar age, and used by the same traffic. These heterogeneities, which may be caused by the laying or maintenance of the track, or by constructional features with different characteristics, are also likely to result in great differences in the rapidity with which these lengths of line deteriorate, necessitating earlier continuous track renewal. The article proposes methods of assessing these heterogeneities by tests based on classic statistics laws. Numerical examples thus deal with: heterogeneities in the W index, by the X to the 2nd power test; heterogeneities in the track gauge by a method called the "ZM test" taken from an American book referred to in the bibliography; correlations between rail dip and lateral displacement under a moving load, by an analysis of sequential correlation. These complex analyses are not used as a basis of routine maintenance decisions, but in investigations for the purpose of explaining abnormal phenomena.

FRA TRACK GEOMETRY MEASUREMENT SYSTEM VALIDATION REPORT
This report covers an extensive testing program which was conducted to validate the track geometry measurement system installed aboard the Department of Transportation Rail Test Cars. The tests were conducted to establish the accuracy and repeatability of measurements made with the high-speed electronic measurement system installed aboard the DOT Test Cars. The validation procedure involved both laboratory and field tests of the electronic measurement system. Comparisons were made between manual and high-speed electronic measurements of rail gage, crosslevel, profile and alignment. Results of these comparisons under various dynamic conditions, speeds, types of rail and rail loads are included in this report. The information contained in this report includes considerable detail which is intended for use by engineering and research personnel who are involved in the design, development, and validation of rail measuring devices.

BLUEPRINT FOR TRACK REHABILITATION?
The Iowa Department of Transportation has been authorized by the legislature, concerned about track conditions in the state, to take several steps. A program of rehabilitation of branch lines has seen work started on ten segments involving expenditure of $8.7 million. Condition of all trackage

in the state is to be monitored annually by a new track-measuring car. Development of a numerical "sufficiency rating" for all trackage in the state will rate ability of the lines to perform in accordance with accepted standards. Steps will be taken to assure sufficient supplies of materials and machines and enough manpower to meet any crash program of railroad rehabilitation which might be initiated at the federal level. So far state, local and railroad funding is involved.

CLOSE-UP OF SOUTHERN POLICIES AND PRACTICES
In a four-part feature, the Southern Railway policies in track maintenance are examined. Southern started early in mechanizing m/w operations and has achieved a high degree of efficiency in manpower use. It has always emphasized rail and tie renewals. In Part 1, The Strategy Behind the Progress, the development of a five-year plan, the acceptance of a high m/w ratio, and use of a track geometry car and rigid quality control are discussed. Part 2, Dual Method of Laying Highlights Rail Practices, tells how a 54-man gang lays eight welded rail strings in a day and discusses welding, heat-treated rail and hardening of frogs. Part 3, Top Efficiency Is Goal in T&S Operations, tells how highly mechanized system gangs are organized around machines, including those which remove ties for possible reuse. Part 4, Innovations Feature Prefabrication of Turnouts, Track Panels, tells how turnouts are produced for rail relay programs and new industrial tracks. Track panels are used in building sidings and industry tracks and for reconstructing tracks damaged during derailments.

OVERALL EVALUATION OF TRACK CONDITIONS FOR THE PURPOSE OF PLANNING SYSTEMATIC MAINTENANCE [Syntetyczna ocena nawierzchni dla planowania napraw biezacych ciagtych]
It is necessary to know what the actual condition of track is to draw up overall track maintenance plans. The author describes a "synthesis" method for evaluating track conditions using an Amsler dynamometer car with Matisa measuring equipment. An index which is a synthesis of track characteristics and condition (Ws) is established on the basis of a statistical analysis of 5 parameters (levelling, gauge, track distortion, superelevation, and alignment). The analysis contains variations of Ws in relation to acceptable train speeds and lineload. The author concludes with a recommendation concerning the use of the Ws index for planning track maintenance operations. [Polish]

TEST TRAIN PROGRAM, SEVENTH PROGRESS REPORT
This report describes the progress of the Rail Engineering and Test Support Program during the period July 1, 1974 to June 30, 1975. Primary emphasis of the program was placed on the establishment of a viable operational track measurement capability. This emphasis resulted from efforts to meet the requirements of the National Track Inspection Program under implementation by the FRA's Office of Safety. Also covered in this report are special tests performed by the FRA test cars; operational improvements to the test car track measurement instrumentation; improvements in data-processing techniques that permit an analysis of track conditions in a more timely and more efficient manner; and highlights of other efforts performed under the Rail Engineering and Test Support Program.

NEW DEVELOPMENTS IN TRACK INSPECTION INSTRUMENTS
Instrumentation for a new automatic track inspection car is currently being built for the Federal Railroad Administration (FRA) by ENSCO, Inc. An existing rail safety research track measurement system, in operational service for several years, has successfully demonstrated that high-speed track geometry measurements can provide useful and timely inputs to FRA regional track inspectors. The new system will include the most advanced features of the instruments previously developed, expanded computer system hardware, and automatic rail flaw detection equipment. The new inspection system is being installed in an 85-foot rail car completely refurbished to accommodate the equipment and operating crew.

MODERN NON-DESTRUCTIVE METHODS FOR MATERIAL TESTING. CATALOGUE: APPLICATION OF THE TEST METHODS; RECOMMENDATIONS
The purpose of this report is to give an overall view of the results obtained so far and the development of non-destructive test methods by the railway Administrations. The Committee collected data on the application of non-destructive tests, of which the catalogue leaflets represent a concise summary. The leaflets of this catalogue refer to a selection of important components which are at present examined by non-destructive test methods on those Administrations included in the inquiry. The descriptions relate to components whose design, or behaviour in service, must be of immediate interest to all who already have experience of them and to those about to adopt similar designs. The sketches provoke thought not only in regard to service performance, but also to the necessity of repairing or of tolerating the presence of certain defects until such time as repairs can be carried out. Documentary report E 29/RP 1 is of considerable assistance for a sound understanding of the Catalogue. The report covers the detection of flaws in axle shafts, wheels, locomotive rod drives, plates, sheets and welded seams, diesel engine parts, and bearings by liquid penetrant, magnetic flux, ultrasonic, X-ray and gamma ray inspection.

Restrictions on the use of this document are contained in the explanatory material.

C3 039270
FLAW DETECTION IN MODEL RAILWAY WHEELS
The purpose of the report is to present the results of a theoretical and experimental study of acoustic pulses propagating within a model railway wheel. The ultimate goal is the development of a method, using either ultrasound or audible sound, for detecting flaws in wheels that are moving. Ultrasonic pulses have been produced on the tread of each model wheel and an experimental investigation has been made of the propagation in the plate and on the tread surface. Echos from artificial plate flaws are identified, and, using pulse-echo and attenuation techniques, thermal flaws on the tread have been located. Records of pulse arrivals are made by photographing the oscilloscope trace with a Polaroid camera. The behavior of these pulses is shown to be in accordance with the predicted propagation of Lamb waves in the plate region of the wheel, Morse waves in the rim and surface waves on the curved tread surface. Artificial plate flaws have also been detected by differences in the spectrum of audio sound radiated into the air by a wheel excited with a random noise input. (Author)

C3 039597
ULTRASONIC EQUIPMENT FOR METAL FLAW DETECTION

In all the principle locomotive and carriage works of British Railways and also in the Acton Works of the London Transport Executive, ultrasonic flaw detectors have become routine testing instruments. This convenient method of non-destructive testing is providing even higher standards of safety for surface and underground rail travel by the location of hidden flaws which cannot be detected by the X-ray method. The use of ultrasonic methods allows every section of the wheels and axles to be rapidly and thoroughly inspected without dismantling the bogies, the saving in time and trouble being thus considerable. Pipe porosity hair-line cracks, slag inclusions, blow holes, laminations, fatigue cracks, and welding flaws are among the many defects which can be detected by this equipment.

C3 039621
APPARATUS FOR DETECTING WHEEL-SEAT FLAWS IN RAILWAY AXLES

The Research Department of the London Midland and Scottish Railway Company undertook the task of devising and developing a method of detecting wheel-seat flaws in railway axles without removing wheels from axles or even wheel and axle assemblies from the coach. The essential item consists of a rigid steel ring of square cross section, split diametrically to allow it to be clamped to the axle under test. Contact with the axle occurs at three spherical seatings, of which two are fixed to the inside of the ring and the third is adjustable and is screwed to grip the axle firmly after the two halves of the ring have been bolted together. The system described comprises essentially, two nominally rigid reference planes, fixed normal to the axle and set one on each side of a possible flaw situated near the inner end of the wheel seat. If such a flaw does exist the strength of the axle will be less in the direction passing through the center of the axle and the centroid of the flaw than in the direction at right angles to it. Details and case histories are given.

HOT-BOX DETECTORS IN THE U.S.A.

The problem is now being solved by the installation of hot-box detectors situated at strategic points beside the track and susceptible to any overheated box on a train passing at speed; they report the occurrence automatically to a controller or other operating officer. There is one detector on each side of the line and if there is an overheated box on one side or the other it is picked up by the detector on that side. The heat signal imposed on the telephone lines is instantaneously transmitted from the detector to the control office. Two separate Harmon F.M. carrier channels are provided, one reporting from each detector. The respective frequencies are 40 kcs. and 55 kcs. Any abnormal temperature is indicated to the controller on a graph, and he arranges for the train to be stopped by a special signal five miles after it has passed the detectors and for a maintenance call-light to be switched on. The train crew answering the call is informed of the position on the train of the heated journal, and decides whether the vehicle involved must be cut off.

FIRST PROGRESS REPORT OF THE COMMITTEE ON HOT BOX ALARMS

The object of the tests was to determine whether a device exists or might be developed which can effectively warn the train crews of the danger of a hot box. As a result of tests it was determined that the sensitive element of the device must be located in the bearing or the journal itself. The alarm should be sounded at a bearing temperature of approximately 350 degrees F for plain bearings. No one type of sensitive element or means of transmission was found superior to the others.

MOBILE REFLECTOSCOPE INSPECTION OF RAILWAY CAR AXLES UNDER ROLLING EQUIPMENT ON THE CHESAPEAKE AND OHIO RAILWAY COMPANY

The Sperry Rail Service ultrasonic reflectoscope was tried to determine if this instrument could be used for fast inspection of caraxle journals for defects while they were still located in place in the rolling equipment. Having established that the reflectoscope was satisfactory for locating the faulty journals under freight cars, it was decided the best place to check these car journals would be the railway freight car repair yards. The King Midget automobile using an 8-1/2 hp driving engine, was modified to become the reflectoscope mobile carrier. This car is described and illustrated. A record is shown of 65 months of operation of the mobile reflectoscope units. A total of 363,821 freight cars have been checked. From this number of cars have been found 1002 cracked or defective journals.

COMMENTS OF SERVO CORPORATION WITH REGARD TO DEPARTMENT OF TRANSPORTATION HOT BOX DECTOR STANDARDS

The test train was equipped with thermocouples imbedded in the bearing and outer box surfaces. Elapsed running time, ambient temperature, bearing and box temperatures were recorded in addition to train speed. All Hot Box Detectors commercially available employ infrared techniques which scan the friction journal box housing, a portion of the frame above the journal box top surface, or a region of the wheel hub. These detection methods are adversely affected by the air steam cooling effect on the outer surface of the target. The thermal gradient and time delay factors in hot box detection on friction journal trucks are illustrated.

INVESTIGATION OF FREIGHT CAR JOURNAL BEARING AND JOURNAL BOX SURFACE TEMPERATURES IN CONNECTION WITH HOT BOX DETECTORS
Laboratory and field tests are described for the Servo Hot Box Detective Unit, which is a track side installation. Some of the conclusions follow. Box surface temperature decreases approximately 0.6 degrees F for each 1.0 degrees F decrease in ambient temperature while the bearing temperature remains constant. The bearing temperatures increase more rapidly than the related box surface temperatures. The box surface temperatures do not always indicate that certain conditions are causing rapid increases in bearing temperatures. Operating conditions, such as restricted speeds, stops, etc., prior to trains passing over hot box detectors decrease the possibility of true hot box conditions being detected. It was recommended that the Servos be adjusted for changes in seasonal ambient temperature. Also it is suggested that the relocation of the sensor be studied.

THE FUNDAMENTALS OF INFRARED HOT BOX DETECTION
Existing data on railroad car plain bearing temperatures are presented and interpreted by means of equivalent thermal circuits. Analyzing the radiation from the car truck, relating it to the characteristics of infrared measuring equipment, and discussing the handling of the resulting data suggests approaches to more efficient use of wayside hot box detectors. The effects of some ambient phenomena are presented. Further study of transient temperature conditions following lubrication failure is suggested.

C3 040166
DETERMINE THE OPTIMUM LOCATION OF HOTBOX DETECTORS
Two methods are presented to determine the optimum spacing of hotbox detectors. In both methods, optimum spacing is determined by economic factors, as well as other considerations. Growth or decline of traffic, changes in types and values of commodities hauled, changes in operating practices and changes in locations of car inspection points, all have a bearing on the results obtained from hotbox detectors. It may be desirable to change locations of detectors to fit new operating and/or traffic patterns. The increasing use of roller bearings must be taken into consideration when locating hotbox detectors. There is a short lead-time between the start of heating in a roller hearing and the presence of a critical case of a broken journal possibly within a distance of 30 miles or less. A good record should be kept of hotbox occurrences, set-offs and derailments, including costs, to determine if the study results are producing savings and reductions in hotbox set-offs and derailments due to hotboxes.

GRS OPTICALLY GATED WHEEL THERMO-SCANNER UNIT-OPERATION INSTALLATION MAINTENANCE
The GRS Wheel Thermo-Scanner Unit is a solid-state system for detecting and indicating abnormally hot journal temperatures of railroad cars traveling at speeds ranging from 5 to 85 mph. In the basic bidirectional system, magnetic wheel detectors on both approaches to the scanner location initiate system operation. The track-mounted equipment consists of two mounting assemblies (scanner and blower), four wheel detectors, three arrester boxes, two junction boxes, and connecting cables. The basic bidirectional system also includes a modular equipment cabinet, with plug-in printed circuit boards, which is designed for mounting in a 19-inch rack in a wayside housing. A basic unidirectional system requires two wheel detectors and a direction relay printed circuit board. Transmission lines for output are described.

HOT BOX RESEARCH
In order to determine the causes of hot boxes and to direct further research on the journal box assembly and truck details for improvement of plain journal bearing operation, a task force was authorized to make a field survey of hot boxes. Many of the undesirable conditions found in this study were of the type that design and material changes could avoid. It was determined that with a good journal lubricator, over a thousand miles could be run before all the free oil was wicked from the box. It was also found that generally 5,000 to 10,000 miles could be run without adding free oil before the bearing was in distress. These data suggest that changes in journal box, bearing, lubricator and other components should be made to eliminate the need for any servicing of these items at intermediate terminals. With the use of a reliable hot box detector to locate journal boxes operating above normal temperature, it appears that trains could be moved through terminals with minimum delay and the hot box set-outs between terminals greatly reduced.

ECONOMIC ANALYSIS OF OVERHEATED JOURNALS
The following conclusions were drawn from this study: 1. The adoption of a rule to scrap all axles having overheated journals, or any other modification to scrap certain axles having overheated journals will not be completely effective in the elimination of broken journals, or have appreciable effect on the reduction of hot boxes. 2. Axles which are severely overheated are more likely to have inherent thermal damage than those which have been slightly overheated. 3. The primary cause of the majority of all broken journals results from burn-offs during overheating. The most effective remedy is the reduction of the incidence of hot boxes. 4. The annual cost of arbitrarily scrapping all axles having overheated journals would be $5,181,903. 5. The annual cost of compliance with a rule which would require that 1/8 inch additional service metal be arbitrarily turned off each overheated journal would be $2,647,165. 6. Ultrasonic testing of car journals during periodic lubrication attention would remove from service journals with cracks or related defects. Annual cost: $874,667.

HOT BOX RESEARCH--FIELD SURVEY ON CAUSES OF HOT BOXES
In order to determine the causes of hot boxes and to direct further research on the journal box assembly and truck details for improvement of plain journal bearing operation, a task force was authorized to make a field survey of hot boxes. This survey was made on 131 repair tracks, in 15 shops, and in 61 transportation yards of 51 representative railroads. The geographical distribution of the railroads was selected to represent all of the regional territories of the United States, and to embrace operations under all of the climatic conditions encountered. Data were collected through the following methods: 1. By examination of 295 cars which had developed 341 hot boxes. 2. By examination of 17,256 journal boxes in transportation yards after switching, both hump and flat, and before servicing. 3. By examination of 2,422 journal boxes at terminals after inspection and servicing by the regular yard forces. 4. By examination of 3,628 journal boxes at intermediate points where no journal box attention is given. 5. By observations of general maintenance practices on repair tracks. 6. By measurement of 1,588 journal temperatures on 10 trains. 7. By examination of 32 journal boxes which had indication of above normal temperature as recorded by fixed trackside hot box detectors. 8. By examination of 158 journal finishes through the use of a profilometer. In this study, primary attention was given to the journal bearing and its immediately related mechanical parts. However, the scope was extended sufficiently to include determination of the condition of such items as springs, center plates, side bearings, truck sides, and bolsters.

ULTRASONIC TESTING OF RAILWAY COMPONENTS
Ultrasonic testing has expanded to the stage where it is a vitally important inspection method for two major railway components, axles and rails. It is likely that the use of the method will extend in many other fields. The success with which ultrasonic testing is now practiced is dependent upon three factors. They are: a thorough understanding of the type and position of flaws likely to occur in the component and the significance of flaw size; a sound knowledge of the principles underlying the use of ultrasonics for this purpose; and, a testing organization which can put sound techniques, well-trained men, and well-maintained instruments of the right type to work.

REPORT ON COMMITTEE ON WHEELS
As a result of two meetings in 1955 and 1956 and Committee action this report is submitted on the following subjects: wheels--cast steel. Progress reports on two experimental designs, AARX-2 and AARX-3 were analyzed and approval of both as AAR standards was recommended. Wheels-wrought steel. Ultrasonic testing was recommended on new diesel locomotive wheels for a two year period to provide additional data for correlation of size of discontinuity with indication. A dimensional study of design F-36 was completed and no changes were recommended. Wheels and Axles. A ballot to discontinue mandatory magnetic particle inspection of freight car axles between wheel seats was submitted. Wheel and Axle Manual. Complete revision of the Wheel and Axle Manual will be made after decision is reached on the adoption of new designs of cast steel wheels. Changes in specifications and designs for axle dimensions for passenger cars, spun multiple wear cast steel wheels, cast iron wheel defects and boring mill practice were also made.

HOTBOX DETECTOR EVALUATOR REFINES DETECTION TECHNIQUES
A hotbox detector data evaluator operates in series with a hotbox detector to receive and analyze the analog temperature use above ambient of each journal of each car as it passes. It calculates the average rise for each car side, and the compares each journal on a given side of the car to the calculated average for that side to establish its ratio. Warning outputs are given whenever the resulting ratio exceeds adjustable preset values for warm and hot. The same process occurs simultaneously and independently for both sides of the car. The data evaluator may be used by itself to operate directly into the conventional signal system or into a wayside visual display panel. Also, a chart recorder may be added in parallel to the data evaluator to provide a permanent record.

L&N HAS EXTENSIVE HOTBOX DETECTOR SYSTEM
Louisville and Nashville Railroad has now 52 hotbox detectors strategically located along main lines and on other lines handling heavy traffic density, such as coal. To more promptly alert train crews of hotbox detector actuation, L&N has installed digital display boards at some hotbox detector sites. Digital readout shows the location of the hotbox from the rear of the train and a flashing-white light tells which side of the train has the hot box. An additional safety feature is that immediately after passage of the train an integrity check is made of the operation of the detector system. If, for any reason, the system fails this integrity check, a flashing-blue beacon is lighted at the detector site to alert the train crew to stop the train and make an on-the-ground inspection of the cars.

C3 041040
HOTBOX DETECTOR SCANS INSIDE
Increased train speeds, while increasing bearing temperatures, have also increased the cooling effect of the air stream and thus have made more difficult the early detection of bearing overheating. Bi-directional operation on single track has further complicated the situation, since the cooling effect is particularly noticeable when the train motion is toward the aperture. A rail mounted scanner, which scans inside the truck sideframe, offers significant advantages: the inside location is less effected by the air stream, is less effected by sun or prevailing wind loading, is less subjected to cooling effect by sun or prevailing wind loading, is less subjected to cooling effect of rainfall, avoids radiation from brake shoes, is indifferent to open or missing lids, and by offering a shorter scan path is less affected by swirling snow. The scanner, which is clamped to the rail, permits increased system gain and provides a more consistent scan, which is important for the increasing number of roller bearings in service. The rail mounted scanner features easy installation, and reduced maintenance since it is not dependent on a rail to tie relationship. The low basic system power requirement of 500 va makes it possible to use a 24 v battery as a standby source.

PULSE EXCITATION OF RAILWAY WHEELS
A review is given of current applications of acoustic principles to testing and performance evaluation of railroad equipment. Also, a brief review is given of previous knowledge of the propagation of dispersive pulses in wave-guides. Pulses of a single frequency are produced at a point on the outer circumferential surface of each test piece and are received at other points along its periphery. Records of pulse arrivals are made by photographing the oscilloscope trace with a Polaroid camera. Experimental results show that pulses originating from a small source on the rim of the model railway wheel propagate directly through the wheel and also through the interior and on the surface of the rim. The behavior of these pulses is shown to be in accordance with the predicted propagation of Lamb waves in the plate region of the wheel and the predicted propagation of Morse waves in the rim of the wheel.

ULTRASONIC FLAW DETECTION IN MODEL RAILWAY WHEELS
This paper describes feasibility studies for ultrasonic inspection of railroad wheel treads and plates. Ultrasonic techniques had an early application in the railroad industry for locating cracks in steam locomotive driving axles and crank pins. Wet and dry magnetic particle inspection is also widely used in the industry as is the liquid penetrant method. Acoustic techniques, however, appear to offer potentially greater convenience than these methods when it comes to wheel inspection.

IMPROVEMENTS OF MAINTENANCE CRITERIA COVERING THE RUNNING GEAR OF SHIN-KANSEN RAILCARS BY MEASURING THE TRANSVERSAL ACCELERATIONS OF THE BODY [SHIN-KANSEN DENSHA SOKO KANRI SHIRYO SEIDO UO KOJO NI KANSURU KENKYU]
Osaka engine shed officials measure, under 200 km/h on line conditions, the body accelerations of Shin-Kansen railcars each time the wheels are re-profiled (every 70,000 km). Following these measurements, an index is calculated in accordance with an empirical formula that is a linear combination of the acceleration occurrence frequencies classified by section (linear combination of the values of the acceleration distribution analysis). Bogie overhaul is scheduled in accordance with the value of this index. In applying this method, the JNR encountered difficulties due to the effect of 3 factors on transversal accelerations: the state of the track, the speed (the index is very sensitive to speed variations of only a few km/h), weather conditions (transversal stability is distinctly improved in rainy weather). The article describes how corrective laws were worked out to eliminate the effect of the first 2 factors. For the 3rd factor, it was decided to limit measurements to periods of wet weather. ACOUSTIC FLAW DETECTION IN RAILWAY WHEELS
Ultrasonic pulse propagation has been studied in quarter-scale model railway wheels. Surface waves traveling around the tread of a wheel have been used to detect simulated thermal cracks using both pulse echo and attenuation methods. Pulse echoes from simulated plate flaws have been found using a transducer positioned on the tread surface to produce Lamb waves in the plate. Plate flaws have also been detected from the differences in the audio frequency acoustic radiation spectra of good and defective

quarter-scale models, using a real time analyzer. The extension of this work to full size wheels with actual defects is currently in progress.

5000 MILE BOX CAR VIBRATION TEST
There has been much research and testing to measure shock and vibration. However, such work has usually been restricted to specialized objectives over a limited territory and without complete instrumentation. This paper describes a 5000-mile test of an instrumented box car in revenue trains over five different railroads. It was part of the AAR Technical Center's Freight Loss and Damage Program and the RPI/AAR Cooperative Truck Safety Research and Test Project. The 60-foot, 70-ton car was operated between Chicago and the West Coast on a round trip involving two different routes.

This paper was prepared for a Panel Discussion on Freight Car Dynamics at the Rail Transportation Division of the ASME, Winter Annual Meeting, New York, New York, 19-20 November 1974.

IMPROVED METHOD FOR MEASURING THE RESIDUAL STRESSES IN RAILROAD SOLID WHEELS
In order to estimate the residual stress in railroad solid wheels, a new technique called plate-cut-out method has been developed. Fundamental idea of this method consists in that the residual stress in the wheel can be separated into two constituent components, by taking account of wheel geometry. These constituent components of the residual stress are determined respectively through simple strain measurements and elastic stress calculations.

SOME OBSERVATION ON FATIGUE PHENOMENA IN A LARGE PLATE SPECIMEN OF SPRING STEEL AFTER SHOT-PEENING TREATMENT
To obtain the fundamental data for the nondestructive finding of fatigue damage in vehicle parts, the fatigue due to pulsating repeated bending in a large plate of spring steel which had been shot-peened to increase its fatigue strength as a vehicle part, was investigated. It was clarified that there were two ways to find the fatigue damage: to observe the changing state of the surface residual stress and to detect the internal cracks non-destructively.

ODOMETERS FOR RAIL APPLICATION
Available mileage counters were evaluated, anticipating the possibility of using mileage intervals, rather than elapsed time, for freight car inspection. Simple, reliable and reasonably low costing devices were required. Only two unpowered mileage counting odometers were uncovered, one built in the U.S., the other in Switzerland. The Swiss device is not currently available in this country, presumably because of its particular suitability to European style trucks. The American built device was tested in eccentric rotation and for accuracy at both low and average freight car speeds. It was concluded that the American unit could serve satisfactorily in freight service, without modification, at what would appear to be acceptable cost levels.

AN IMPROVED METHOD FOR MEASURING THE RESIDUAL STRESSES IN RAILROAD SOLID WHEELS
These residual stresses are those resulting in particular from heating due to braking applied to the running surface of the wheel. The suggested measurement method admits that stresses in the wheel have two possible causes: a stress due to rim/plate interaction; a residual stress which remains in the plate after its separation from the rim. It stems from this analysis. Once strain gauges have been placed: the plate is cut by a lathe out of the wheel; the rim is sawn; and opening displacements are estimated by a simple elastic stress calculation. Diagrams and tables give the results of tests carried out on three types of wheel.

COMPUTERIZED DATA ACQUISITION SYSTEM
The system described relates to tests of the performance and durability of diesel engines. The system is designed as a tool for the test operator to enable him to get better data faster. In front of him and adjacent to throttle and dynamometer controls is an Operator's Panel mounting a group of push-button switches, indicator lamps and projection type digital readouts. Any parameter of the test may be displayed on the right-hand side of the panel by pressing the Display button and three Number buttons to define the data point of interest. At the start of an engine test, the operator sets the speed control potentiometer to give the required wide open throttle speed, he then types into the computer the "On Cycle" command. From then on throughout the control period set point adjustments are made, at 1/10 second intervals, as a required percentage of both speed and throttle. Repeatability of the cycle over a 1000-hour certification run is excellent and adjustments due to engine improvement or deterioration can be easily accomplished. The techniques of carrying out total Real-Time control and the calibration of gaseous emissions analyzers have been developed and the software written.

RAILWAY DYNAMIC TESTS
The verification of running safety and the quantitative assessment of the comfort of railway vehicles involves the taking of many dynamic measurements. The author first lists the range of the main recordings required and explains how they are taken: fitting of gauges, isolation of the phenomenon to be studied and transformation of the results into readings that can be interpreted more easily (usually an electric process), amplification, filtering, remote transmission of this data, reception and recording. The complex behaviour of a moving vehicle means that numerous phenomena must be recorded simultaneously and continuously by a whole series of measuring instruments. The author describes and explains in three sections the techniques used for measuring stresses and wheel-rail interaction, the series of measuring instruments, and the interpretation of the many and varied experimental results obtained, particularly with the TGV 001 trainset and the Z 7001 railcar. These results are very close to those obtained by calculation; they show the high value of the method using an analogue computer. [French]

THE S.N.C.F. EQUIPMENT LABORATORIES
The author, Ingenieur en Chef at the SNCF, Head of the Equipment Control and Laboratories Department, explains that these laboratories are now housed under one roof following the gradual amalgamation of six laboratories previously operating on the different railway networks. These networks comprised several laboratories on the Western Region (chemistry, physics, mechanical tests and metrology), and each on the South West (various mechanical tests and chemical analyses), Northern (mechanical tests), Eastern (mechanical tests) and former Alsace-Lorraine (various tests) Regions. These Laboratories have, since 1973, been completely centralised. The article therefore deals successively with the functions of these laboratories, their organisation(staff and means facilities), their main activities over the last two years. It highlights the existing facilities and the diversity of the work carried out: the equipment modernisation policy will be continued, in order that the research work planned in various spheres may be carried out in optimum conditions. PRINCIPLES AND CRITERIA FOR THE DESIGN OF A RAILROAD TRACK TEST FACILITY
This paper discusses principles and criteria for design of a track test facility such as will be built by the Federal Railroad Administration to support various track research programs aimed at improving design and maintenance procedures. It is suggested the facility be as versatile as possible so that tests can include determination of stresses in rails due to vertical and horizontal loads, study of axial rail forces induced by moving trains and track buckling caused by temperature stresses and moving trains. Construction of permanent structures such as concrete piers should be avoided whenever mechanically possible.

ANALYTICAL AND EXPERIMENTAL DETERMINATION OF NONLINEAR WHEEL/RAIL GEOMETRIC CONTRAINTS
The wheel/rail geometric constraint relationships for actual wheel and rail profiles are generally nonlinear functions of wheelset lateral displacement. Two of these relationships which strongly influence the lateral dynamics of

railway vehicles are the effective conicity and gravitational stiffness. An algorithm for the digital computer is presented that calculates these nonlinear relationships for arbitrary wheel and rail head profiles. An experimental apparatus was developed to determine the location of the wheel/rail contact points as a function of wheelset lateral displacement for arbitrary profiles. Experimental data obtained with this apparatus are presented for various cases which validate the results of the analytical procedure.

FATIGUE CRACK PROPAGATION THROUGH WELD HEAT AFFECTED ZONES
Fatigue tests were performed on specimens containing weld heat affected zones at two orientations to the stress axis. Two steels were used, one a low alloy steel and the other a mild steel. It is stated that, since the tests were performed on actual heat affected zones under known stress conditions, the conclusions can be applied to the behavior of fatigue cracks in actual structures under operating conditions. The observations suggest that, when fatigue cracks are present, the integrity of a welded structure may depend on the toughness of the component with the lowest flow stress.

A STUDY OF PRE-CRACK FATIGUE, PART I
The report is an examination of current technological posture in materials fatigue, especially that area of fatigue before the formation of a finite or 'technical' crack. A computerized search of the literature was performed by the Defense Documentation Center leading to the establishment of a bibliography which was intensively examined. The various concepts and rules of fatigue damage were critically examined as were their effects on fatigue analysis. The fatigue implications of Non-Destructive Evaluation (NDE) were also reviewed with the objective of recommending new approaches. Throughout all, a number of specific recommendations for future activity were made and discussed. These are summarized at the conclusion of this report. (Author)

STRESSES AT RAIL JOINTS AS INFLUENCED BY BOLT HOLES
The failures of rails caused by bolt holes of joints (end breaks) have recently come to occupy the majority of rail breaks. In order to prevent such breaks it was customary to reduce the diameter of the bolt holes or to keep the holes away from the rail ends. The present writers conducted experiments upon joints of the structure actually used for 50 kg/m rails, bolts of different diameters, rails with bolt holes of different intervals and fishplates with bolt holes of different diameters and different intervals with an aim of ascertaining what type of a fish joint is the most durable.

RAILWAY TRACK VIBRATION INDUCED BY TRAIN MOVEMENT
The railway track under train movement suffers progressive deterioration, which is equivalent to multiplication of repeated train load and vibration induced. The paper presents the results of measurements on the aggravated track vibration and the comparative study of track vibration on the concrete ties and on the traditional ties. Ballast acceleration in two sections laid with concrete ties using tie-pads of 110 t/cm spring constant averaged 23 percent and 35 percent respectively, less than that of the section laid with common ties. The value in a section laid with concrete ties using tie-pads of 250 t/cm spring constant averaged 24 percent larger. There is a conspicuous difference in occurrence distribution of acceleration at the welded joint.

RAIL WEAR LIMITS
The Southern Railway, after reviewing rail wear conditions which were thought to have been a principal contributing factor to derailments, found that approximately 40 percent of loss of rail head wear for 130-132 lb. rail was the amount beyond which such derailments had occurred. Limits to show the top wear limit and side wear limit to be allowed for the different rail sections for various classes of track. The corresponding limits for the smaller sections of rail were pretty much a matter of judgment, using the limits for the 130-132 lb. sections as a guide.

STUDIES ON CORROSION FATIGUE BY POTENTIAL MEASUREMENT
Using specimens made of mild steel (SS-41), fatigue tests were carried out both in air and in the corrosive medium of 1 N sodium sulfate solution acidified to pH 2.2. During fatigue testing, the corrosion potential of a specimen was recorded by a vibrating reed electrometer and the rate of corrosion was determined by colorimetry of total iron in waste solution. The results of potential measurement show that under alternating stress, the potential decreases after keeping a constant value for some hours. By the wet-dry stage fatigue tests, it is confirmed that the period until potential decreases accords with the so-called "Incubation Period", that is concentrated stress at the bottom of corrosion pits just reaches a fatigue limit, with initiation of potential decrease. In the end, the incubation period can be known by potential measurement, and by repetition of a few wet fatigue tests. A curve of stress concentration which rises with numbers of stress cycles under an acidic environment can be traced.

TEST RESULTS BY FULL SIZE WHEEL-AXLE FATIGUE TESTING MACHINE

For the perfect solution of the problem of preventing train accidents due to axle failure, it is necessary to get an accurate grasp of mechanism of fatigue crack initiation and its propagation in wheel axle. From this standpoint, it was decided in 1964 to develop a full size wheel axle testing machine and the developed machine was set in RTRI and now, several kinds of fatigue tests have been carried out using this machine. This report describes the general performance of the machine and a few fatigue test results about old axles or new axles. The forms of wheel-seat are four kinds and the heat treatments of axles are two kinds.

MUTUALLY PERMISSIBLE WEAR PROFILES OF WHEEL TYRES AND OF POINTS AND CROSSINGS. ASSESSMENT CRITERIA FOR THE PERMISSIBLE WEAR PROFILES OF WHEEL FLANGES AND SWITCH COMPONENTS.

Studies include the investigation of the wear forms of a great number of worn wheel flanges used on various types of vehicles (passenger coaches, wagons, railcars, electric and diesel bogie locomotives) and of worn rails in areas containing points and crossings so as to obtain an adequate basis, adapted to practical demands, for arriving at a judgment. Starting from a characteristic wear profile of a flange a track guage was developed, permitting the verification of the compatibility of the wear profiles of the ironwork of switches with such a flange.

Measurements conducted using the gauge enable development of wear forms of rails endangering the traffic to be detected (particularly in sections containing switches and stock rails) and they indicate, at the same time, how this risk can be eliminated and how their use can be prolonged by reprofiling operations. The results of the studies are that it will be possible to deduce, from an analysis of the geometry of the contact between flange wear shapes and track, the compatibility criteria adapted to practical conditions and only requiring simple measures to be taken on the wheel and the switch work items (checking by means of the gauge). This procedure will lead to a decisive improvement of the riding safety of vehicles.

Restrictions on the use of this document are contained in the explanatory material.

DISCUSSION ON THE STRENGTH OF WHEEL-AXLE FOR HIGH SPEED TRAIN AND SOME FUTURE PROBLEMS

When the train speed increases to more than 200 km/h, the variance and increase of wheel-load will be more remarkable than in present cars. The train speed must be increased carefully, the bogie construction, the track construction and its maintenance method must be fully investigated. In future, problems of the thermal crack, tire flat and residual stress are very important for wheel-tire and the fatigue strength under complex stress amplitude and the study of increasing press-fit parts strength are very important for axles. According to all data, the critical speed of wheel-tire will be 300 km/h.

REPORT NO. MR-439 ECONOMIC SURVEY OF AXLES WITH OVERHEATED JOURNALS

In order to determine the economics involved in this subject, a survey was made in the main wheel shop on five large railroads in the United States, covering the following items: (Item 1) How many axles are scrapped due to all causes except those handled for overheated journals? (Item 2) How many new axles are now being used as replacements for axles which are scrapped due to condemning limits for wear on wheel seats, journals or uncorrectable defects such as cracks? (Item 3) How many axles are now being used to replace axles which were overheated and badly scored and gouged? (Item 4) How many axles are considered useable, machined and then tested and found to be defective and subsequently scrapped under present Interchange Rules? (Item 5) What is the approximate expense of reclaiming by turning, magnetic particle testing for cracks, and placing axles in condition for use

under current Interchange Rules? The data thus obtained was analyzed and these conclusion were reached: The adoption of a ruling to arbitrarily scrap all axles which had an overheated journal will not eliminate broken journals from other causes, or affect the number of hot boxes; The principal cause of the greater number of all broken journals is burn-offs as a result of being continued in operation without being detected while overheating; Further reduction in the number of hot boxes will most effectively reduce these incidents; The net annual material and labor costs of arbitrarily scrapping axles having overheated journals which are presently reconditioned for further service under current Interchange Rules, based upon the secondhand value of the replacement axles, is estimated to be $403,752.13.

DURABILITY TESTS ON TRACK COMPONENTS
Use of a Vibrogile is found the most simplified and effective method for determining the durabilities of various track components such as the fastenings, ties, pads, etc. It was felt necessary to perform durability tests on the fastenings and other components, using a hydraulic fatigue testing machine which can apply a repeated pressure of constant magnitude with accuracy, though without any vibration, and thereby supplement the Vibrogile testing. Thus, the durability tests were carried out on the fastenings for the existing line and the new Tokaido trunk line, using both the testing machines.

TRACK-TRAIN DYNAMICS STUDY PROJECT TR-14 RAIL-VEHICLE INTERACTION STUDY REPORT NO. 1 (PRELIMINARY ANALYSIS OF SAMPLE DATA)
As a result of various derailments, a task force was formed to investigate the dynamic forces exerted by locomotive and freight car wheels against the rail. Critical study was directed at the 3 and 2 axle trucks of high horsepower locomotives, 85 feet TFC cars, and 50 feet box cars. The objective of this investigation was to determine if dynamic forces of sufficient magnitude to cause derailment were being generated by equipment, track structure and operating practice, and to recommend whatever corrective action might be indicated. Extensive field tests of wheel-rail interaction were conducted in various territories between Los Angeles and Pine Bluff, Arkansas. An analysis of these test results led to the following general conclusions: 1. Dynamic forces of sufficient magnitude to cause derailments are being generated in every day operation of revenue trains. 2. The forces are also sufficient to cause greatly accelerated wheel and rail wear. 3. Forces of sufficient magnitude to exceed the ability of the track structure to resist permanent deformation in alignment are also being generated.

FATIGUE TESTS OF RAIL WEBS
The study of the fatigue strength of rail webs has been continued. Tests were made on T-shaped specimens cut from the web of a 112-lb RE rail, under a range of stress which simulated as nearly as possible stress conditions encountered in service, namely, a bending stress ranging from a maximum compressive stress at the surface to a tensile stress 20 percent as great. Since the fatigue failures were in compression, the cracks progressed very slowly, and the criterion of failure was taken to be the number of cycles when the crack could be first detected. Eight T-shaped specimens were cut from the same piece of 112-lb rail and were shot peened. Tests indicated that shot peening raised the endurance limit approximately 32 percent over that for the unstamped specimens with the surface as rolled. To get some measure of the reduction in fatigue strength resulting from corrosion, it was suggested that fatigue specimens be cut from a corroded or rusty rail and tested in the same manner to determine the amount of weakening due to a rusty, pitted surface. A short piece of very rusty rail was obtained from which specimens were cut for these tests. The curve for these date indicates an endurance limit of 57,000 psi at 10 million cycles, or a reduction of slightly less than 3-1/2 percent below that for the non-corroded specimens. To observe the effect of water corrosion on fatigue strength, several specimens were tested with tap water dripping continually on them. The fatigue curve shows an endurance limit of 56,000 psi at 40 million cycles, which is approximately the same as for the rusty rail specimens.

FIFTH PROGRESS REPORT OF THE SHELLY RAIL STUDIES AT THE UNVERSITY OF ILLINOIS
Several specimens of alloy steel were received for rolling-load tests to study their resistance to shelling. The chemical analyses, Brinell hardness and some physical tests of these steels, are given in Table 1. The heat-treated specimens were short lengths of rails and very little materials is available for physical tests until the rolling-load tests have been completed. Photographs of the shelling cracks for some specimens are shown. Heat-treated low alloy rails were much superior to any other specimens and compare very favorably with the 3-percent chromium rails and heat-treated carbon steel rails. The 3-percent chromium rail stood up to 5,000,000 cycles and the laboratory heat-treated carbon steel rolled 4,560,000 cycles before complete failure. The two tests made on the silico-manganese spring steel rails were discouraging as these specimens developed a brittle type of fracture after only 983,000 cycles and 657,000 cycles, respectively. Photographs of both of these failures are shown. The rolling-load tests of the as-rolled alloy steels were also discouraging as the best of these ran approximately one million cycles in the cradle-type rolling machine. These alloy steels could, or course, be heat-treated to produce physical properties which would give much better rolling-load tests.

DEVELOPMENT AND CHARACTERISTICS OF FRACTURES UNDER ENGINE BURNS IN RAIL TOGETHER WITH INVESTIGATIONS AS TO THE EFFECTIVENESS OF WELDING UP ENGINE BURNS BY OXYACETYLENE OR ELECTRIC METHODS
This is a progress report covering rolling-load tests and metallurgical investigations on engine-burned rails. In summary: a driver burn of a rail causes extreme hardness because of the development of a martensitic structure. This constituent develops from the process causing the burn, namely, (a) friction heating and (b) rapid quenching. The martensite transformation apparently creates quench cracks because of the volume change. The quench cracks greatly reduce the fatigue resistance and the rail may fail in a shorter time. Attention should be given in the repair of driver burns by welding, to removing parent metal containing quenching cracks beyond each end of the burned area in addition to the burned metal, before weld metal is applied. Study should also be given to means of making the weld to obtain a minimum of oxide inclusions. Numerous photographs document engine burns and quench cracks in rail.

FIFTH PROGRESS REPORT OF THE ROLLING-LOAD TESTS OF JOINT BARS
This is a report on the tests of joint bar failures and it gives consideration to the revision of design and specifications Observations of tests are: Joint bars for 131-lb RE rail subjected to a wheel load increased in proportion to the increased section modulus of the bars, thus giving equivalent bending stress, render approximately the same joint bar life as the 112-lb bars. The cyclic life of the 131-K14 36-in. bars tested was somewhat longer than that of 24-in. bars of the same type. Top surface bearing at the rail end is wider on TR bars with the 11/16-in. fillet radius than on 112-lb headfree bars with 3/8-in. fillet radius. The average cyclic life of TR bars greater than that found with 112-B34 bars. Rolling-load tests on one lot of 112-B34 bars show an increase of cyclic life resulting from shot-peening. Variations in hardness from bar to bar of the same heat may result from variations in quenching temperature. Surface decarburization usually found on joint bars is readily detected in the Rockwell Test.

THE EFFECT OF THE RATIO OF WHEEL DIAMETER TO WHEEL LOAD ON EXTENT OF RAIL DAMAGE
This is a report of progress on studies of pressure as affected by the area of contact between wheel and rail. One phase of this investigation involves the conduct of rolling load tests of rails subjected to wheels of various diameters and loads. To summarize, a depth hardness survey on a 112-lb rail removed from service after approximately 12,000,000 tons of traffic shows the maximum hardness to be at a depth of approximately 0.04 in. at a distance of 1-3/6 in. from the center of the head toward the gage side, the maximum hardness being Rockwell C 34.6. Tests on a full section 131-lb rail under a 75,000-lb load after 1,333,000 cycles (100,000,000 tons) of testing are as follows: For the 33 in. wheel--a hardness of Rc 15 on the tread and a maximum of Rc 32 at a depth of 0.15 in.; for the 50 in. wheel--a hardness on the tread of Rc 23 and a maximum hardness of Rc 27.4 at a depth of 0.10 in. Using "mutilated" head specimens and a 50-in. wheel it was found that a 58,000-lb load could be carried for 100,000,000 tons, but that a 63,000-lb load would break down the rail tread after 15-45 million tons.

SECOND PROGRESS REPORT OF THE SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS
The laboratory studies of the cause and prevention of shelling of rail surfaces are carried on in cooperation with the AREA Committee on Rail, Assignment 11-Investigate causes of shelly spots and head checks in rail surfaces for the purpose of developing measures for their prevention. Low strength of the steel, as indicated by low Brinell hardness, seems to be a significant factor in the development of shelly spots on rails. No defects were found in the metal of these rails which might have contributed to the development of shelling. It was also found that the shelling on these rails developed differently from that described as starting internally in last year's report on shelly rails. Several photographs are presented to illustrate the shelling that occurred. The rolling-load tests to compare the flow of various kinds of rail steels under laboratory controlled conditions, described in the 1942 report, have been continued, and the results are now complete on 21 specimens. Eight rails have changed less than one hundredth of an inch and a ninth rail was only slightly over this value. In contrast to these rails are 12 rails which changed in profile over two hundredths of an inch. It will be noted that all the rails except two which changed in profile over two hundredths of an inch were below 300 in Brinell hardness.

C4 033311
INVESTIGATE CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL SURFACES FOR THE PURPOSE OF DEVELOPING MEASURES FOR THEIR PREVENTION
As the subcommittee investigates this subject more fully, it has been found that shelling is a much more serious and wide spread condition than was first realized, and while the shelly condition may be visible in some cases, in many others fractures of the rail may occur without the defect becoming noticeably visible on the surface of the head; therefore, it is doubly important that a solution be found. In addition to a study of rail-steel compositions, heat treatments, wheel and rail contacts and pressure, the subcommittee may turn to a study of mill practices as a possible cause of shelly steel, or it may finally resort to a consideration of larger diameter wheels or lighter loads on the wheels. If the answer lies in some special composition of rail steel or in heat treatment, the investigation must enbrace a study of the possibility that the new chemistry or heat treatment may give rise to some other types of defects or that they may lead to excessive difficulties or expense in production. While this assignment covers both shelling and head checking, very little mention has so far been made of the latter. At one time the subcommittee was of the opinion that one solution would cover both defects, but recent developments indicate that this may not be true. This report covers shelling only.

C4 033314
STUDIES OF THE PRESSURE AS AFFECTED BY THE AREA OF CONTACT BETWEEN WHEEL AND RAIL. EFFECT OF WHEEL SIZE
The following is a progress report on one phase of this investigation, namely, rolling-load tests in which wheels of various diameters are rolled to and fro on a short length of rail for the purpose of determining the number of cycles of load application required to produce failure. The results of the rolling-load tests to fracture show considerable "scatter" and no very marked difference between the results of tests under a 50-in. wheel and those from tests under a 33-inch wheel. The vertical wear on rail 757C (33-in. wheel) was 0.046 in. at failure, whereas the wear on rail 757C1 (50-in. wheel) at 580,900 cycles was 0.041 in. At failure, 750,100 cycles, the wear on rail 757C1 was 0.0425 in. A second type of test being tried to ascertain the effect of wheel size on the rail is to measure the depth of work hardening in the rail head. The rail head appeared to have been work hardened down to a depth of about 0.45 in. by the 33-in. wheel with a maximum hardness of 296 at a depth of 0.15 in. A test on a section from the same rail rolled with the 50-in. wheel appears to have been work hardened down to a depth of 0.20 in. with a maximum hardness of 269 at a depth of 0.10 in.

INVESTIGATE JOINT BAR FAILURES AND GIVE CONSIDERATION TO THE REVISION OF DESIGN AND SPECIFICATIONS
Rolling load tests have been conducted more or less continuously for two years with this machine and valuable information has been reported in the various committee reports. This information has dealt with fatigue life of joint bars, wear, stresses, effect of bolt tension, effect of abnormal conditions of joint bar fit, behavior of various designs of bars, etc. The following tests to be made on the rolling-load machine: (a) effect of "cocked" position of bars, (b) effect of design of bars, (c) effect of bolt tension on rail end breakage, (d) determination of fatigue strength of joint bars. Observational measurements were made during the year and the traffic carried over this test and the resultant joint bar wear are not yet sufficient to justify definite conclusions. Careful examination was made of all joint bars removed for evidence of cracks. One bar made of rail steel was found to have two small cracks on the top fishing surface.

SPECIAL COMMITTEE ON STRESSES IN RAILROAD TRACK. SEVENTH PROGRESS REPORT
Since 1914 this committee has conducted analytical and experimental investigations on the action of railroad track under the loads of locomotives and cars running at various speeds and for a variety of conditions. The tests herein reported were made to obtain information on the action of various types of rail joints in track when subjected to the loads of locomotives and cars at speeds up to 90 miles per hour. Testing equipment enabled tests to be made accurately and expeditiously in a way that had not been accomplished before. Tests were undertaken particularly to obtain information on the action of different forms of rail joints in track under the traffic of locomotives and cars running at various speeds and to learn the magnitude of the bending moments developed in the joint bars as compared with those developed in the full rail away from a joint. It was also desired to learn if possible how speed of train affects these various matters. To serve as a basis of comparison, the stresses and moments and depressions of the full rail in the same track under the action of the same locomotive and cars were needed. Tests were conducted at Elkton, Md. The test site was on a 14-min. curve to the right with superelevation of 1-1/2 in. Ahead of and behind this curve the compound curve became 33 min. The total curve extended over a distance of about a mile.

ON THE LIFE OF RAIL
Annual trend of rail failures of the Japanese National Railways in recent years amounted to 5264 in 1963. There are included in rail failures the numbers of broken rails, cracked rails and defective rails all together, they do not always cause interference to train operation. It is known from the figures that end break ranks the first and amounts to more than 60 percent. The number of end breaks is divided into two parts, namely in tunnels and out of tunnels. End breaks in tunnels are more frequent for their track length and the rails in tunnel have shorter life than the ones out of tunnels, due to unfavorable conditions of corrosion in tunnels of our country. End breaks almost occur as results of rail fatigue by train loads. Stress induced on rail varies in magnitude according to train speed, wheel load, lateral force and position of wheel contact on rail, and the stress distribution was found in many measurements to be a normal distribution or its combination in most cases.

C4 033324
SEVENTH PROGRESS REPORT OF THE JOINT INVESTIGATION OF FISSURES IN RAILROAD RAILS
The development of detector cars made possible the detection of many fissures before rail fracture had occurred, but it did not touch the problem of prevention of fissures. A "rolling-load" testing machine was designed and built which subjected a specimen of rail to repeated cycles of wheel load and bending moment. Before testing in this machine an etch test to detect the presence of shatter cracks was made on the rail from which the specimen was cut. Rolling-load tests showed the following results: Only shatter-cracked rails developed fissures, but not all shatter-cracked rails developed fissures. It is the complex stresses directly under a wheel load which cause cracks to develop into fissures. Bending moment tends to cause fissures to take a transverse direction, and accelerates their spread. No greater wheel load was required to start a fissure in a heavy rail than in a lighter rail. The minimum wheel load which started a fissure in the rolling-load tests was 40,000 lb. The wheel load necessary to start a fissure, the theoretical shearing stress in the zone where shatter cracks are located, the fatigue strength of rail steel, and the weakening effect of minute cracks (shown by fatigue tests of specimens) form a coherent picture of the mechanism of fissure formation and spread. The solution of the problem of preventing shatter cracks in rails was attacked by making tests of specimens from rails cooled in air and also controlled cooled. A large amount of study has been given to the problem of finding a nondestructive test which could be used to detect shatter cracks in new rails. Shatter cracks are so minute that changes, due to these shatter cracks, in properties or structure of metal around them, are masked by other variations in the metal. Unfinished work of the investigation relating to fissures includes formulation of proposed standards for control cooling of rails and for bend tests for acceptance of rails. Numerous photographs detail rail defects of the type described.

INVESTIGATE JOINT BAR FAILURES AND GIVE CONSIDERATION TO THE REVISION OF DESIGN AND SPECIFICATIONS
This assignment to investigate joint bar failures, included the study of cracks which may or may not lead to ultimate breakage. The two most common types of cracking are illustrated in Figures 1 and 2, namely, (1) fatigue cracks originating in the spike slot, and (2) fatigue cracks originating at the upper contact surface of the bar. To study possible means of eliminating the cracking of joint bars, tests in track and tests in the laboratory are being conducted along the following lines. 1. Resistance to cracking by improving the physical properties. 2. Photoelastic studies as to effect of design and bolt tension. 3. Fatigue tests, using full size bars of various design in assembled joints. 4. Observations as to the effect of saw swelling of the rail end.

PROTECTION OF RAIL JOINTS FROM CORROSION TO PREVENT RAIL END BREAKS
Many parts of the railway track including the rails are made of carbon steel. Carbon steel excels in strength but is prone to be corroded. Rail end breaks are considered as fatigue destruction caused by corrosion. Since stress and corrosion act at the same time, cracking is developed easily. It is because the fatigue strength of a rail decreases sharply in acid environments, that end breaks are more liable to occur in non-electrified sections than in electrified sections. Since corrosion has much to do with end breaks of rails in tunnels, the application of a proper protective method prevents end breaks of rails.

RESIDUAL STRESSES IN THE RAIL
When rail fasteners are loosened, the rail bends because of the accumulations of deformations caused by stress, workhardening or unevenness of stress. The resultant bend of a rail is the result of the nature of the rail as in the differences between a common or quenched rail. Residual stresses in rail tend to decrease which finally lead to rail deformation as a result of the loss of equilibrium of the forces.

SHELLING OF RAILS EXPERIENCED IN JAPANESE RAILWAYS
In some local lines of the Japanese National Railways and in major privately owned railways and subways in the Kanto and Kansai districts, rail failures caused by shelling of rails are showing signs of increasing. AREA Committee for Rail Shelling says that in curved tracks, if the rail heads and wheel flanges are lubricated, the incidence of shelling increases, but if

lubrication is stopped, head checks, flaking and shelling conspicuously decreased. Rate of progress of the fatigue caused by contact should be made to balance with the rate of the progress of the wear. Allowing some wear to arise and also preventing for large plastic flow to occur, such failure may be prevented.

RESULTS OF TRIALS WITH A NEW TYPE OF BOGIE DESIGNED BY THE SNCF
These tests dealt with the truck Y 207 and considered particularly the transverse stability of this truck at speeds of from 140 to 245 km/h, with wheel tires in tread worn condition, corresponding to 350,000 km of operation, and with tires worn to profiles to generate "shaking". After the wheels on this truck had actually made 350,000 km (217,000 mi.) without requiring turning for sharp flanges or instability on the track, and having an average depth of tread wear of 2 mm, this vehicle was tested at 140 km/h. These tests were the first ever run at speeds over 200 km/h with wheel treads in such worn conditions, and have significant results.

STRESSES ACTING ON THE RAIL–RECENT FINDINGS
Increased axle pressures and reduced wheel radii give rise to higher stresses in the rail head. If the permissible shearing stress is exceeded, fatigue fractures will occur in the rail head. This can be counteracted by using a steel of greater strength and purity. Also of importance are the additional flexural tensile stresses at the lower edge of the rail head. This permits an indirect measurement of the guiding efforts.

WHY METALS BREAK
To list some of the principal modes of failure at present known: 1 Collapse due to buckling or general yielding, 2. fatigue, 3. brittle fracture, 4. creep, 5. stress corrosion, 6. corrosion fatigue, 7. tearing or shear failure. This paper has endeavoured to list some of the failure mechanisms which can lead to fracture in metals, and to show that the tensile strength of the metal has virtually no significance in any of the important failure modes, although it may be useful as a simple basis for comparison between different steels or non-ferrous alloys. Photographs show failures of rail, axles, wheels and bogies.

EFFECTIVENESS OF ALLOYING RAIL STEEL WITH CHROMIUM
Service tests have proved that type R-50 railway rails made of steel containing 0.63 to 0.75% C and 0.7 to 1.0% Mn and alloyed with chromium (0.5 to 1.0%) have an increased (by a mean 25%) resistance to contact-fatigue defects, less wear per 100 million gross tons of freight, and less rippling of the surface after use than carbon steel rails of standard composition. These advantages are obtained if the total C1/4 Mn content of the steel is not lower than 0.88%.

STRESSES IN RAIL HEADS--COMPARISON BETWEEN THEORY AND EXPERIENCE [SCHIENENKIPFBEANSPRUCHUNG-VERGLEICH ZWISCHEN THEORIE UND PRAXIS]
This article describes the latest investigations into the problems of rail loading and stresses. Laboratory experiments with a plastic model of a rail are described, with the results charted. These are related to the tests and experience of the German Railways in their investigations of rail failures and damage. Charts are included which show the relations of the shearing stresses in the rail head to the wheel diameter and axle loading, the stresses increasing as the wheel diameter decreases or as the axle load increases. WELDED RAIL JOINT FRACTURES AND THEIR EFFECT ON 200 KM/H OPERATION
JNR conducted a series of tests to determine the effect of broken welded rail joints on trains running at high speed. A rail gap of 20 to approximately 30 mm was employed since this was considered the likely amount just after a rail fracture in winter on the New Tokaido Line. The train used for this test consisted of six 2-axle bogie type electric rail-cars with an axle-load of 15 tons. Items measured included: rail deflection, rail stress, stess on the fastening device, track vibration acceleration and sleeper stress and the like; most of these were measured using wire strain gauges. On-the-rolling-stock measurements included: wheel side thrust, whee load, bogie stress, car body vibration, axle box vibration and similar forces. The results of the test indicate that train operation on the New Tokaido Line is judged as completely safe from the point of view of possible broken welded rail joints, in that even the lateral discrepancy of ends of the broken rails and wheel side thrust at the train passing the broken point were found to be less than 1/2 of respective maximum limits for safe train operation, and values for car body vibration and other items were also found to be sufficiently small.

DERAILMENT OF ELECTRIC PASSENGER TRAIN
The derailment of the last coach of an electric multiple-unit down passenger train on December 13, 1963, which subsequently came into glancing contact with the side of another passenger train, was caused by axle fatigue. This fatigue would have been detected if the prescribed frequency for ultrasonic inspection had been observed. It was suggested that no axle be tested less frequently than every 18 months. One passenger was killed and 31 injured.

TRACK STRESS RESEARCH
The purpose of this work was (1) to verify the speed allowance formula, (2) to investigate the increment of stress over and above the static effect under normal conditions from track defects, (3) to investigate the conditions of support at rail joints, (4) to investigate the stability of ballast, and (5) to investigate the effects on rails and sleepers of the lateral forces set up by the hunting movement of locomotives. In regard to (1) and (2) it was found that experimental static deflections and stresses are in reasonably close agreement with calculated values. In regard to (3), it was concluded that stronger fishplates are needed to facilitate maintenance and rail joints of inadequate strength are the cause of much of the impact effect. Increasing the number of sleepers will reduce this impact effect. In regard to (4), the shape of the sleeper was found experimentally to have no noticeable influence on its deflection under a given load, but stress distribution between the sleepers and subsoil requires investigation. In regard to (5), further investigation on curved track was recommended to confirm the consideration that design to rolling stock to reduce nosing on the sharper main-line curves would reduce the secondary stresses and thus offset the increased stress due to centrifugal effects.

THE EVOLUTION OF THE AMERICAN RAIL
A review is presented of the development of the railway rail in America, including the change from iron to steel, the evolution of the modern American flat-bottom section, up to 152 lb. per yd. in weight, and present-day American rolling methods. Rail sections arranged in chronological order from the 5 ft. long, cast iron plate, used in 1767, to the 131 and 152 lb. rails introduced in 1930, are shown to trace the development of the

American rail. Results are reported of a study to compare 100 lb. and 131 lb. rails as to maintenance costs and life, as affected by increasing weight loads. The heavier rails extended the life, not only of the rails, but also the sleepers and fishplates.

HOW RAILS BREAK
The manufacturing defects described are in ingots; in rolling methods; a transverse fissures, the fractures caused by stresses set up in cooling. The failures described arising from service conditions may be caused by excessive wear; fatigue or impact; rail-end batter; corrosion in tunnels, at water troughs, or at wet ashpits; slipping by wheels; faulty heat treatment, welding or cutting; corrugation; or war damage. Rail failures in India in 1929 due to rolling defects resulted in the use of impact testing on the side of the rail-head being added to test specification. The temperature equalization scheme adopted by British mills in 1928 to avoid transverse fissures is given.

NEW BRAKE SHOE CUTS STOPPING TIME, REDUCES WEAR AND SPARKING
A new brake shoe completely interchangeable with the standard metal shoe promises better train control, increased life and almost total spark suppression. Key to the breakthrough is an alloy of iron which exhibits a vastly different metallurgical structure from that of a standard shoe. The Samson shoe reduced stopping distance 32 percent and confirmed the improvement in train handling. The Samson retained the favorable friction characteristics of the standard metal shoe at static breakaway and low speed. Comparative sparking under drag braking conditions tested with cheese cloth placed in the trajectory of sparks leaving the wheel. At 45 mph, sparks from the standard metal shoe ignited the cheesecloth in seven minutes; Samson caused no fire.

ON THE USE OF INDIVIDUALLY SUPPORTED FREE ROLLING WHEELS ON RAILWAY VEHICLES [ZUR FRAGE DER VERWENDUNG VON LOSRADERN IM SCHIENENFAHRZEUGBAU]
The kinematics of wheel-sets on railway vehicles is discussed in theory. The tests are reviewed which were made of individually supported, free rolling wheels in frames under vehicles without a rigid connecting axle from wheel to wheel. The conclusions of this study point out the following: free rolling wheels have no guidance capabilities along the rail; wear on the curves is not avoided by free wheels. Safety factor against derailments is less than with conventional wheel sets, since the free wheel cannot develop sine waves in its running, it runs free of such lateral vibrations and is therefore quieter. TRAILS WITH GLUED WHEELSETS
One of the most recent developments in the metal adhesives field is their use in the assembly of wheelsets. One reason for this is the increasing demand for lighness of unsprung parts. The normal method of assembly of wheelsets by interference press fit has reached the limits which the materials can withstand. A careful choice of the adhesive to be used is most important in all cases, but especially so for such highly stressed parts as wheels, axles and tyres. With these factors in mind, the German Federal Railway decided on an experimental application of the process. Four axles were assembled using adhesive methods in the repair works at Stuttgart-Bad Cannstatt. For the joints between the wheel hubs and axles a very strong adhesive of low viscosity was chosen, but it was decided to press on the axle in the usual manner. A first test on a wheelset testing machine at the Minden Research Institute took the form of running 10,000 km with a constant axleload of 17 tons. This produced no displacement of the glued components, and it was noted that the wheelset ran remarkably quietly.

WHEELSET DEVELOPMENT REVIEWED BY ENGINEERS
Design and wearing qualities to accommodate increased speeds and axleloads predominate in the papers delivered at the Third Wheelset Conference. Spalling of wheels experienced on North American rapid transit systems had been brought about by wheel slip and it was recommended that a total adhesion system should be considered at the design stage of coaches. In introducing synthetic brake blocks where wheel tyre cracking existed and it was considered that tyre steels which should be used were those which did not have a hardening tendency and soft steels of low carbon content which were immune from heat cracking. Resilient wheels for use under rail vehicles for suburban and main line railways, cast steel wheels, hollow-tread profiles, wrought-steel wheels, and non-alloy wheels are also briefly discussed as well as cast steel wheels.

ULTRASONIC RAIL TESTING AT THE ROLLING MILL
Studies have shown that fatigue defects which appear in rails in the track can always be traced back to segregations in the metal, inclusions or micro-cracks. Metallographic tests which show up these defects are lengthy, costly and must inevitably be restricted in scope because they involve destruction of the specimen tested. Consequently, it was necessary to find a non-destructive method of detecting these defects by sounding the whole length of the rail head. The ultrasonic method using echoes was chosen by SNCF and ORE. The Ralus equipment was designed to detect heteorogeneities which are particularly harmful to the performance of the rail in the track: non-metallic inclusions and flakes located in the critical zone of the rail-head where most fatigue defects originate. Studies have shown that the Ralus testing method does give a reasonable indication as to the quality of the rails.

DERAILMENT AT TYSELEY
An express passenger train comprising 12 coaches hauled by a Type 4 diesel-electric locomotive was approaching Tyesley North signalbox on the down main line at 60 to 65 mile/h when the bracket on the locomotive supporting part of the a.w.s. equipment became loose. The wheels of the rear bogie of the locomotive and of all 12 coaches derailed. Examination of the fractured bracket bolts confirmed that high stress fatigue failures had occurred in the four bolts. Use of maximum tightening torque of 758 lb-ft is essential to achieve the longest life under fatigue loading conditions. It was also recommended that the bracket design should be re-examined to see if longer bolts could be used.

INTERACTION OF WHEEL AND RAIL WITH RESPECT TO TRACKING, WEAR, FREE ROLLING AND STRESS IN WHEEL SETS

The author examines the interaction of wheel to rail with respect to tracking qualities, wear of wheel tread and rail, free rolling and stress in the power wheel sets under power or braking. A picture is shown comparing the stress lines in the rail under a wheel with the flange away from the rail with that where the wheel tread and flange both exert pressure on the rail. The verification of the theoretical considerations of these conditions by actual measurements has been made by modern techniques, which are closing the gap between theory and practice.

DEVELOPMENTS IN SPHERICAL ROLLER BEARING AXLEBOXES--2

The carrying capacity of a roller bearing is increased to a greater extent by using larger diameter rollers rather than by increasing the number of rollers. Except for the difference in the end faces of the rollers, the rollers in the new SKF Type C spherical roller bearings are symmetrical. The close conformity and the uniform distribution of the load over the roller length--give an increased carrying capacity of approximately 15 percent. This means approximately three times longer fatigue life, a factor of no little importance. The bearings are pictured in several railway applications.

EXPERIENCE OF UNDULATORY WEAR OF RAILS

Undulatory wear on corrugation in rails is universally considered to be of two main types: roaring rails or washboard track; and what is sometimes described as saddles. The majority of railways consider that speed has no relationship with corrugations. Undulatory wear appears from 3 to 12 months after laying. The general opinion is that braking decreases washboarding but increases saddles. In the U.S.A. experiments with an acetylene torch to temper the Martensitic area of the high polished spots of washboard corrugations caused the ridges in the track to disappear. Various methods of grinding have been tried, but none have proved permanently successful.

C4 037667
A WHEEL PROFILE: FOR BETTER RIDING AND LONGER WHEEL LIFE

Riding qualities can be improved and wheel life can be extended by making rather modest modifications to conventional profiles. The present AAR profile has one major shortcoming in common with the conventional British profile, and one additional problem that is unique to railroading in North America. The common problem is that there are two points of contact between the wheel and the rail when flange guiding is required. The uniquely American problem is associated with the inward cant at a 1:40 angle whereas the angle of the tread face is 1:20. Because of the angle between the rail and the tread face, there is rapid tread wear immediately after wheels are turned and an attendant loss in lateral riding qualities. The proposed profile uses a basic taper of 1:40. A flange throat contour which at all points has a slightly larger radius than the head of the rail, and a short section of flange face at a 70-degree angle. The region of the tread face which gets the least use is relieved at a 1:10 tamper. Using a modified flange throat contour will improve the steering action of a wheel set lateral movement of the wheel will be opposed by a smoothly increasing lateral restraining force and on a curve the rolling radius of the outside wheel can increase much more than is possible with a conventional wheel set.

DISC BRAKES IN THE U.S.A.
In 1948 the Union Pacific Railraod decided to use disc brakes in new stock. When the first disc-braked cars were put in service, they were mixed with cars equipped with clasp brakes. Trains composed exclusively of cars with disc brakes were assembled. The results have been a reduction in noise and in jolting when trains are being stopped. Thermal cracking of wheel tires has been virtually eliminated. Certain interesting cost figures have been got out comparing the use of clasp and disc brakes on one of the trains over a 12-month period. The cast-iron tread shoes of the clasp brakes required renewal after every round trip of 4,598 miles, 73 changes of shoes thus being made during the year; the disc brake shoes ran an average of 90,000 miles each, and so required an average of 3.73 changes only. Over a full year, the renewals of short clasp brakes cost a total of $48,865.60 and of the long type $65,045.26, whereas the corresponding expenditure for Budd disc brake renewals was $7,221.48.

FRICTION MATERIALS FOR RAILWAY BRAKING
The Ferodo composition brake block is compared to cast iron brake blocks. The braking characteristics are shown for the average of 20 stops using emergency brake applications of a train travelling 50 mph. The deceleration time for the Ferodo brake was greater than the cast iron brake, but the stopping distance was less. A composition brake block is less abrasive to the wheel than a cast iron block, and the product of wear less harmful. Although the Ferodo block still wears more rapidly than the wheel, its life has been found to be equal to as many as five cast iron blocks in some instances. Flange profiles are shown comparing the two types of brake blocks as to flange wear.

SPECIAL COMMITTEE ON CONTINUOUS WELDED RAIL
Rolling-load tests were made of specimens of continuous welded rail in the 12-in stroke machine on four acetylene welds, 4 electric welds, and 4 thermit welds. All of the thermit welds failed in this test. One acetylene weld also failed just below 2 million cycles. Other rolling-load tests were made in a 33-in. stroke rolling machine primarily to test the welds in the rail bases. All the acetylene and electric welds ran to over 2 million cycles without failure. Two thermit welds developed failures in the rail heads. A few other observations on possible causes of weld failures are listed, including grinding burns electrode burns, and cases where the flame goes out in oxyacetylene welding. The fastenings subcommittee reports five methods used to anchor welded rail across open-deck steel viaducts or long deck steel spans.

SERVICE TESTS OF DESIGNS OF MANGANESE STEEL CASTINGS IN CROSSINGS AT MCCOOK, ILLINOIS
This report covers the service performance of the solid manganese test castings in the crossings between the double-track lines of the Baltimore and Ohio Chicago Terminal Railroad and the Atchison, Topeka and Santa Fe Railway at McCook, Illinois. This solid pedestal design that was not depth hardened on the tread corners was retired after a service life of 3.60 years. This casting was removed from service because of the combined weakening effect of the cracks from the top to the bottom of the casting. On June 3, 1957, for the same defects, the solid pedestal design with depth hardening was retired after 4.44 years of service in the same crossing. Although the USS depth-hardened casting had more cracks at its retirement than the unhardened specimen, it is judged that the major portion of the increase in life for the depth-hardened one can be attributed to that treatment.

ESTIMATING WEIGHTS OF RAILS IN THE TRACK
The Railimeter measures rail in two directions simultaneously, and indicates the weight of the section in lb. per year by a pointer on a scale. If side cutting is present, a reading from a side-cut gage is subtracted from the reading of the Railimeter. Where the rail is galled it is of course necessary to displace the chair at the gall when measuring the weight of this section. A chart estimating rail life based on the Railimeter reading is illustrated. The results obtained with this instrument compare favorably with more laborious methods previously used.

TRACK MAINTENANCE AND HIGH CAPACITY TRUCKS
The high capacity truck from the maintenance of way standpoint is the means by which the increased gross weight of the large modern freight car is transmitted to the track, roadbed, bridges, trestles, viaducts and culverts, over which it must pass. As such, its design, dimensions and position are of vital concern to those responsible for the satisfactory operating condition of the railroad. Stress in rails and joint bars, track deflection, maximum load on ties and effect on undergrade bridges require specific consideration in determining whether or not a car can be accepted for movement; and if so whether it will be free-running or whether it will be restricted as to speed and routing. An immediate concern in relation to high capacity car trucks is the anticipated increase in shelling rail failures due to increased bearing pressure. Shelling rail failures are the result of the plastic flow of metal from the middle portion of the head toward the guage corner under high shearing stresses produced by intense wheel loads eventually starting a horizontal crack. The Joint Committee on Relation between Track and Equipment has recommended maximum axle loads of 52,800 pounds on 33 inch wheels, 58,400 pounds on 36 inch wheels, and 62,400 pounds on 38 inch diameter wheels.

MAINTENANCE CHECKS FOR ROLLER-BEARINGS
SKF has introduced an instrument for shock-pulse measurement of roller-bearings. The technique is based on spalling or flaking damage in roller-bearings producing mechanical shocks. Short-duration high-frequency oscillations produced by the shocks are transmitted to the bearing housing and by fitting measuring nipples to the housing at selected points, the shocks can be registered by an accelerometer. The magnitude of these is a measure of the degree of damage.

SNCF PROBES THE 200-300 KM/H SPEED BAND
Recent tests at high speeds have shown that ample adhesion exists to overcome train resistance at 300 km/h and no technical factors need prevent commercial operation on steel rails at this speed. High speed running does not seem to produce any particular wear of parts other than wheels, although a close eye is kept on the friction linings that damp the pantograph. For the track, the SNCF does not consider it economically desirable to raise maintenance standards beyond those now considered necessary for speeds of 150 km/h. The policy is to build the rolling stock in such a way as to exert no greater forces on the track at high speeds than the trains of 20 years ago caused at the lower speeds then prevailing. Ride quality and current collection are discussed.

WEAR OF RAILS ON CURVES
Abrasion caused by locomotives and electric motor coaches, the condition of the track, and methods of alleviation are discussed. Insufficient information is available to say what type of vehicle produces the most rapid wear in the outer rails on curves. Increase in tractive effort may result in increased transversal reaction and greater lateral wear of the rails. Rate of wear varies inversely as the radius of the curve, but no quantitative relation between degree of wear and radius has yet been established, nor have the effects of irregularities in curvature. What is certain is that excess or deficiency in cant causes unequal wear on rails.

FLANGE AND RAIL LUBRICATION
The Japanese National Railways has experimented with systems to reduce wheel and rail wear. Results of tests show that rail oiling reduces electric current consumption by 66%, reduces wheel wear to 1.25%, and reduces rail wear to 1%, compared with dry rail. Three systems have been suggested for lubricating the rails: site lubrication where it is picked up by the flange; flange lubrication in the vehicle; and automatic lubrication of the inside rail edge. A comparison of various devices to accomplish lubrication is included as well as a description of each system. Benefits of lubrication for different situations are included in a series of tables and charts.

HEUMANN-LOTTER TYRE PROFILE
The Heumann-Lotter tyre profile was evolved with the idea of giving somewhat greater safety against derailment of locomotives and rolling-stock. This profile was applied to all engine and tender wheels, and was felt to be of particular value with tender-first running with the tender nearly empty, a condition which gave the greatest risk of derailment. Before adoption as the standard profile by the German Federal Railway, 68 percent of all tyre-turning costs were due to needed flange re-profiling. Observations showed that the tyre mileage was 30 percent greater with the new profile than with the old.

WEAR AND CORROSION OF RAILS
The use of the Shaw Rail Contourograph to measure vertical wear is described and illustrated. The wide limits of specific rail wear on the British Railways and London Transport are shown as a result of corrosive influence of atmospheric pollution in tunnels and industrial areas. Annual wear is approximately proportional to the square root of the number of axles passing per annum. A comparison between the British and American rail wear values shows much lower values in America for specific wear at the same traffic intensity. This may be partly because of the higher carbon content in America where the relative humidity is above 80 percent for much fewer hours per annum, and atmospheric pollution from industry is less concentrated than in Britain. The effects of steel composition, axleload and braking on rail wear are discussed.

HEUMANN TYRE PROFILE TESTS ON BRITISH RAILWAYS
A new tire profile, based on the studies of Prof. Heumann, was designed and is illustrated. This tire profile should assist in ensuring good riding qualities, increase the resistance against derailment and this in turn should reduce tire and rail wear, and ensure a favorable wear pattern. This can be done by ensuring one-point contact running and a gradual transition of the throat profile. The result of trials carried out with standard 32 ton British Railways coaches running on B4 type bogies with 3-ft. wheels, positive axle guides, 19-1/2 in. effectively long swing-links and helical springs throughout are shown. Ride index values during acceleration and wear patterns for the tires are given. The tests have shown beneficial results, although further tests are needed.

TYPES OF SLEEPERS AND SLEEPER MAINTENANCE
Wood, steel, and concrete sleepers are compared based on experience to date with each type. No alternative has been found to the cross-tie or sleeper and timber was almost universally preferred at the time. Steel sleepers begin to fail from corrosion followed by cracks around the baseplate. Concrete sleepers may fail through cracking with ultimate exposure of the reinforcement. On an annual cost basis concrete may prove to be the cheapest sleeper-but this opinion is based on an estimated 50 year life for pre-stressed sleepers and experience is insufficient to justify the estimate. Preservation of

wood sleepers is usualy by creosoting. The article concludes that treated timber sleepers with fastenings are approximate in cost to steel sleepers, with concrete sleepers costing more than either.

MANGANESE-STEEL AXLEBOX LINERS
Wear of axleboxes, more than any other single feature, is responsible for requiring locomotives to be returned to the workshop for repairs, and the mileage between shoppings is directly connected with the wear-resisting properties of the materials of which the axlebox rubbing surfaces are composed. It became clear that any considerable improvement in shopping mileage would require different material for the flat surfaces of the axleboxes, and the practice of fitting manganese steel liners to roller bearing axleboxes suggested a line of attack. Details for fitting axleboxes with new liners are presented. The leading features which were observed during examination in the shops and sheds following mileage runs average 80,000 miles shows. 1. The surfaces of the liners which are in contact with one another become work hardened in service and take on a high polish. 2. A very interesting feature has been that reduction of "knock" or wear in a longitudinal direction has had also a beneficial effect on lateral wear. 3. Bolts and rivets of the horn liners have remained tight. 4. Scoring of the liners has been negligible. The manganese steel liner has been adopted as standard and it has fitted to new construction of all types. Apart from the potential increase in shopping mileage, the liners already are proving of considerable value from an operating point of view in reducing development of rough riding.

RUBBER-CUSHIONED RESILIENT WHEELS FOR MAIN-LINE RAILWAYS
Most types of rubber-cushioned resilient wheels, including those for tramways and for narrow-gauge railways, consist of three metallic discs. Between these discs are placed either circular rubber blocks, positioned in one or two concentric rows, depending upon axleload, or a single pair of large rubber discs, which may be divided into segments. The central metal disc is fixed either to the wheel or to the wheel hub. Several applications of rubber-cushioned wheels, both on tramways besides main and secondary railway lines, have shown considerable reduction of maintenance costs for the mechanical parts and electric equipment, particularly collectors, because of the radial and tangential flexibility introduced by these wheels. The reduction of the wear on tires and flanges with resilient rubber-cushioned wheels, must result in a corresponding reduction of the wear of the rails.

REDUCING FLANGE-WEAR ON BOGIE LOCOMOTIVES
The phenomenon of relatively rapid flange-wear on sharp curves with the bogies of Bo-Bo and Co-Co locomotives must be accepted pending the results of further research into the reduction of bogie weight and unsprung weight, the height of the bogie centre of gravity, different relative speeds of the axles and motors, weight transfer, etc. Flange or rail lubrication using a lubricant matched in viscosity to suit the ambient temperature lengthens the flange life from six to nine times, this factor varying according to the tire steel used. A change from tires of "D" steel to those of 70-ton tensile steel alone can increase flange life by as much as three times. A combination of lubrication, hard tires, and the fitting of a centralizer linking the movement of the two bogies and which is capable of drastically reducing flange forces on curves, will improve flange life by 12-15 times.

WHEEL AND RAIL LUBRICATION
Remarkable increases in life of rails and wheel flanges through lubrication, by as much as 700 percent, are quoted by Dr. Fritz Birmann, in his paper "Lubrication of Rails and Wheels." The requirements of a lubricating system to reduce wear of rails and tires, are that the lubricant must be prevented from spreading to the running surface of the rail, thereby reducing traction; that the efficiency of the system must not be spoiled by dust, dirt or weather influences; that the lubricating devices and spray nozzles must be profile free on the rail and vehicle; and that lubrication must not start too late on the curve, so that it is preferable, where possible, to lubricate tires before entering the curve.

RAIL CORRUGATION--CAN IT BE PREVENTED
This is a research report which attempts to determine the causes of rail corrugation. The author suggests that higher rail speeds may cause rail corrugations or undulations as deep as 0.01, which accelerate rail wear. A relationship is established between the natural frequencies of rail vibration and the wear length of the corrugation. Further experiments are required into the possibility of eliminating corrugation by axle redesign as well as changes in rail profile and tie spacing.

MECHANICS OF WHEEL AND RAIL
Tire-profiling tests undertaken in New South Wales to reduce oscillation resulted in an increase in the severity of the oscillations, which was directly traceable, not to the contact of the flange root with the edge of the rail, but of the steeply inclined portion of the tread adjoining the flange root. This is a well-known characteristic of all worn or hollow tire profiles. The objective of the tests was to defer the formation of the objectionable tread ramp near the flange in a worn tire. The design specifically allowed that there should always be a portion of the root radius still available to contact the edge radius of the rail. Diagrams representative of each of the tire contours and conditions of service are reproduced. In these diagrams, there will be noted a step developed after service at the junction of the flange root and the recess due to flange wear.

C4 039480
WHEEL HUNTING AND IRREGULAR RAIL WEAR
In addition to the "hunting" of rolling stock wheels, there is the constant side-to-side movement of individual pairs of wheels. The standard taper of coning of wheel-treads is at 1 in 20, so the tread of a new tyre may be at right-angles to the centre-line of the rails. Experiments have been tried in varying the angle of taper of the treads and the radius of the railhead, but the wear of tires and rails complicates the problem, and hitherto has made it difficult to come to any final conclusion as to how the hunting problem may be solved. Persistent bogie hunting can cause bogie stock to ride uncomfortably. Of even greater importance is the wear-and-tear of rolling stock and the damage to rails caused in this way.

C4 039481
THE MOVEMENTS OF RAILWAY VEHICLES ON THE TRACK AND THE FORCE ARISING THEREFROM
A critical analysis is given of the interaction of flanges and rails, together with a resume of the scientific principles involved. The friction arising between wheel and rail is fundamental for all railway transport. The frictional force R is equal to or less than the product of the frictional factor f and the wheel load Q, which are the variable quantities. As the direction of force R coincides with the resulting sliding motor between wheel and rail, its action is opposed to the direction of motion. Force R determines not only rolling resistance, but also that due to curves, guiding pressure, security against derailment, maximum tractive and braking power, axle strain, wear of rail and flange, and--last but not least--freedom from hunting. Methods to determine the precise position and value of R are discussed.

PULLMAN'S APPROACH TO CENTER PLATE PROBLEMS
Tests were conducted on fabricated cushioned underframe center plates using a Hy-Cube car, using a car rocking device designed to excite a fully-loaded car at its natural roll frequency. Results were correlated with field service reports. Tests were in progress on the rocking device using a 100-ton covered hopper car. The conclusion of the two-year test program on cushioned underframe cars has indicated these results: rock and roll is instrumental in center plate wear and breakdown; breakdown originates in the transition radius and propagates into the transverse and longitudinal reinforcement; the 3/8" radius is not satisfactory for today's fatigue environment; longitudinal reinforcement on the center plate should be located over the outer circumference of the bowl; a flat center plate application significantly reduces the attachment pre-stress in the transition radius; both fabricated and cast center plates can develop cracking unless fatigue design is considered; the center plate application is related to car configuration; and supplemental snubbing devices that reduce car body roll would increase the fatigue life of center plates.

BALL AND ROLLER BEARINGS IN MODERN ROLLING STOCK
An increasing number of specifications calls for ball or roller bearings to be fitted at all vital points for locomotives and coaches. Advantages which have been realized include: (1) up to 85% lower starting and about 10% lower running resistance. (2) Reduced charges for inspection and maintenance. (3) Fewer hot boxes, resulting in an increased availability factor. (4) More economical use of lubricants. (5) Maintenance of axle and valve gear centres as designed, by virtue of the absence of wear. In the construction of locomotives and rolling stock generally, the following gives a fair idea of the extent to which this type of bearing has been used: locomotives: axleboxes, bogie driving, truck, and bogie pivots; spring compensation beams. Rolling stock: axleboxes bogie pivots. Diesel-engine vehicles; axleboxes; gearboxes; engine bearings; generator, armature bearings; motor armature bearings.

APPARATUS FOR DETECTING WHEEL-SEAT FLAWS IN RAILWAY AXLES
The Research Department of the London Midland and Scottish Railway Company undertook the task of devising and developing a method of detecting wheel-seat flaws in railway axles without removing wheels from axles or even wheel and axle assemblies from the coach. The essential item consists of a rigid steel ring of square cross section, split diametrically to allow it to be clamped to the axle under test. Contact with the axle occurs at three spherical seatings, of which two are fixed to the inside of the ring and the third is adjustable and is screwed to grip the axle firmly after the two halves of the ring have been bolted together. The system described comprises essentially, two nominally rigid reference planes, fixed normal to the axle and set one on each side of a possible flaw situated near the inner end of the wheel seat. If such a flaw does exist the strength of the axle will be less in the direction passing through the center of the axle and the centroid of the flaw than in the direction at right angles to it. Details and case histories are given.

A NEW FATIGUE DEFECT IN RAILS
The shelling defect has been most commonly encountered in the 131-lb standard flat-bottom section, though it has been reported in some degree in all sections from 100 lb. upwards. The first manifestation of the trouble is the appearance, on the running surface of the rail near the running edge of dark spots, which indicate the presence of horizontal planes of separation of the steel within the rail-head; these may occur at a number of different levels in the same rail. The shelling is the result of wheel action on the rail causing failure of the metal, either by direct stress exceeding the elastic limit, or by loss of ductility which is the outcome of constant reversals of stress. Factors which may influence the relative severity of the shelling are the inclination of the rail, the superelevation, the bearing pressure exerted by the wheels, the radius connecting the flanges and the treads of the wheels, and the radius of the gauge corner of the railhead.

RAIL WEB FAILURES
Out of 30,881 failures of new rails in U.S.A. tracks in 1942-51, and removed during that period because of defects, 13,554, or 44 percent, were web failures. The great majority of the latter were failures within the area of the rail joint. Laboratory and track tests showed that many web failures could be explained by corrosion-fatigue but not by corrosion alone. Various factors increase the web stresses at rail ends. One is poor or irregular fit of fishplates; loose or worn fishplates or loose fishbolts have a bad effect, as they are liable to cause greater impacts to develop under the rolling load. Excessive gaps at the rail-joints or battered rail ends similarly tend to increased impacts.

THE SAFE LIFE OF RAILS EXAMINED
The rail sections considered are the 109-lb. fb and rBS 95-lb. bh rail, both in common use on British Railways. Among the conclusions reached by the authors is the fact that the rail sections standardized by British Railways are of sufficient strength for long life under existing steam traffic where maintenance is good and corrosion not severe. But, they believe that rail life should be governed by the type, speed, and quantity of traffic carried rather than by loss of weight. Furthermore, they suggest that any practical way of altering rail joints to increase their life should be investigated and that the development of special joints for the ends of welded rails would appear necessary irrespective of any stress-relieving requirement.

WORK-HARDENING BOLT HOLES IN RAIL ENDS
Analysis of rail failures has shown that the most frequently occurring type of failure is that classified as "4d" which takes the form of radial cracking from one or both boltholes known as star cracking. Various methods of improving the fatigue strength of drilled rails have been tested. The greatest improvement has been obtained by work-hardening the surface of the holes, by intially drilling undersize followed by broaching or drilling drifting with a spherical tool to the required size. The work hardening has resulted in increasing the fatigue strength of the rail by 50 percent, a figure which is maintained after exposure to corrosion. No trouble was experienced in workhardening any of the holes, including those where the axis is inclined to that of the rail.

THE RAIL SHELLY CRACK IN JAPAN
Investigation into the growth mechanism of shelly cracks and a method of prevention is reported. Examinations included track condition, materials quality, loading condition and friction and wearing phenomenon of affected rails. It was found that in the ordinary contact condition, the contact stress between tyre and rail is so large that plastic flow is caused. With the progress of plastic deformation, steel becomes hard and its elastic limit rises. After these changes, rail surface becomes fit for ordinary wheel load. Though before this time the progress of plastic flow nearly stops, the crack grows through the fatigue due to rolling with slide. It was also found that the existence of ferrite in the surface layer seems to take part in the growth of the crack. As a first step in preventing shelly cracks, rail steel should be strengthened against fatigue. Water decreases the wear of rail and accelerates the development of crack. These conditions promote the growth of the crack due to the rolling fatigue. Secondly, though the decrease of stress is difficult to realize in general, the decrease of lateral force and the decrease of contact stress by decreasing the difference of both curvatures in contact part of wheel and rail are found effective. Thirdly, as it is clear that the existance of water is unfavourable, total stop or restraint of watering is very effective. Since the same effect is achieved by oiling, it is necessary to be careful not to oil excessively.

REPORT ON THE CHARACTERISTICS OF STEELS AT LOW TEMPERATURES--COUPLER INVESTIGATION
The report discusses problems in finding a basis for coupler failures between geographic areas. The parameter for comparison was the number of failures per freight car miles travelled. Conclusions are that more couplers fail during cold than hot months. The critical temperature for failure occurs a few degrees below freezing.

ALUMINUM IN ROLLING STOCK; THE VALUE OF RESEARCH AND DEVELOPMENT
In Canada, aluminum is considered standard for box cars roofs, the inside lining of refrigerator cars, brine tanks, hopper cars for bauxite and alumina, hopper car hatch covers, piggy-back trailers and passenger car furnishings. The properties of aluminum which make it ideal for use in rolling stock are good strength and impact resistance, light weight, excellent corrosion resistance and good fabricating characteristics. Service experience and impact tests, which were more rigorous than conditions encountered normally, have shown that all-welded aluminum hopper cars are strong and rugged enough to withstand such severe treatment. Impact and fatigue test results are reported for several types of aluminum cars. The lightness of aluminum cars mean that fewer of these cars are required to transport a given cargo. The excellent resistance of aluminum to the weather and corrosive cargoes means that annual maintenance costs can be lowered appreciably. The life of the aluminum cars will be governed by failure due to mechanical causes rather than corrosion and even after their normal service life they will have a high scrap value.

RECENT EVOLUTION IN ON THE RAIL INSPECTION ON THE S.N.C.F.
Ultrasonic probing enables an operator, shifting a transductor over the surface of the railhead, to assess the extent of a crack. Rail inspection by ultrasonic apparatus employs two methods: vertical probing by a straight line transductor where the steel is subjected to a longitudinal beam of waves; and oblique probing by a transductor subjecting the steel to a refracted beam of transversal waves forming an angle of 65 degrees to 70 degrees with the vertical. The transversal fatigue cracks due to rail-head fatigue often causing railbreaks are detected by oblique probing. The present permissible speed at which the transductors are made to move along the rail is 12 km/h. The annual number of rail-breaks on the inspected lines which was about 1,100 has fallen to under 400, the majority of breaks being due to defects non-spottable by probing.

THE BEHAVIOUR OF THE MOTIVE POWER AXLES (WHEELS) ON THE S.N.C.F.
Wheel-set stresses are modified by the action of the strains inherent in service which may be categorized as follows: those affecting the shrinking-on; those which correspond either to vertical effort exerted by the wheel on the rail, essentially cylical, or to the lateral reactions of the rail on the wheel both cyclical and erratic (abnormal shocks); and those set up by a temperature rise, due to braking. The SNCF has tested, both in the laboratory and in service, the diverse stresses as they are linked up with strains. Common damages to wheelsets are described and are shown. Wheel manufacturers are using the test results to enhance wheel design criteria.

RESEARCHES ON INCREASING THE FATIGUE STRENGTH OF PRESS-FITTED AXLES
Fatigue tests with 50 mm dia. press-fitted specimens, heat-treated by Tufftride process or other processes, were made to determine the influence of those treatments upon fatigue strengths, sigma(sub omega 2) and sigma(sub omega 1). These are fatigue strengths based upon complete fracture of the shaft and initiation of minute fatigue cracks in fretted region. Main results obtained as are as follows: tufftriding is strongly effective to increase sigma(sub omega 1) as well as sigma(sub omega 2); if the superficial compound layer of iron and nitrogen is removed, sigma(sub omega 1) is lowered but sigma(sub omega 2) does not change; specimens, heated in Argon gas at the same temperature as Tufftride process followed by quenching in water, have the same sigma(sub omega 2) as that of Tufftrided ones. It is concluded that the increases of sigma(sub omega 1) and sigma(sub omega 2) by Tufftriding are due to the hard compound layer and the compressive residual stresses.

DEVELOPMENTS IN THE QUALITIES AND SERVICE CAPABILITIES OF PRESENT-DAY RAIL STEELS
The service requirements are discussed for steel rails, which are constantly increasing to bear the heavier axle loads and higher speeds, and with increased resistance to wear, fatigue and fractures. The progress in the manufacture of rails is related, including the improvements in profiles, dimensions, quality and physical properties, as shown by tables and charts. The forseeable limiting area of tensile strength for self-hardening alloy steel for the rails is given as 192,000-206,000 psi. Improved resistance must be developed to wear, plastic deformation crushing and fractures in the rail head, by raising the tensile strength, yield point and fatigue limit. [German]

C4 040028
STEEL TIES FOR FIRST CLASS TRACKS
There is a revival of interest in steel ties due to newly designed shapes and improved manufacturing processes. The new ties have a higher moment of inertia and greater strength. Annealing after the cold working insures greater fatigue resistance and reduces the likelihood of cracks developing. Advantages of steel ties include: long life, the possibility of re-use later in secondary lines, and the reclamation possible after a derailment. Under switches, the longer lengths of steel ties are more easily provided. On electrified lines, steel ties provide an ideal grounding connection. The better quality of steel makes the welding process more usable for fastening the rail holding plates to the ties without the possibilities of fractures. [German]

STUDY OF RAIL FAILURES IN THE TRACK--STANDARD RAIL FAILURE STATISTICS
The main object was to define the type and form of presentation of rail-failure information to be supplied by various ORE Member Administrations so as to permit the better use of such information-and to draw some concrete conclusions. Committee D 88 found great difficulty in identifying a suitable denominator to which the rail failures could be related for purposes of comparison between administrations. In the absence of a more reliable denominator rail failures were related to the kilometres of track concerned with the type of failure being compared. This should enable Administrations to decide whether their present policies in regard to choice of rail section, steel quality, rail welding, joint design, track maintenance policy, rail renewal frequency (only to quote the main factors), require any alteration.

Restrictions on the use of this document are contained in the explanatory material.

SUITABILITY OF SIX-AXLE LOCOMOTIVES FOR C&O--B&O SERVICE--THE INTERACTION WITH TRACK STRUCTURE
A series of tests was conducted with 6-axle locomotives in heavy, coal drag service on Cranberry Grade to investigate the interaction of locomotive tractive power and track conditions. Particularly, the performance of 6-axle locomotives in this service was investigated to determine the relative merits of that design versus the 4-axle units previously used. Five major areas were found to be significant and completely interdependent: I. Locomotive wheel life with 6-axle units. II. Rail cleanliness affects locomotive adhesion. III. The condition of the track and the rail govern overall acceptability of 6-axle locomotives. IV. Operating practices covering the use of sand are related to increased wheel wear and increased track maintenance. V. Instrumented wheel tests: A. To determine to what extent and under what circumstances the wheel and rail wear attributable to 6-axle locomotives exceeds that of 4-axle units. B. To determine effect of track surface on locomotive riding qualities. C. To determine suitability of 6-axle locomotives.

OBTAINING A SMOOTH-RUNNING BOGIE--2
An approach to improve the conventional type truck as used on multiple-unit and locomotive-hauled stock by considering its faults is suggested. The tendency of the bogie to snake can be greatly reduced by guiding both axles rigidly in the frame and so forcing them to remain parallel, i.e., within 0.04 in. by using roller bearings. The second method of attacking hunting is to prevent the whole bogie frame from snaking by deliberately introducing friction to discourage it from rotating slightly about its pivot. The sidebearer friction will rise in step with tire wear and snaking tendency if the sidebearers are greased only once when the tires are profiled.

CARRIAGE AND RAILCAR BOGIES: THEIR DESIGN AND DEVELOPMENT--IV
Design factors considered in this part include brake ratios; axle fatigue; adhesion, and P.D. More effective braking will require ratios 1:1.5 to 2.2 of the tare weight, cut back to 0.8 at lower speeds. A routine method of axle fatigue calculation indicating the influence of such design variables as fillet radii, type of vehicle, speeds, whether four-wheeler or bogie, and so on, relating to dynamic load allowance and other factors is long overdue. Adhesion improvement through truck linkage to the body at low level requires care that bogie pitching will not cause high stress peaks at the kingpin or cause intense shuttle of the body.

LATERAL OSCILLATIONS OF BOGIE BOLSTERS
It is imperative to break away from the adherence to general recipes regarding spring rates and swing link angles of inclination often regarded as a universal panacea against ailments generally diagnosed as "bad riding." Vertical leaf springs succeed only in increasing the lateral centering force thus reducing the effective length of the swing link arrangement and increasing its natural frequency, inadvertently acting as swing link spoilers. So far as design layouts are concerned detail components should be used along rational lines, each component being allowed to perform the basic function allotted to it. Thus swing links should be permitted to swing and dampers used to ensure damping. Excessive body amplitudes sometimes encountered with some designs can be controlled with the aid of lateral centering springs preferably with a non-linear characteristic and here suitably shaped rubber units can be of great help.

DISCUSSION ON STRESSES IN RAILROAD TRACK
The inspection tests of rail-joints in track made for the purpose of learning the source of the wear of the joint bars and the rail, the places of wear, information bearing on the mutual interaction of the worn bars and rail when under load and when the bolts are newly tightened, and other information relating to the stability and maintenance of the rail-joints have given desirable information. The occurrence of high stresses in the unloaded worn joint bars in track due to the tightening of the bolts was found to be as great as 30,000 and 40,000 lb. per sq. in. and in a few cases as high as 60,000 lb. per sq. in. The stresses were fairly proportional to the amount of the lateral bending put into the bar by tightening the joints, measured from the loose condition. The instruments designed and built to facilitate the measurement of profiles and shapes and straightness of joint bars and rail and their position with respect to each other in the joint have proved satisfactory.

WHEEL, AXLE, AND RAIL STRESS PROBLEMS RELATED TO HIGHER CAPACITY CARS PART 1 AXLE PROBLEMS
This paper submits some fundamental considerations in the design of axles and propose two new axle designs of 72,000 and 80,000 pounds capacity. Larger axle design standardization must satisfy a wide range of car geometry factors such as (a) center of gravity height from 72 to 94 in and (b) wheel diameter ranging up through 40 in. The effect of these factors on axle capacity is shown by curves derived from the Reuleaux formula; serious deficiencies in this formula are also discussed. Other primary axle design factors presented are (c) wheel seat design (f) effect of switches, frogs, and crossings (e) effect of curved track (h) effect of flat spots and shellouts of wheel treads.

BRITISH RAILWAYS INVESTIGATIONS INTO THE PROBLEM OF AXLE FATIGUE FAILURES UNDER THE WHEEL HUB
This paper discusses the problem of the fatigue failure of railway axles and points out the main factors contributing to failures of this type. The reasons behind the investigation currently in progress are described and the results obtained to date are given. Future work is detailed and it is shown how the results of these experiments should enable a more satisfactory axle service performance to be obtained. A certain amount of increase in axle fatigue strength has been obtained by the straightforward application of metallurgically better materials--as happened when wrought iron was replaced by steel. However, because of the overriding importance of shape in a component subjected to fatigue loading, as an axle is, it can be predicted that the use of even higher strength steels will not produce proportionate increases in axle fatigue strength unless allied to a shape of axle which excludes, as far as possible, all notch and stress concentration effects.

WHEEL, AXLE, AND RAIL STRESS PROBLEMS RELATED TO HIGHER CAPACITY CARS--PART IV-EFFECT ON RAIL
Those items that have been found advantageous in reducing shelling caused by higher capacity (85 to 100-ton) cars are wheel loads should be limited in proportion to wheel diameter. Higher strength material in the rail will greatly reduce shelling but not entirely eliminate it (under the wheel loading conditions existing with 70-ton capacity cars before the allowable load was increased 5%). Modified rail head contours in today's modern rail sections which approach the average worn wheel condition, have been helpful in reducing shelling. Rail lubrication on curves extends the rail life but results in the removal of more rails for shelling rather than abrasive wear.

WHEEL, AXLE, AND RAIL STRESS PROBLEMS RELATED TO HIGHER CAPACITY CARS--WHEEL PROBLEMS
Factors to consider in selecting a wheel for high capacity cars--aside from dimensional compatibility with the rail and truck, are wheel class, wheel diameter, and rim thickness. Rim thickness determines replacement period and is primarily a function of car utilization. Wheel diameter determines stress in the contact area of the wheel tread and rail. Wheel class determines relative resistance of wheels to wear and service damage, principally shelling and thermal cracking. Safety and economy of the operation depends largely on freedom from excessive shelling, thermal cracking, and rapid wear, all commensurate with the cost of new wheels, reconditioning, and maintenance.

A THREE-DIMENSIONAL FINITE DIFFERENCE SOLUTION FOR THE THERMAL STRESSES IN RAILCAR WHEELS
A numerical solution is presented for both the transient temperature and three-dimensional stress distribution in a railcar wheel resulting from a simulated emergency brake application. A computer program has been written for generating thermoelastic solutions applicable to wheels of arbitrary contour with temperature variations in both axial and radial directions. The results include the effect of shear stresses caused by the axial-radial temperature gradients and the high degree of boundary irregularity associated with this type of problem. The program has been validated by computing thermoelastic solutions for thin disks and long cylinders; the computed values being in good agreement with the closed form solutions. Currently, the computer program is being extended to general stress solutions corresponding to the transient temperature distributions obtained by simulated drag brake applications. When this work is completed, it will be possible to synthesize the thermal history of a railcar wheel and investigate the effects of wheel geometry in relation to thermal fatigue.

ANALYSIS OF RESIDUAL, THERMAL, AND LOADING STRESSES IN A B33 WHEEL AND THEIR RELATIONSHIP TO FATIGUE DAMAGE
This investigation involves the problem of service loading conditions that produce the highest stresses and the possibility of fatigue damage. Static loading, rim heating, residual stress measurements, and fatigue tests were made in the laboratory on representative b33 wheels. A series of simulated loading conditions was studied and the resulting stresses combined by simple superposition principles. The resultant stress patterns were compared with fatigue test results using the modified Goodman relationship. In this way the service loading conditions that produce fatigue damage may be predicted.

EFFECT OF DESIGN VARIATION ON SERVICE STRESSES IN RAILROAD WHEELS
The continuing trend of present railroad operating practices toward higher wheel loads and speeds has created the need for better design criteria to insure that wheel configurations are the best attainable. Computer programs to simulate service braking and loading conditions have been applied to various wheel designs and the braking and loading stresses computed. The results indicate that cyclic stresses of significant magnitude may occur under different operating conditions, so fatigue concepts are important in wheel design considerations. There was no one optimum wheel design for all possible service conditions, although several configurations showed promise. A method was proposed for optimizing design for specific service conditions to safeguard against fatigue damage.

WEAR OF IN-SERVICE SWITCH RAILS
A series of three related letters address the problem of excessive wear in switch points. Attempts to relate the wear problem to rail chemistry and hardness are described. It was thought that rail with higher carbon content would resist flow and show less wear than rail low carbon contents. Hardness could not consistently be related to wear.

RAIL ABRASION AND END BATTER OF CONTROL COOLED 131 LB. R.E. RAILS

This is a progress report showing results of rail abrasion and end batter of control cooled 131 lb. R.E. rails rolled and treated by various manufacturers and laid during 1935. The Illinois and Bethlehem rails were laid on the Middle division No. 4 westbound passenger tracks on tangent and 4 degrees 0" curve east and west of Lewistown, Pa. The Carnegie and Inland rails were laid on the Panhandle Division No. 1 eastbound passenger and freight track on tangents and curves ranging from 3 degrees 14' to 7 degrees o" west of Carnegie, Pa. It was found that for the tangent track the differences in both abrasion and batter as between thermal treated and ordinary hot bed cooled rails are hardness of the rail has resulted from the thremal treatment. The information for curve is not directly comparable on account of wide variations in curvature where measurements were obtained. There have been no transverse fissures or other failures in either the test or comparative rails during the three year period between measurements.

STRESS CORROSION OF RAIL WEB STEEL (STATIC)

The test included six rail joint segments containing one bolt hole with a bolt inserted to make the joint. It also included twenty steel specimens taken from rail steel which were subjected to static bending stresses. The twenty corrosion test specimens were tested after nearly twelve and one half years of exposure to the elements. The joint segments were tested approximately one month later. All of the test specimens were cleaned throughly and examined in the laboratory by Magnaflux and Magnaglow methods for the presence of corrosion cracks. While there was considerable pitting to be found, the laboratory examination disclosed no cracks in any of the specimens. This test shows that static stress combined with corrosion has little or no effect upon the development of cracks in rail web steel.

DETERMINATION OF PLASTIC FLOW IN RAIL HEAD

The purpose of the test was to determine the amount of plastic flow which takes place in the gauge corner of a rail on the high side of a curve under conditions which produce shelling. The rails were laid on the Bolivar Curve. At this location the track was laid with 140-lb., 1948 rail, which in August 1953, was showing flaking and light shelling. This is a 4-degree curve with 4-inches superelevation, authorized speed 45-mph, and carries moderate to heavy eastward freight traffic. Records kept in connection with another test indicate a tonnage of approximately 29,000,000 gross tons annually. The three test rails were installed August 17, 1953. Inspection September 12, 1955, showed light flaking on all three rails. On the high rail of curves there is a flow of metal at the top gauge corner of the rail toward the gauge side. This flow of metal extends to a depth of 1/4-inch to 3/8-inch below the rail surface. The magnitude of deformation is positive evidence of shear stresses well beyond the yield point of the steel.

C4 040279
RAIL WEB STRESSES IN HIGH SPEED TERRITORY

The purpose of the present test was to determine if possible the cause of frequent split web failures in the joint on 131-lb. RE rail on the Fort Wayne Division, and in 152-lb. PS rail on the New York Division. Web failures in 131-lb. and 152-lb. rail on the Fort Wayne and New York Divisions are adequately explained by the corrosion fatigue theory. The ocassional bolt hole failures in 133, 140, and 155-lb. rail are not readily explained. A 50% allowance for impact is justifiable based on measured wheel loads. Application of reformed bars changes stress distribution in the rail web and in many cases increases web stresses, accelerating rail web failure. Loose bolts and increase in rail end gaps increase rail web stress. The results of this test emphasize the need for protection of rail steel against corrosion, for maintaining standard bolt tension, a good fit between bars and rail, and good surface through joints.

C4 040281
ALLOY STEEL RAIL (CHROME-VANADIUM OR "CV")

The CV rail was laid in October 1953, in connection with regular rail renewals. The location was selected because it was one where moderate shelling had developed in the previous 131-lb. rail over a period of about 11 years. A total of 47 CV rails were laid--16 on the low side and 31 on the high side of the curve. Measurements of gauge superelevation, ordinates and rail head wear were made. A final inspection of CV rail was made on October 29, 1959, at which time 30 CV rails remained in track. There was no indication of shelling, although, some flaking was noted on the CV rail, and there was no indication of rail and defects. The results of this test have shown the CV alloy steel of the composition used to be unreliable. Its good wearing qualities and superior resistance to shelling are over-shadowed by its poor resistance to impact.

FLAME HARDENED AND HEAT TREATED STOCK RAILS

Flame hardened and heat treated stock rails were installed at locations where the open hearth stock rail had shown short life due to excessive wear, primarily flange wear. Flame hardening and heat treating produced a Brinell hardness on the rail head of approximately 350. Both the flame hardened and heat treated stock rails gave better performance than the open hearth stock rail; however, the flame hardening process resulted in considerable vertical distortion of the stock rail, as much as five feet in 60-ft. As a result, this type of hardening was discontinued. While this test was installed initially to investigate the reduction in flange wear, the use of heat treated stock rails to date and the results of heat treated rails used for other purposes indicate that they provide greatly increased life and reduced maintenance as compared with ordinary stock rails where crushing and plastic flow cause frequent renewal.

FLAME HARDENED VS HEAT TREATED AND MANGANESE CROSSINGS

The purpose of this test was to determine the relative value from a service point of view of flame hardened crossings, as compared with heat treated and manganese crossings. Two flame hardened, one heat treated and one maganese crossings were installed on new timber supports in a two over two track crossings, making an angle of 71 degrees 38'. All crossings were interchangeable. These crossings were installed on May 2, 1953. On the September 8, 1954, inspection it was found that excessive batter on one of the flame hardened crossings made renewal necessary. Initial cost, maintenance required, as well as service life indicate a preference for the heat treated crossing over the flame hardened.

ANALYSIS OF TAPERED ROLLER BEARING DAMAGE
Tapered roller bearings, damaged in field applications or laboratory tests have been subjected to a systematic analysis of such damage to prevent its recurrence in the field or to gain knowledge of its control in the laboratory. A method of analysis is described which has been developed for examining such bearing damage. The essential steps of the analysis are described with emphasis on the visual classification and metallographic examination of the damage. Bearing damage is classified in two major categories, that resulting from contact fatigue, and that due to other mechanisms. Damage which is related to material, surface finish, geometry, local asperities (grooves and bruises), the lubricant viscosity is usually due to contact fatigue. Damage due to other mechanisms is that which results from obvious mechanical, chemical, or electrical factors in the application which either change bearing geometry or eventually cause contact fatigue.

A VIBRATING RIG TEST FOR RAILWAY BEARING GREASES
A test rig utilizing a standard reaction type vibration test machine was developed to determine the consistent stability of grease lubricants in anti-friction bearings. This program was undertaken in view of the ever increasing demands upon greases in railway service and also the lack of direct correlation among performance characteristics obtained through existing standardized bench tests, full scale rotational tests lacking vibration, and those characteristics displayed in the field. General performance of the products tested appeared to be insensitive to the parameters of vibration within the range of parameters occurring in service. A 48 hours test which subjects the test cartridge to 4 G's at 38 cps with the grease bulk temperature thermostatically controlled at 180 F emerged as the condition which yielded results duplicating field service conditions.

FATIGUE TESTS OF FREIGHT CAR AXLES 5 1/2 TIMES 10 INCH JOURNALS
The series of fatigue tests was concluded on a proposed design of raised wheel seat freight car axle with "as forged" (unmachined) body between wheel seats. The proposed design has a considerably greater fatigue strength in the wheel fit than the Standard Freight Car Axle (Black Collar Design). One group of Standard Freight Car Axles had an abnormally low fatigue resistance of 13,000 psi in the body portion between the wheel seats. This value was raised to the normal value of 17,500 psi by stress relieving at 1150 degrees F for six hours. One group of axles of the proposed freight car design had a similarly low body fatigue resistance of 13,000 psi. Machining the axle body was found to be beneficial in improving the fatigue resistance. This finding may mean that unfavorable residual stresses due to straightening were removed by machining.

STUDY OF VIBRATION FREQUENCIES UNDER IMPACT CONDITIONS
A study is presented of vibration frequency characterisitcs under impact conditions for typical friction type draft gears used on railroad freight cars of a comparison of typical instrumentation records showing force-closure clutch action of typical and of representative electronic equipment used to measure these vibration forces. When determining the reaction-force characteristics of draft gears during closure, careful selection of instrumentation must be made. Instrumentation having a flat frequency response of 0 to 600 cycles is prefereed in order to attenuate the higher frequencies encountered in friction-draft-gear characterisitcs. Instrumentation having higher frequency response can be used but this usually results in confusion in interpreting the records to determine the fundamental force measurements.

R.M.C. PLASTIC RAIL JOINT PACKING WITH VERMICULITE BASE
R.M.C. Plastic Rail Joints Packing is a cake composed of vermiculite impregnated with an asphalt oil and rust inhibitors. It is placed at the end rail behind the joint bar for the purpose of lubricating and protecting the joint. No-Ox-Id "A" is a rust inhibiting grease used for the same purpose. Comparison was made of these two substances by applying them to alternate 10 joint stretches. While the damage to rail ends by corrosion fatigue, which was found in so many cases with the original R.M.C. packing, does not seem to be repeated with the Vermiculite packing, there is no evidence that the overall protection is superior to that given with No-Ox-Id "A". The protection to the rail end in most cases appears to be inferior. Since rail web failures have been reduced in new rail designs, and since there was a lack of apparent benefit from the use of packing, the use of packing was abandoned.

STRESSES IMPOSED BY PROCESSING
Types of residual stress, measurement and formation are discussed. Residual stresses were measured on two different sizes of truck axle shafts of 1 11/16-in. and 2 1/8-in. diameter. Two specimens were taken for residual stress investigation from each shaft, one toward the flange end and the other from the splined end. Metallurgical examination was made. Results of completely reversed torsional fatigue tests made on 1 11/16-in. diameter shafts are presented. Fatigue tests were made in rotating bending on full-size large-diameter shafts of two different designs. Fatigue results are summarized. Residual stresses were measured in these large shafts. Favorable surface compressive stresses were determined for these shafts water-quenched from the tempering temperature as compared with nil stresses in those aircooled. It was concluded that favorable thermal stresses were a very important consideration in improving fatigue strength.

FATIGUE OF LARGE SHAFTS BY FRETTING CORROSION
Rotating bending fatigue tests were made for the AAR on sixty-six shafts of 9 1/2 inches diameter. A press-fitted member was mounted on each shaft. Fatigue failure initiated in the shaft under the fitted member. Six different engineering steels were used for the shaft forgings. Some steels were normalized and tempered while others were quenched and tempered. Two groups of specimens were quenched below the critical temperature to develop residual compressive stresses in the surface zone. All shafts were run 85 million stress reversals unless breakage developed earlier. The maximum allowable bending stress of endurance limit to prevent the shaft breaking off under the fitted member for all normalized and tempered or quenched and tempered shafts ranged from 9,500 to 12,500 lb. per sq. in. The two groups of shafts given a subcritical quench gave endurance values of 18,000 and 19,000 lb. per sq. in.

IMPROVEMENT IN FATIGUE RESISTANCE OBTAINED BY WATER QUENCHING UNTREATED 5-1/2" TIMES 10" PASSENGER AND FREIGHT CAR AXLES FROM 1000 DEGREES F
Fatigue tests were made on eleven passenger car axle assemblies and seven freight car axle assemblies prepared from axle forgings which had been modified by water quenching from 1000 degrees F. These forgings were originally produced to AAR Spec. M-101-49, Grade A, but were given this subsequent treatment to determine the improvement in fatigue resistance that could be obtained from the beneficial thermal residual stresses produced by quenching from below the critical. It was concluded that water quenching untreated axle forgings does not improve the resistance to initiation of fatigue cracks in the wheel fit portion, but does greatly increase the resistance to breaking off in the wheel fit. In some cases over 100%.

FATIGUE TESTS OF FREIGHT CAR AXLES 5 1/2 TIMES 10 INCH JOURNALS
This report concludes the series of fatigue tests made at the Canton Laboratory on a proposed design of raised wheel seat freight car axle with "as forged" (unmachined) body between wheel seats. These tests constitute a part of the program undertaken to develop an improved freight car axle. The conclusions drawn from this investigation are as follows: 1. The proposed design "as forged" raised wheel seat freight car axle has a considerably greater fatigue strength in the wheel fit than the Standard Freight Car Axle (Black Collar Design) due to two factors: (a) The removal of the black collar and use of the raised wheel seat design gives an improved shape, resulting in at least 13% greater fatigue resistance to breaking off in the wheel fit. (b) The increased diameter at the wheel seat decreases the stress at that location by 21%.

INVESTIGATION OF AXLE JOURNAL FILLETS AND DUST GUARD SURFACES RESULTING FROM CONTACT WITH JOURNAL BOX DUST GUARD FLANGES
In order to determine the extent to which damage was occurring with the dust guard opening in its present configuration, the Research Department made a field survey of axles coming into the wheel shop for attention. A total of 126 dust guard seats and fillets of axles were examined. During this examination it was observed that the following damage was occurring: 1. Pounding at the fillet, 2. Wear at the juncture of the fillet and dust guard seat diameter, 3. Grooving at the fillet caused by pressure on the dust guard seat diameter cold working the metal. As a result of damage to axle fillets by contact with dust guard wall surfaces, the Car Construction Committee reviewed the matter and decided that the dust guard wall projection should be modified to prevent damage to journals and also to provide better retention of oil in the journal box.

COMPOSITION BRAKE BLOCKS--INTERACTION BETWEEN COMPOSITION BRAKE BLOCKS AND WHEELS
The service tests with various makes of K-block on the Berliner S-Bahn are described. The object of the tests was to study the interaction of the two friction elements, block/wheel. Although a strong tendency for the formation of cracks in wheel tires had occasionally been observed with K-blocks, in the service tests such a tendency could not be detected. All the stages of grooving and follow-wear were present on the tires. Similar phenomena had been observed by the SNCF on suburban services. Experience gained by the DB showed that some difficulty arose due to metallic particles sometimes becoming embedded in the braking surface of the block. K-blocks were used extensively on the London Transport Underground lines. Thermal cracking, tire spalling and wear constituted a special problem on the frequently-stopping motor coaches with heavily-loaded small diameter wheels, running in tube tunnels. The performance of a K-block depended on various parameters: characteristics of the block and of the wheel steel, application conditions, service conditions, weather, and shape of block. The development of a universal K-block would be difficult.

COMPOSITION BRAKE-BLOCKS-TESTS WITH COMPOSITION BRAKE-BLOCKS OF VARIOUS DIMENSIONS AND SHAPE
The German State Railway conducted the necessary tests on the bench and on the Berlin S-Bahn. The tests were based on the assumption that the wheel wear might be diminished if the shape of the composition brake blocks was altered from the usual rectangular shape taken over from cast-iron blocks. A number of different geometrical shapes of the friction surface of composition brake blocks were considered. The coefficient of friction under various conditions was similar with all block shapes tested. None of the block shapes tested produced any bad side effects. It was not possible to find any significant differences between the different block shapes when braking with one block per wheel or with two blocks per wheel; though tire wear for braking with one block per wheel was slightly lower than that for braking with two blocks per wheel. The tests have not revealed any compelling reason for diverging from the customary simple rectangular shape brake blocks.

GENERAL PROBLEMS CONNECTED WITH WHEELS AND THEIR ASSEMBLY: SOLID CAST-STEEL WHEELS, WHEELS OF DIFFERENT DIAMETER AND SHAPE--THIRD CONTRIBUTION TO THE STUDY OF SOLID CAST-STEEL WHEELS

In this report an account is given of the running tests, the braking tests on the wheel testing machine and the test runs on steep falling gradients. The running tests employed wheels of 730 mm diameter with treated wheel-rim of non-alloyed steel with a carbon content of either 0.61% or lower than 0.5% with an ultimate tensile strength of 115 to 130 hbar and 84 to 101 hbar respectively. Other tests were made with solid wheels of 920 mm diameter made of Wt steel (carbon and manganese content lower than or equal to 0.52% and 0.80% respectively. These tests consisted of falling-gradient runs on the St. Gothard line and of runs on flat sections under loaded wagons. Some wheels were also submitted to tests on the test rigs at MINDEN, VITRE-sur-SEINE and DERBY, in order to determine their behavior under the effect of heat generated by braking (liability to thermal cracks and deformations of the wheel-rim). Finally, one wheel of 730 mm diameter and wheels of 920 mm diameter of Wt steel were submitted to investigations in the laboratory and the latter wheels were in addition, studied with a view to the stresses developed. The braking tests carried on the rig with 730 mm diameter ABEX wheels have given unfavorable results. The running tests in commercial service have also given unfavorable results (spalling of running-tread). Concerning the GRIFFIN wheels of the same diameter, the running tests have also supplied disappointing results, there wheels displaying spalling or even perhaps flaking. The ABEX and GRIFFIN wheels of 970 mm diameter with treated wheel-rim and somewhat high carbon content showed a good behavior in SWEDEN during tests under high load (25 t/axle) but very mild braking conditions, the climatic conditions however being very severe. The 920 mm ABEX wheels, ordered in Wt steel have shown a good behavior during the running tests and during the braking-tests on the MINDEN, VITRY and DERBY rigs (resistance to thermal cracks). However, during the falling-gradient runs on the St. Gothard line, they had given rise to deformations reducing the play of the axle.

QUALITY OF RAILS AND MEANS OF GUARANTEEING IT--FALLING WEIGHT TESTS AND DEFINITION TESTS (1ST AND 2ND SERIES OF TESTS)

The main object of these tests--was to define and to standardize the conditions of use of the falling weight tests laid-down in UIC Leaflets 860-1-0 and 860-2-0, for the acceptance of rails of current quality and rails of nontreated steel of a quality resistant to wear. It was concluded that a falling weight test, irrespective of its type, is not representative of the fatigue behavior of rails in the track, but it was considered advisable to retain for the time being, such a test on complete pieces of rail, to make it possible to detect and eliminate brittle rails with a large degree of probable success and to maintain each rail production within a truly characteristic and correct scatter range.

C4 040416
BEHAVIOUR OF THE METAL OF RAILS AND WHEELS IN THE CONTACT ZONE-RESIDUAL STRESSES IN THE RAIL (CONTINUED) STUDY OF THE WORK-HARDENED ZONE

This report contains the results of measurements taken to study the work-hardening caused by traffic, and more especially the changes in the residual stresses in the rails near the running tread which constitute an important factor in the study of rail fatigue phenomena. About 5 mm below the surface the work-hardening is very large, and the rail is the center of a hydrostatic pressure zone extending down to a depth of approximately 10 mm, this then changing into a tensile one with a maximum at about 15 mm. This may explain why the fatigue cracks (of the kidney-shaped flaw type) tend to originate at a depth of 10 to 20 mm but do not develop in the upper highly compressed zone. Furthermore, the residual-stress fields vary from one section of the rail to another, probably as a result of the oscillations of the wheel-loads due to short-wave rail corrugations.

C4 040417
BEHAVIOUR OF THE STEEL AT THE POINT OF RAIL-WHEEL CONTACT- INTRODUCTORY STUDY ON THE CAUSES OF SHELLING CRACKS IN RAILS

This report reviews pertinent literature on the subject of shelling cracks in rail head. From the research conducted at the University of Illinois it is concluded that shelling cracks in rail heads are primarily due to fatigue under repeated rolling action. Obvious methods of reducing the development of shelling cracks would be to reduce wheel loads on the rails, to use larger diameter wheels or to use stronger rail steels. Future research should be directed towards the closing of the gap between standard fatigue data and the fatigue phenomenon as it occurs under contact stresses due to rolling action. At the moment, the prime difficulty in correlating tensile or torsion and rolling contact fatigue data stems from insufficient knowledge of stress distributions modified with respect to elastic theory by plastic deformation.

C4 040418
PROBLEMS OF INTERACTION OF VEHICLES AND TRACK--WORN PROFILES OF RAIL HEADS AND WHEEL TYRES

As a result of a large number of tests it has been proved that service wear on wheel tires and rail heads leads to definite profiles. These worn profiles are to a large degree independent of the initial profiles of tires and rail heads. In the worn condition the profiles maintain their form and are not subject to any further change. The worn profiles are characterized by good mutual conformity and thus by little increase in wear. The worn profile of tires results in a shortening of the wave length of the periodical wheel set motions (hunting) in the track clearance. It was concluded that to wear new profiles of rail heads and tires should be adapted as much as possible to the worn profile. The use of special wheel tire profiles promise no lasting influence on the riding quality of vehicles. Therefore other design measures on the vehicles should be preferred to control the hunting motion.

SHELLY RAIL STUDIES AT THE AAR RESEARCH CENTER

Rolling-load test results obtained in a cradle-type machine are listed. Macrographs are presented to reveal cross-sectional qualities of shelly rail. Slow-bend test results are tabulated for flame and induction-hardened rail. It can be noted that all of the rails tested showed excellent results and that no effective stresses were set up between the head and web due to flame and induction hardening.

ROLLING-LOAD AND SLOW-BEND TEST RESULTS OF BUTT-WELDED RAIL JOINTS

In the period from October 1, 1965, to October 1,1966, sixteen rolling load tests and six slow bend tests were conducted on butt-welded rail joints at the Association of American Railroads Research Center. The joints were made by the thermite (Thermex Metallurgical, Exomet and Orgotherm), submerged-arc and oxyacetylene pressure-butt-welding process. The rolling-load tests were made on a 12-in-stroke rolling-load machine. Welded specimens were tested for various reasons including: (1) to determine the quality of the submerged-arc-welded rail joints, (2) to evaluate 115-lb thermite welded rail joints made by the Exomet process, (3) to determine the seriousness of making butt welds from rails with hairline cracks of (pipe) in the web. (4) to investigate the possible detrimental effects of a collar that was not removed from an Orgotherm thermite welded rail joint. The slow bend tests were made with the rail resting on supports 4 ft. apart and loaded at 2 points, one on each side of and 6 in. from the weld. These tests were made with the rail base down, thereby subjecting the head to a compressive stress and the base to a tension stress. For satisfactory service performance a minimum of 1.5 in. of deflection and 140,000 psi modulus of rupture are being used as tentative criteria for oxyacetylene and electric-flash pressure butt welds. A summary of the slow bend test results is provided.

SHELLY RAIL INVESTIGATION, ROLLING-LOAD AND SLOW-BEND TEST RESULTS

Two methods presently employed for improving shelling resistance is the addition of alloying elements and the heat treating of rail. The rolling-load tests in a cradle-type machine are designed to evaluate these methods of improving the resistance to shelling. Rolling-load test results obtained from these cradle-type machines for the period between October 1, 1965, and October 1, 1966, are shown. The S-13 series were initiated to compare the effects of welding prior to flame hardening and flame hardening prior to welding. The electric-flash butt welds were made from secondhand 132-lb HF rail and flame hardened by the Hammon process. Specimens S-13A and S-13C failed after being subjected to 389,800 and 656,900 cycles, respectively. As a result of this performance, rolling-load tests were conducted on welded joints made from 132-lb HF secondhand rail having no flame hardening applied. These joints, S-13E and S-13J, shelled after being subjected to 1,088,000 and 1,163,000 cycles, respectively. Rails flame hardened by the Linde process developed shells after being subjected to 1,254,400 and 844,900 cycles in the cradle-type rolling-load machine. During this period there were no slow-bend tests.

BEHAVIOUR OF THE METAL OF THE RAILS AND WHEELS IN THE CONTACT ZONE--ENQUIRY INTO THE PROBLEM OF SMALL DIAMETER WHEELS APPENDIX 3

The observations made at the Mairy mine concerning the wheel-rail dynamics are discussed. The width of the rolling band is wider than on the SNCF and can be explained by wear of the wheel and rail. It could also be due to transverse elastic deformation of the wheel. The calculations and measurements are summarized which were carried out in the laboratory of the SNCF to investigate the influence of the load, the curvature of the rail and the tire, and more particularly of wheel diameter on the stresses to which these components are subjected.

BEHAVIOUR OF THE METAL OF THE RAILS AND WHEELS IN THE CONTACT ZONE--ENQUIRY INTO THE PROBLEM OF SMALL DIAMETER WHEELS

This report summarizes the responses to an enquiry into the effect that a reduction in the diameter of wheels would have on the behavior in service of the rails and wheels. Information was collected on the subject of P/D ratios (P = load per wheel in tons, D = diameter in meters) and includes an analysis of tests carried out by the U.S., Russia, Germany, the British and the French. Very different values of P/D were found, depending on the railway and especially on the type of steel in the rails.

DERAILMENT OF A PASSENGER TRAIN CONSISTING OF A DIESEL LOCOMOTIVE WITH SIX-WHEEL TRUCKS, A BAGGAGE CAR, AND A COACH

Three letters discuss the derailment of June 7, 1968. A sketch of the derailment area and photographs of sections of the track involved are included. This derailment is characteristic of a number of derailments that have occurred on curves at or near permissible speed of passenger trains having locomotives with six-wheel trucks, derailment apparently occurring first of the rear truck of the locomotive unit or the lead truck of the baggage car following. In each case the high rail of the curve was overturned. A high ratio of L/V is required to overtrun a rail and it is unlikely that this high a L/V ratio would be developed in track unless there is some unusual condition such as a jack-knifing of couplers between cars, an unloading of the lead wheel of the truck on the high rail, or some severe wedging action of the truck between rails due to a malfunction of the truck components.

TEST TO DETERMINE VERTICAL AND LATERAL FORCES IMPARTED TO THE RAIL BY A TYPE U28CG GENERAL ELECTRIC LOCOMOTIVE, SANTA FE CLASS 350

The test runs were made using a train consisting of two lightweight chair cars and three baggage cars and a locomotive of two units, one having the instrumented truck. Tests were run at speeds up to 90 mph on dry rail and

moderate temperature. The test results show lateral forces of substantial magnitude being exerted on the rails, an occasional one having a finite duration of ten feet. They also show vertical wheel loads of low value in some locations. The test results indicate it is possible for these two conditions to occur simultaneously on two or three adjacent wheels of a truck and produce an effective L/V ratio of sufficient magnitude to overturn the rail.

C4 040472
RESULTS OF ROLLING-LOAD AND SLOW-BEND TESTS OF BUTT WELDED RAIL JOINTS
In the period between October 1, 1966 and October 1, 1967, 22 rolling-load tests were conducted on butt welded rail joints but no slow-bend tests were conducted. These butt welded rail joints were made by the oxyacetylene and electric flash butt welding process. The rolling-load tests were made on a 12-in-stroke rolling-load machine. Investigation 214 (samples A through F) was conducted to determine the seriousness of hairline cracks (segregation and pipe) on oxyacetylene pressure butt weld quality. Five of the six joints with stood 2,000,000 cycles of repeated loadings without failure, which is considered a run-out, and one joint (214E) failed after 897,100 cycles. A macroscopic examination made on transverse sections cut from the end of each rail prior to welding indicates that this failure originated from a fishtail. Investigation 220 (samples A through F) is a continuation of the problem presented in investigation 214 but was conducted to determine the effects of hairline cracks on joints from rails of heavier sections. It was found that fatigue of the failed specimens originated in the fillet between the head and web and can be attributed to a shear drag introduced while removing the weld upset. Investigation 226 (samples A and B) was conducted to evaluate two electric flash butt welded joints from which the upset metal had been ground from the top and sides of the head and bottom and sides of the base

but not removed from the web. An examination of the fracture surface to determine the fracture mechanics indicates that this failure originated in the fillets between the web and upset metal. Investigation 230 (samples A and B) was conduced to evaluate oxyacetylene pressure butt welded joints made with a new type of welding head. Joint 230A failed after 33,500 cycles of repeated loading and joint 230B withstood the 2,000,000 cycle minimum requirement without failure. This failure can be attributed to the lack of fusion at the weld interface.

C4 040474
INVESTIGATION OF FAILURES IN CONTROL-COOLED RAIL

In the period between October 1, 1966 and October 1, 1967 there were seven failures in control-cooled rail, three service and four detected, investigated by the metallurgical laboratory of the AAR. Investigations 132-10A and B involved two rail specimens both having a detected transverse discontinuity in the head. These transverse discontinuities were detected by a detector car. Rail specimen 132-10A was identified as a 100-lb RE. This failure should be classified as a transverse fissure from hot torn steel. Rail specimen 132-10B was identified as a 132-lb RE. This failure should be classified as a detailed fracture from a shell. Investigations 132-12A and B involved two rail specimens both having a detected internal imperfection in the web. These internal imperfections were detected by a detector car and a hand test. Both rail specimens were identified as 132-lb RE. It was noted that both these rails have a pipe, and a non-metallic entrapment (slag) commonly associated with pipe, in the web. Investigation 135-16 involved a rail that failed in service. This rail was identified as a 112-lb RE. A photograph of the fractured faces showed a fatigue ring development. This fatigue ring development (detail fracture) started from a longitudinal separation close to the running surface of the rail head, then turned downward to form a transverse separation at a right angle to the running surface. This failure should be classified as a detail fracture from a shell. Investigation 135-28 involved a service failure that resulted from a derailment. This rail was identified as a 112-lb RE. This failure was caused by an impact force of unusually high magnitude that is believed to have been the result of a derailment. Investigation 135-29 involved a rail that failed in service. This rail was identified as a 115-lb RE. This failure was attributed to the presence of a base seam in conjunction with a high impact loading at subzero temperatures.

THE DUAL ROLES OF DESIGN AND SURFACE TREATMENT IN COMBATING FATIGUE FAILURES

The problem of producing components which will have satisfactory lives under repeated stress conditions requires a twofold approach. In the first instance the design must take account of any stress concentration effects in the component by geometrically distributing the material in the most efficient way so as to reduce such stress concentration effects to a minimum. The second approach is based on the fact that fatigue failures in the vast majority of cases are initiated on the surfaces of components. The designer must consider what deleterious surface effects occur on the component being designed, and counter these with the use of a surface treatment applicable to the particular case being studied. The present-day incidence of fatigue failures in all branches of engineering 90 percent of all service failures, is intolerably high. The importance of the twofold approach in designing for fatigue loading conditions is extremely important.

RHEOSTATIC BRAKING WITHOUT MOTORING ALL AXLES

The power circuits for the system are shown. The detailed sequence of events during a stop using rheostatic braking is as follows: A command is received to brake at one of the specified rates (1.5, 2.1, or 2.6 mph p.s.), both electro-pneumatic and rheostatic brake circuits are energized. When a rheostatic braking current has been established on every equipment on the train a change-over relay is energized and this releases the air brakes on all cars. The rheostatic braking continues to build up through the operation of a camshaft switching unit, which reduces progressively the degree of field divert until it is checked by the operation of the rheostatic current limit relay (RCLR) when the current value is reached which represents the maximum which can reasonably be permitted under tare conditions. The performance is shown which was obtained with the equipment in terms of percentage of train energy dissipated rheostatically for various speeds of entry and various rates of retardation. The degree of success which is achieved with this scheme will be revealed by the extent to which wheel wear is reduced.

THIRTEENTH PROGRESS REPORT ON SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS

One specimen of a chromium-vanadium rail, heat treated to 490 Brinell hardness gave a rolling-load test of 21 million cycles. Ten specimens of high-silicon rails gave rolling-land tests that averaged 2,307,000 cycles. Two specimens of 140-lb. chrome-vanadium alloy rail, gave rolling-load tests that averaged 3,625,000 cycles. One shelling crack started at a segregation streak in the rail. Rolling-load tests to produce detail fractures from shelling indicate that both chrome-vanadium alloy rails and heat-treated carbon-steel rails resist the production of detail fractures better than standard carbon-steel rails. All rolling-load tests to produce shelling indicate that rails with higher hardness, with corresponding increase in mechanical strength, give longer laboratory rolling-load tests.

THE EFFECT OF STRESS RAISERS AROUND A BOLT HOLE ON THE FATIGUE LIFE OF A RAIL

A universal fatigue testing machine was obtained and a bending fixture was designed. The function of the machine is to apply a vertical vibratory force to any specimen. The alternating force is applied 1800 times a minute to an elastic test specimen, and can be adjusted between zero and 5000 lb. The 132-lb. RE section was used because it represents the heaviest of AREA sections, and the 140-lb. PS section was used because it had a bolt hole location in the heavier web area. The severity of the defects varied from light to heavy drill gouges, and from light to heavy burrs, as well as the location of the brand one the edge of the hole. The effect of the stress raisers on the fatigue life of the rail sections is very pronounced. All these stress raisers around the bolt hole were produced in the manufacturing process. The statistical data indicates that a bolt hole drilled with a dull or improperly sharpened drill through a brand reduces the fatigue life of the rail by 50 percent.

SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS

Rolling-load tests are reported for the following types of rail: (1) German abrasion-resistant rails; (2) basic-oxygen standard carbon-steel rails; (3) basic-oxygen high-silicon steel rails; (4) 115-lb. standard carbon-steel rails; and (5) flame-hardened rails. Mechanical tests are presented for Japanese induction-hardened 119-lb. rails.

MEASURES TO COUNTER FATIGUE FAILURE IN RAILWAY AXLES

This paper reviews the experience in London Transport of fatigue cracking in railway axles, and presents the results of laboratory fatigue tests on full-scale axle specimens under simulated rotating bending. The investigation was undertaken with the aim of entirely eliminating fatigue cracking and fretting under the press fits of wheel-axle sets. Cold rolling of wheel seats strongly inhibits the propagation of such fatigue cracks but it does not prevent their initiation. The introduction of a stress-relieving groove, such that the edge of the press fit overhangs the groove, leads to a marked reduction in fretting and increase in life of test specimens, and the results of a limited service test suggest that the presence of such a groove reduces the stresses under the wheel hubs to a level at which cracking is eliminated.

THE SULZER 12LDA29 DIESEL ENGINE AS APPLIED TO RAIL TRACTION

It is very difficult to make a fabricated structure which has no 'stress raisers' due to either bad geometry or lack of welding quality. Any fabricated structure which carries a high general stress is likely to develop fatigue fractures in certain areas. In order to avoid this situation and provide an engine structure which will reliably last the life of the engine, it is necessary to design the engine to a standard which will avoid a generally high stress and avoid areas which will concentrate stress. It will also be necessary to ensure a very high standard of welding quality. The additional expense and weight penalty of raising the standard of the structure in this way will tend to narrow the economic gap between the fabricated structure and the cast structure and may indeed close it completely.

EXPERIMENTS ON THE SETTING OF RAILWAY BALLAST UNDER REPETITION OF LOAD

Four types of ballast were laid a top 30 cm layer entirely composed of standard crushed stone; upper 20 cm composed of crushed stone and lower 10 cm of standard screened gravel; upper 10 cm of crushed stone and lower 20 cm of screened gravel; and 30 cm entirely composed of screened gravel. Comparison between the Grade 1 crushed stone with size distribution as produced and the one with size distribution modified by screening to 30 to 50 mm indicated that the setting rate of the ballast composed of the latter was 21% slower than that of the one of the former. Comparison between the wooden and the concrete ties used in the experiment with reference to both types of ballast revealed that the ballast setting under concrete ties was 50% less than under wooden ones. A ballast of screened gravel with coarse sand fillings was compared with the one of the same material minus sand. It was found that the setting rate of the former was very much slower than that of the latter; it means that good stability will be gained if the cavities are well filled.

SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS

Four rolling load tests of high silicon-vanadium rails averaged 1,850,000 cycles. Two similar tests of high silicon-chromium-vanadium rails ran 1,682,000 and 5,805,400 cycles. One more test of standard carbon rails flame hardened by the Union Pacific Railroad ran 11,501,100 cycles. Two rails containing 0.047 percent columbium ran 2,051,000 and 2,304,800 cycles, and the rails developed excessive flow at the gauge corner. Pictures are shown of induction-hardened rails from service. This method of treatment did not prevent early shelling failures. Five specimens were tested to develop detail fractures from shelling.

SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS

Two rolling load tests were made on a high-silicon rail which ran 1,944,400 and 1,480,000 cycles. A standard carbon-steel rail gave unusually long tests of 4,371,000 cycles. These specimens deformed considerably before the shelling cracks were visible on the side of the rail head. Two induction-hard-

ened 50-kg rails from Japan gave rolling-load tests of 517,400 and 718,300 cycles. One double-flame hardened specimen ran 4,185,000 cycles in the rolling-load test. This is a much higher test than previous flame-hardened specimens. Single flame-hardened rails ran from 1,490,000 cycles to 3,[illegible]800 cycles, which are also very high rolling-load tests for flame-hardened rails. Two rails with high manganese and high silicon were tested. The rolling load tests varied from 1,792,400 cycles to 3,260,500 cycles. Three specimens were tested to develop detail fractures from shelling. They developed failures at 2,007,400; 5,204,900 and 4,492,200.

ROLLING-LOAD-TEST RESULTS OF WELDED ENGINE-WHEEL BURNS ON RAIL SUPPLIED BY THE SEABOARD AIR LINE RAILROAD

The oxyacetylene-welding method is the standard procedure for repairing wheel burns. Two welds of this type were prepared as controls. Eight engine-wheel burns were then welded by means of the electric-arc method. The first six welds were made on 115-lb RE rail and the last four welds were made on 132-lb RE rail. In this type of test 2,000,000 cycles without failure are considered a run-out. All of the welds were checked ultrasonically for defects. The oxyacetylene welds had the best results, in that one ran to 2,000,000 cycles without a failure and the other ran to 589,000 cycles, failing from a detected inclusion. The electric-arc welds failed prematurely at 49,000 to 159,000 cycles. The microscipic examination of fractures revealed taht a sharp line of demarcation between the weld metal and rail metal existed as well as very fine porosity on the interface. This porosity in all of the electric-arc welds was the cause of the failure. The microsocpic porosity in the interface could not be detected ultrasonically whereas the indication of the inclusion was very definite.

SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS

Laboratory tests of chrome-vanadium rails give high cycles for failure but with considerable scatter in results. Rolling-load tests are reported on six extremely high-silicon rails with 1.63 percent silicon. These specimens did not give as good results as previous tests on rails with less than 1 percent silicon content. Rolling-load tests are reported on six induction-hardened rails. These rails resist flow or abrasion on the gauge corner but develop shelling cracks in the laboratory tests sooner than standard carbon-steel rails. Two detail fractures from shelling were produced in laboratory rolling-load tests of 136-lb chrome-vanadium rails with Brinell hardness of 368 and 373. These two rails ran 2,837,900 and 9,258,500 cycles.

SIXTEENTH PROGRESS REPORT ON THE ROLLING-LOAD TESTS OF JOINT BARS

Seven tests using 115 RE bars with easements on the top bar surfaces to depths of approximately 0.220 and 0.110 in were completed. The shallow easements were effective in eliminating gouging of the bars by the rail ends. Six joints with shallow easements averaged 349,080 cycles. Twelve tests of joints using 132 RE bars with the same type of milled easement were completed. Two bars with deep easements failed. The shallow easements were effective in preventing gouging of the bars. Average cycles for failure for 6 joints with deep easements were 611,630 and average cycles for failrue for 6 joints with shallow easements were 583,530 cycles.

FIFTEENTH PROGRESS REPORT OF THE ROLLING-LOAD TESTS OF JOINT BARS

Six tests of U.S.S. compromise joints, from 132 RE to 115 RE rail section averaged 288,800 cycles. All of the failures originated at the center of bar length at the change of section at the base of the bar. Six tests of Du-Wel compromise joints from 132 RE to 115 RE rail section avaraged 237,600 cycles. Five of the failures were from the base and one was from the top, and all six failures started at blowholes or porosity within the cast steel. Five tests of 115 RE, 36-in. headfree, bars with milled easements 1-1/2 in. long and approximately 0.200 in. in depth averaged 278,080 cycles. Two bars failed through the center of the milled easement and two companion bars revealed cracks in the easements. Fatigue tests on small specimens cut from joint bars tested under two ranges of stress indicated endurance limits from 26,000 to 72,000 psi. Both increasing the Brinell hardness and grinding the surface, in general, increased the endurance limit.

FATIGUE TESTS OF RAIL WEBS
This report covers corrosion fatigue tests using a corroding agent of tap water mixed with sufficient sulfuric acid. Specimens were stressed at a rate of 150 cycles per minute for the first 1,000,000 cycles or until a crack had been detected. After 1,000,000 cycles, the speed of testing was increased to 800 cycles per minute and maintained at that rate until the specimen cracked, or until 10,000,000 cycles had been reached. From these tests it may be concluded: that the stresses in the upper rail fillets on tangent track outside of the joint bar limits at the rail end and at the first bolt hole with the new 115 RE rail section and new AREA bolt spacing are well within limits that can be tolerated, provided no unusual corrosion conditions exist that substantially reduce the fatigue strength of the rail steel.

SUMMARY OF FATIGUE TESTS OF FREIGHT CAR AXLES AND ESTIMATED EFFECT OF OVERLOADING
This report was prepared to accumulate and consolidate all data now available for consideration on the problem of overloading of cars in order to resolve the question as to whether the strength of axles and other car conditions justify changes in the present rules which would permit or restrict heavier loading. With a 10 percent overload, the estimated number of axles which will fail before running their full life expectancy is 72 percent. With a 20 percent overload, the estimated number of axles which will fail before running their full life expectancy is 100 percent.

TESTS OF ELECTRIC FLASH BUTT-WELDED RAILS
This paper describes rolling-load tests and physical tests of specimens of 131 and 130-lb electric flash butt-welded rails which were undertaken to determine if stress relief treatment would be necessary. The 131-lb. rail was set up for rolling-load tests of weld 73 in. in a 33-in. stroke rolling-load machine. The second rolling-load test was made on weld 52 in the 131-lb. rail, which was supplied with all the flash metal ground off except under the rail base. 1. The first two-rolling load tests that failed at a bolt hole and stress raiser on the rail webs emphasize the damaging effects of such conditions. 2. The rolling-load tests which ran over 2,000,000 cycles with 60,000-lb. wheel load without failure, are considered very satisfactory for welded rails. 3. The bend tests of 132-lb rails gave higher tests than unwelded 131-lb. rails, and as high as any previously tested rail welds. 4. Some of the physical tests indicate that the welds which were not stress relieved were slightly stronger than the stress relieved welds. However, the difference is negligible and no conclusions on this subject should be based on tests of only two welds.

FATIGUE COMPARISON OF 7-IN. DIAMETER SOLID AND TUBULAR AXLES
The object of this experimental investigation was to determine the fatigue resistance of solid versus tubular type axles for railroad car service. Solid axles tested represented conditions consistent with existing railroad specifications. The tubular axles investigated were of two types; one of which was tested with permission of A.A.R. and the results reported by the manufacturer, the other was tested as a separate project in order to contribute information on certain questions pertaining to the fatigue strength of axles. Rotating cantilever beam fatigue tests were made on axles about 7 in. in diameter using steel of about S.A.E. 1045 analysis. Comparison of axle fatigue resistance due to a press-fitted wheel was made between "as-forged" solid members and seamless tubes in "hot-rolled" and several conditions of heat treatment. Results showed that tubular axles having high tensile strength values may or may not exhibit greater fatigue strength than those having lower physical properties. Observations on the effect of residual stresses are given. Some tubular axles showed greater fatigue strength than the solid ones.

WHAT CAUSES WHEEL TREAD DEFECTS? PART 1: SHELLING
Studies were made of wheels that shelled in service after being subjected to the usual on-tread braking as well as a wheel equipped with disc-type brakes. These studies have indicated that shelling is essentially a fatigue failure that is caused by rolling loads. The formation of structurally weakened metal as the result of the heat of braking friction is believed to accelerate the formation of shelling cracks. Macroscopic examinations of radial-tangential sections from shelled areas have indicated that shelling is caused by cracks that form at angles of 30 to 50 deg to the tread surface. Because shelling cracks are oriented at 30 to 50 deg to the tread surface they are assumed to be caused by high shear stresses developed by rolling loads.

EIGHTH PROGRESS REPORT OF THE ROLLING LOAD TESTS OF JOINT BARS
Twelve tests of 133 RE head contact 36-in. bars averaged 509,200 cycles. Twelve tests of 115 RE head free 36-in. bars averaged 1,462,450 cycles. Five of the joints ran to 2,000,000 cycles with no failure. Micrographs, taken on all failed bars, revealed decarburized bar surfaces to varying depths up to 0.024 in. No clearly defined correlation between cycles for failure and depth of decarburization was apparent. Brinell and tensile tests on 12 of 100 failed bars from service indicated higher hardness reading near the surface of the bars than at the center of the head. Ten of the 12 bars tested failed to meet the specifications of 100,000 psi, minimum tensile strength and 11 fell short of the 70,000 psi minimum yield point.

RAIL FRACTURES RESULTING FROM ENGINE WHEEL BURNS, INCLUDING EFFECT OF REPAIRING SUCH BURNS BY OXYACETYLENE OR ELECTRIC WELDING
Twenty-one specimens were artificially burned with the wheel rotating at a speed of 15 mph, the rails being applied to the moving surface of the wheel for 3-sec. intervals. The burns produced by this method were approximately 1-1/2 in. wide by 2-1/2 in. long and appeared to be quite uniform in nature. A tabulation of the rolling-load tests completed on these specimens up to the present time is shown. Up to the present time no explanation can be offered for the difference in fatigue life due to the location of the built-up metal on the engine burn. Tests have not progressed far enough to lead to any conclusions.

EIGHTH PROGRESS REPORT OF THE SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS
Two rails were selected from the high side of a 4-deg curve. These rails had carried 63,385,600 tons of traffic at average speeds of 35 mph. One rail showed flaking along the gauge corner over its entire length and had also developed 6 or 7 small black shelly spots. The second rail contained 30 black shelly spots. During the past year, 23 specimens have been tested in the cradle type rolling load machine. The chemical analysis, physical properties and results of rolling-load tests of these specimens are shown. The laboratory rolling-load tests produce shelling failures similar to the deeper type of shelling which develops in service. It is also believed that the laboratory tests give a quick method of determining the relative length of service which can be expected in track as compared with standard carbon steel rails. Preliminary results of service tests of rails tested in the rolling-load machines last year give indications of this correlation but the service tests are not as yet completed.

MEASUREMENTS OF STRESSES IN 132 RE RAIL ON TANGENT TRACK--SANTA FE RAILWAY
Three test sections are as follows: new AREA design, headfree 36 in. joint bar for 132 RE rail, with bolt spacing of a 3-1/2--6--6 in.; same joint bar design with bolt spacing of 4-1/2--9 in.; and same joint bar design with bolt spacing of 2-1/2--6-1/2--6-1/2 in. This installation offered an opportunity to obtain measurements of stresses developed under regular traffic in the new 132 RE section. On tangent track under conditions typical of main line operation, it may be concluded: that the stresses in the upper rail fillets on tangent track outside of the joint bar limits have been reduced with the new 132 RE section to well within the fatigue strength of rail, steel, and that the concentrated rail web stresses within joint bar limits at the rail end and at the first bolt hole with the new 132 RE rail section and the new AREA bolt spacing are well within limits that can be tolerated, provided no unusual corrosion conditions exist that substantially reduce the fatigue strength of the rail steel.

FATIGUE TESTS OF RAIL WEBS
Two sets of tensile specimens were cut from the webs of the rails; one set parallel to direction of rolling, and the second set transverse to direction of rolling. Physical properties of the rail web steel as determined by these tensile tests are listed. Only slight differences in the physical properties of the two groups of specimens were disclosed. Previous studies of the fatigue of rail webs in the laboratory indicated a fatigue life several times greater than was actually obtained in service at some locations. Since corrosion of the rail web was quite heavy at the locations where early service failures occurred, it was thought that the discrepancy was due to corrosion. The S-N diagrams are shown for the tests completed to date with no corrosion on the specimens. The S-N diagram is shown for specimens under completely reversed stress, with tap water corrosion, have not revealed as great a reduction in fatigue corrosion, hav not revealed as great a reduction in fatigue life of rail webs as service failures indicate.

SERVICE TESTS OF MANGANESE CROSSINGS
The report covers the comparative tests of designs of solid manganese steel crossing frogs at McCook, Illinois, the tests of manganese insert and solid manganese crossings on structural steel and longitudinal timber supports, and tests of crossing frog bolt tension. Some of the designs included in the tests are more resistant to the development of fatigue cracks than others, but in none were the developed stresses low enough relative to the fatigue strength of the manganese steel to give the service life under heavy traffic that should be expected. Four railroad crossings were installed in the double-track main lines of the Indiana Harbor Belt Railroad and the Chicago and Western Indiana Railroad. The structural steel T-beam support was placed under one each of the solid manganese and insert crossings and the other two crossings are carried on longitudinal bolted crossing timbers. The inspection made in 1947, after approximately one year's service, showed all castings in the four crossings to be in good condition with no-flangeway cracks. A plan of the flangeways of the four crossings showing the flangeway cracks as found on May 7, 1948 is presented. The extent of the cracks was about the same, regardless of kind of support, for the two types of crossings.

FATIGUE TESTS OF MANGANESE STEEL
All specimens were tested under a range of stress from a maximum compressive stress to a tensile stress 50 percent as great. Endurance limits at 10 million cycles were indicated as follows: As-cast surface 38,000 psi; ground surface 42,000 psi; shot peened surface 48,000 psi. Corrosion fatigue tests using a 5-percent solution of sulfuric acid were made on unprotected specimens with as-cast, ground, and shot peened surfaces, and the S-N diagrams approached a vertical line at approximately one million cycles for all specimens. The protective paint coating applied to three groups of specimens proved to be beneficial, although not totally effective in increasing their fatigue life under 5-percent acid corrosion. A few hardness tests on unstressed specimens indicated little difference in hardness for as-cast and ground surfaces and a much greater hardness for shot peened specimens.

WHAT CAUSES WHEEL TREAD DEFECTS? PART 2: THERMAL CRACKING
United States Steel undertook an investigation of wheel-tread defects. Shelling was shown to be the result of repeated stress application to the rolling wheel, which apparently caused the tread metal to fail in shear. Cracks propagate from below to the tread surface. When two of these cracks of opposed orientation meet beneath the tread, metal between them is loosened and finally expelled. This is the typical shelling type of failure. While shelling apparently is not caused by braking, there are wheel defects which can be caused by stresses that develop in the wheel rim as a result of thermal gradients generated by friction between the tread and brake shoe during braking. Shelling and thermal cracking of railroad wheels shorten wheel life, and checking brought on by severe braking may occasionally result in a complete wheel failure.

TENTH PROGRESS REPORT ON THE ROLLING-LOAD TESTS OF JOINT BARS
Twelve tests of 115 K4 headfree, oil quenched 36-in. bars averaged 748,500 cycles. Four tests of 132 RE headfree 36-in. bars, not oil quenched, averaged 78,750 cycles. Four tests of 132 RE headfree 36-in. bars, not oil quenched, with the top fishing surface cold worked by rolling averaged 90,770. Four tests of 132 RE headfree 36-in. bars, not oil quenched, with easements ground 1/16 in. in depth over the central 2 in. of the top fishing surface, increased the number of cycles to 182,900. For the 2 joints in which the easements were carried completely over the top surfaces of the bars, the average cycles increased to 316,650. Tensile tests on 81 specimens selected from 347 failed bars from service revealed that 36 percent passed the yield point specification of 70,000 psi and 69 percent passed the tensile strength specification of 100,000 psi.

C4 040816
TENTH PROGRESS REPORT OF THE SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS
Repeat cradle type rolling-load tests on two specimens of manganese chrome, vanadium alloy rails gave high cycles for failure 8,117,000 and 9,635,000 indicating that these alloy rails may be several times as good as standard carbon steel rails. A 115-lb. heat-treated standard carbon rail gave 9,625,000 cycles in the cradle rolling machine, which indicates that this type of rail is as good as the manganese, chrome, vanadium alloy rails. Rolling-load tests are reported on high silicon rails, nickel alloy bars and rails, and flame-hardened rails, but none of these particular specimens gave tests comparable with the maganese, chrome, vanadium alloy steel or the heat-treated standard carbon steel rails. Metallographic examination of 14 failed rails which had developed detail fractures in service located rather large inclusions in the steel near the fractures in half of these rails.

C4 040817
SUMMARY OF PROGRESS OF INVESTIGATION OF STRESS RELAXATION IN RAIL STEEL
Relaxation of stresses in small bar specimens is being studied as a function of time and temperature, and rolling-load fatigue tests are being run on small specimens. These specimens were cut from a 152-lb rail rolled in 1939. The rail had shelly spots throughout its length. Measurements are made before bending after bending and before heating and after heating and removal from the jig. A summary of test results is shown in a plot of percent stress relaxation versus time at temperature. For temperatures lower than 900 deg F., the amount of relation is quite small. After an initial period, the amount of relaxation at a given temperature increases only slightly as time at temperature increases.

TWELFTH PROGRESS REPORT OF THE ROLLING-LOAD TESTS OF JOINT BARS
This report covers tests of joint bars conducted during the past year. The criterion for bar failure is taken to be the number of cycles of loading to propagate a fatigue crack to one-half of the bar height. 1. Twelve tests of 132K44 headfree, long-toe bars with pressed easements averaged 832,290 cycles in the rolling-load tests. Physical properties of these bars were well above AREA specifications. 2. Twelve tests of 132 RE headfree, 36-in. bars with pressed easements averaged 406,590 cycles, an average only about half as great as previous tests on this type of bar. 3. Tests on five 115 RE bars which failed in service indicated low hardness and low physical properties. 4. Tensile tests on 20 specimens from 50 failed bars from service for 100-lb rail indicated that 11 of the 20 passed the AREA specification of 100,000 psi tensile strength and 8 of the 20 passed the AREA specification of 70,000 psi yield point. 5. Micrographs on both laboratory tested bars and failed bars from service indicated depths of decarburization from less than 0.001 in. to 0.028 in.

TWELFTH PROGRESS REPORT ON SHELLY RAIL STUDIES AT THE UNIVERSITY OF ILLINOIS
This paper summarized the past year's progress on shelly rail studies at the University of Illinois: 1. Stress relieving of specimens during laboratory rolling-load tests at either 1000 or 800 deg F have not appreciably increased the life of the rails. 2. Rolling-load tests of commercially flame-hardened rails gave tests about 50 percent above the average for standard carbon steel rails. 3. Rolling-load tests of high silicon steel rails gave tests almost double the average for standard carbon steel rails. 4. An electric furnace 60-lb steel rail with European chemistry gave very low tests in the rolling-load machine--94,400 cycles. 5. Metallographic examination of 17 shelly rails from service found only 1 rail which contained extra large non-metallic inclusions, which could explain why it had developed shelling in service. 6. Using a special rolling-load machine, detail fractures from shelling were produced in five standard steel rails and one alloy rail. 6. The cause of shelling in service appears to be that present wheel loads are too heavy for the small area of contact between wheel and rail, so that as a result of the flow of the steel, internal stresses are produced that exceed the capacity of the steel to withstand such stresses. 7. Laboratory rolling-load tests indicate that stronger rail steel, such as high silicon steel rails, intermediate manganese chrome-vanadium alloy rails, or heat-treated rails should give longer life before shelling develops in service.

FINAL REPORT ON THE STUDY OF SIMULATED RAILS UNDER REPEATED ROLLING LOAD
This investigation has studied some of the factors which might contribute to shelly failure formation. The investigation has been directed particularly toward a study of the effects of progressive plastic deformation resulting from repeated rolling-wheel loads. Some variables introduced were wheel load, wheel radius, and cycles of repeated rolling load. Experimental evidence suggests that plastic deformation occurs in a rail with early successive load repetition. Further, the tests show that, although deformation is inelastic, many of the effects of the variables studied would be qualitatively predictable by elastic equations such as the Herz equations and this work suggest that smaller wheel loads or larger diameter wheels would be quite helpful. It is also interesting to note that the Herz equations would suggest the use of higher strength rails for longer rail life. This is also in agreement with general observations from actual service and from laboratory tests of rail.

C4 040833
FATIGUE TESTS OF RAIL WEBS
Two specially designed vibratory machines were used to determine the fatigue of less-than-full-size rails because rolling-load machines were unable to break the web of full-sized sections. In all tests a constant ratio of compressive to tensile stress was maintained, the bending stress on the top side ranging from a maximum compressive stress to a tensile stress 20 percent as great. The specimens were cut from two sections of 112-lb. RE rail. The fatigue curves show that reduced fatigue strength results from stamping. These data would indicate an endurance limit of approximately 59,000 psi, for unstamped specimens, and 51,000 psi for stamped specimens at 40 million cycles. At one million cycles, the reduction in fatigue strength for the stamped specimens is slightly over 20 percent. Although these tests were made on specimens instead of a complete rail section, the stresses were of the same order of magnitude as the web stresses which occur in the field, thus affording a measure of the reduction in fatigue strength of a full-sized web which may be ascribed to the presence of stamped numbers.

C4 040870
RAIL DESIGN AND SERVICE MEASUREMENT OF RAIL WEB STRESSES OUTSIDE OF JOINT
The report on rail design deals primarily with the revisions of design to improve the strength in the upper web fillet of the rail to better resist the high range of stress that occurs on curved track on the gauge side at this location. The work described on rail design in the report was occasioned by the occurrence of web failures in the 131 lb. RE rail section on the low rail of curves after considerable traffic had been carried and there had been a reduction in height of section because of rail wear. The cause of split web failures (head and web separations) in 131 RE rail has been found to be corrosion fatigue. Laboratory and service stress measurements have demonstrated that this section develops high stresses in the upper web fillet gauge side, on the low rail of sharp curves. Based on practical experience, mathematical theory, and laboratory and service tests using modern strain measuring equipment, the 140 PS rail section has been developed to retain all the desirable characteristics of the 131 RE section and eliminate its weaknesses. The report contains a detailed drawing of the 140 PS rail section developed from this research and which is now known as the 140 RE rail section, having been adopted by the American Railway Engineering Association as a standard standard section. A detailed drawing of the 133 PS section and of the 155 PS section which were developed from this research are also included in the report.

STANDARDIZED FORMAT FOR RAILROAD ENVIRONMENT WITH APPLICATION TO FATIGUE DESIGN AND TESTING
This paper outlines a format for recording railroad environmental spectrum data that utilizes the standard arrangement of the modified Goodman diagram. In this form the environmental data is applicable to theoretical finite life fatigue design and to variable-cycle spectrum-type fatigue testing. Maximum loadings for operational guidance, equivalent static design analysis, lading damage studies, and proof testing are also accurately portrayed. The extensive environmental data requirements for modern design dictate the need for standardization of data format and content to provide compatibility of data from various sources and facilitate formation of the national data bank required by the railroad industry.

DETECTING THE PROPAGATION OF KIDNEY-SHAPED FATIGUE FLAWS IN RAIL HEADS ON THE LINES OF THE HUNGARIAN STATE RAILWAYS
The author discusses the cause and propagation of kidney-shaped fatigue flaws in the rail head as well as the measures designed to prevent fractures. The main purpose is the description of the functional relationship between the propagation of the fatigue flaw and the traffic load. The formation of flakes in the rail material, the hardness of the rail head and the notch effect set up in the rail head by internal flaws are discussed. It is found that the propagation of the flaws is jointly caused by a number of processes such as microinclusions, oscillatory movements of dislocations, high stresses in the rail head, etc. The positions of the initial centres have been investigated by examining and measuring several fractures. Methods for calculating the height of the fissure and its inclination towards the vertical are developed. An analysis is made of the development of fatigue flaws as a function of the traffic load, and the existing relationship is established by an equation. In determining the effective cross-sectional area of the rail, the wear of the rail is also taken into account and added to the area of the fatigue flaw. After an analysis of the permissible threshold values, certain specifications are suggested, and the size of the flaw area in percent of the total cross-sectional area of the rail head is indicated with the aid of nomographs. In addition to the manual examinations, the introduction of ultrasonic high-speed testing vehicles is urgently recommended. In modern railway operation, ultrasonic testing is the most suitable method of detecting dangerous flaws; but the influence of human subjectivity in evaluating the results must be eliminated by using modern computers.

THE EFFECTS OF FATIGUE UPON METALS JOINED BY WELDING AND BOLTING
Fatigue failures occur in railroad bridges, highway bridges, crane runway girders, large ships, and railroad cars. Fatigue failures are a serious problem and expense. A railroad bridge was reinforced by welding flange plates to the structure, but this introduced severe stress concentrations which led to failure, by fatigue cracking. Numerous fatigue studies have been made, producing stress-life relationships. Fatigue testing machines have been developed, capable of applying repeated cyclic loading. This article covers welded, bolted, and riveted connections, and their testing. Diagrams and photographs are included. The comments of the delegates are included.

THE EFFECT OF SURFACE FILMS ON FATIGUE CRACK INITIATION
The suppression of fatigue crack initiation by surface films can be viewed in terms of two mechanisms: (1) protection against environmental attack, and (2) suppression of surface plasticity. These two mechanisms are described in detail. Environmental protection requires a flawless coating which is impermeable to the active component of the environment and resistant to fracture under repeated cyclic strain. Suppression of plasticity requires a film with an elastic modulus greater than the substrate metal. The stiffer coating repels dislocations from the surface and suppresses the development of slip bands and crack initiation. (Author)

FAILURE MODES OF ROTATING SHAFTS
It is the intent of this paper to present the principal modes of failure of rotating axisymmetric shafts made of ductile material. Shear failure as a result of overtorque is generally the first consideration. This is covered by elementary texts on stress analysis. However, should the strength of a design be adequate to carry the shear stress from torque, failure may still occur by either fatigue or buckling. In addition to fatigue and buckling, one must consider impact as a cause of possible overstress. Thus this paper shall consider fatigue, buckling and impact as modes of failure for rotating shafts.

ISOLATION AND ABSORPTION OF MACHINERY VIBRATION
The problem of isolating machinery vibration from both rigid and nonrigid foundations is considered, and reasons why predicted levels of force transmissibility are often exceeded in practice are discussed and illustrated by representative examples. Both one-and two-stage mounting systems are analyzed. The machinery, and the intermediate mass of the two-stage mounting system, may sometimes be supported on rubber antivibration mounts by multiresonant flanges or feet, which are represented here by short shear beams. Two long clamped-clamped beams comprise the nonrigid foundation considered, and it is shown how the levels of transmitted force vary when these beams (a) are suitably mass loaded, (b) are held rigidly by a central clamp, or (c) are damped by the attachment of dynamic vibration absorbers of optimum design and relatively small mass. The internal damping of the rubber mounts, the shear-beam feet and the foundation beams is considered throughout.

FRACTURE MECHANICS APPROACH TO FATIGUE ANALYSIS IN DESIGN
Many engineering structures are subjected to cyclically varying (fatigue) loads during service. Fatigue analysis, or the estimation of fatigue lives of such structures, is therefore an essential part of engineering design. In this paper, the fracture mechanics approach to fatigue analysis is described. This approach has evolved over the last decade, and is based on the assumptions (i) that there are preexisting flaws or cracks in a structural component, or that cracks are initated early in the life of the component, and (ii) that the fatigue life of the component is determined principally by the rate of growth of these cracks under cyclic loading. Characterization of the rate of fatigue crack growth in terms of fracture mechanics parameters is discussed. The relationship between these parameters and those commonly used in fatigue analysis is identified. A procedure for estimating fatigue lives from crack growth data is outlined. The importance of various loading and environmental variables on fatigue life prediction is considered. A number of example problems are given to illustrate the procedure and the various effects.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Part one of this report discusses a laboratory investigation of 132-pound rail made from vacuum degassed steel. The purpose of this investigation is to determine whether rails made from vacuum degassed steel and air cooled are comparable in properties with rail steel produced by currently common practices. The manufacturing process and test specimens are described. Rolling load tests, drop tests, slow bend tests, Charpy impact tests, hardness tests, and chemical analysis are performed. Macroscopic and microscopic examinations and physical property determinations are examined. The properties of vacuum degassed steel rails without controlled cooling were comparable to those manufactured by conventional techniques. Part two is a report on a field inspection of vacuum degassed steel rail on the Norfolk & Western Railway. Slight curve wear was noted in the high side rails, and slight rail wear was noted on the low side rails. No shelling or head checking was noted.

SOME ASPECTS OF SERVICE DEVELOPMENTS IN RAIL-HEAD METAL
Service developments in rail-head metal characterized by the presence of white etching regions have been studied. After the development of microstructural white-etching regions resulting from traction and adhesion conditions, spalling begins as a result of trains passing repeatedly over these hard and increasingly brittle areas. White-etching regions on a car-dumper hoop rail resulted from impact during loading and unloading of the dumper, because these areas were in contact with mating guide wheels in the normal load and unload positions of the car dumper. White-etching also results from the effects of repeated loads on the vertical face of non-end-hardened bolted rail. A rolling-contact fatigue test concludes that rail steels have longer life at lower maximum static contact stress levels than at higher stress levels.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail are discussed and methods for their prevention are presented. Two phases of the project include the inspection of heat-treated rail and alloy-rail service test installation on curves with a history of shelling, and the laboratory investigation of shelling rail involving rolling-load and slow-bend tests. Field inspections are made at test installations on the Norfolk and Western, Chesapeake and Ohio, Great Northern, and Pennsylvania Railroads. Results of the inspections are presented for each respective railway. It is concluded that the heat-treated rails show generally good results and promise considerably more service.

RESULTS OF ROLLING LOAD AND SLOW-BEND TESTS OF BUTT-WELDED RAIL JOINTS
Results of 13 rolling-load and 13 slow-bend tests of butt-welded rail joints are described. The butt welded rail joints are made by the thermit (Exomet and Orgotherm process), the electric-flash and the oxyacetylene pressure butt-welding processes, and are submitted for testing to evaluate the various welding methods. Rolling-load tests are made on either use 12 in. or the 33 in. stroke rolling-load machine; slow-bend tests are made on supports 4 ft. apart with a two-point loading 6 in. on each side of the weld. Results of rolling load tests indicate that with the thermit weld orgotherm process and the thermit weld type from Exomet, Inc. a rail broke, but otherwise no failures occurred in butt-welded rail joints. Results of slow-bend tests indicate that a rail broke in each test situation, but that there was good structure in Southern Railroad's Thermit Weld (Orgotherm) specimen.

C4 052287
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail are explored and methods for their prevention are presented. Heat-treated-rail and alloy rail service test installations are inspected on curves with shelly histories, and laboratory investigations of shelly rail involving rolling-load and slow-bend tests are also made. Service test installations on the Great Northern Railway of rails rolled from continuously cast blooms, fully heat-treated rails, Columbium-treated rail, and Curve-master rail, were inspected, and contour tracings of the rail inspected were made. Service test installations on curves are designed to study both resistance to wear and flow and resistance to shelling. Two methods presently employed in improving these properties are the addition of alloying elements and heat treating. The addition of certain alloying elements improves resistance to wear and flow but does not necessarily improve resistance to shelling. The use of other alloying elements may improve both of these properties. It is shown that rail if properly heat treated, will be improved in both of these properties. If improperly heat treated, the results are detrimental rather than beneficial.

C4 052294
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail are determined, and methods for their prevention are discussed. Two phases of the investigation include the inspection of heat treated and alloy rail service test installations on curves with shelly histories and the laboratory investigations of shelly rail involving rolling-load and slow-bend tests. The usual service test inspections are made of the fully heat-treated and alloy rail installations to corroborate the observations of previous years. Investigations featured include the service test installation of induction-hardened rail on the Great Northern Railway and on the Norfolk and Western Railway and the test installation to compare high-carbon rail with blue-end rail on the Pennsylvania Railroad. New developments in induction and flame hardening of rails to increase their resistance to shelling are also reported.

C4 052295
RESULTS OF ROLLING-LOAD AND SLOW-BEND TEST OF BUTT-WELDED RAIL JOINTS
Results of rolling-load and slow-bend tests of butt-welded rail joints are reported. Welding methods include submerged arc, thermit process, and oxyacetylene pressure process with abrasive-wheel-cut weld faces and with variations in upset pressure and Btu input. Welds with magnaflux and ultrasonic indications of defects are also included in tests. It is noted that results, particularly results of submerged arc process, represent initial work on developments needing considerable further refinement. Results on thermit welds are representative of the results obtained in previous test of such welds, except those made by the Southern Railway, which show results meeting the standards established by tests of oxyacetylene pressure butt welds and flash butt welds for the first time. Investigations of welds with magnaflux and ultrasonic indications indicate a lack of uniformity existing in judging these indications at the inspection stations.

C4 052309
AN INVESTIGATION OF WELDING USED RAIL WITHOUT CROPPING
Investigation is made of welding used rail without cropping. If such a procedure, using the electric flash method, is satisfactory, economic savings of cropping the rail prior to welding and scrapping cropped rail ends would ensue. Tests are summarized, and findings discuss calculated stress range at bolt holes, effect of weld on bolt-hole stress, and relation of test conditions to track conditions. It is concluded that the electric flash pressure weld reduces fatigue strength at bolt holes and increases the possibility of a progressive fracture developing from a bolt hole. Bond-wire holes or welds on sides of butt-welded rails suggests another possibility for progressive fracture. Use of two half joints each side of the weld has no appreciable effect on fatigue strength at the bolt hole regarding development of a progressive fracture from the hole. Use of special washers with high-strength bolts is effective in removing stress concentration effect of the bolt hole, but the procedure is not practical. It is noted that the calculated range of repeated stress at bolt holes to be expected with continuous welded rail in track is so near the fatigue strength as to give little assurance that fatigue cracks would not develop at bolt holes in time.

C4 052324
SERVICE TEST OF SOLID MANGANESE STEEL CROSSING FROGS WITH PRESTRESSED CONCRETE SUPPORT VERSUS TIMBERS
An inspection of a service installation of a prestressed concrete crossing support is presented. The crossing had been given normal maintenance during the service period. At the end of the first winter the concrete was performing much better than the timbers, with very little vertical movement during traffic. After heavy rainfall the wet subgrade condition resulted in vertical moving of timbers double that of the concrete. A concrete corner was broken off at the point of failure in one of the post-tensioning rods, but there was no evidence of further distress due to reduction of effective rods from six to five. No cause for the break was found. A record of maintenance costs was not kept.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL: METHODS FOR THEIR PREVENTION
This report is presented in two appendices. Appendix 8-a covers the inspection of service tests of fully heat-treated and alloy rail installations. There are five tests of fully heat-treated rail, three of high-silicon rail, one of chrome-vanadium, and one of columbium-treated rail. The heat treatment in some locations has shown considerable value in extending rail life under shelly conditions and in resisting head flow on the low side of curves. The high silicon and low-alloy rails show a resistance to wear and shelling. The chrome-vanadium rail shows excellent performance. Appendix 8-b covers 1) rolling-load tests to produce shelling in high-silicon chrome-vanadium rail, columbium-treated rails, basic-oxygen standard carbon rails and flame-hardened rails; and 2) end-quench hardenability curves determining the quenching characteristics of some of the low-alloy rail steels. High-silicon chrome-vanadium rails rated high in rolling-load tests. End-quench hardenability curves are given for four rail steels to furnish information on the quenching characteristics of low-alloy rail steels.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
This informational progress report is contained in two appendices. Appendix 8-a covers inspections of service tests of heat-treated and alloy-rail installations at 11 locations. There were five tests of heat-treated rail, three of high-silicon rail, and three of chrome-vanadium alloy rail. Heat-treated rail continues to show decided increased life over standard rail. Use of heat-treated rail on the low side of curves has increased life of rail 5 to 8 times, and on high sides 1 1/2 to 4 times. High-silicon rails have shown greater resistance to the detrimental effects of heavy wheel loads on the low side of curves than standard rails. Chrome-vanadium alloy rails show greater resistance to wear than standard rails. However, in this test the chrome-vanadium alloy steel of the composition used was unreliable. Appendix 8-b covers rolling-load tests to produce shelling in 136-lb high-silicon vanadium rails, failed shelly rails from service, and rolling-load tests to produce detail fractures from shelling. Results of tests of 115-lb columbian rail and tests of 133-lb rail single flame hardened by the Union Pacific Railroad are also reported.

C4 052334
SERVICE PERFORMANCE AND ECONOMICS OF 78-FT RAIL; SPECIFICATIONS FOR 78-FT RAIL
The service test of rail laid in 78-ft lengths on the Illinois Central Railroad was covered in this progress report. The prime purpose of the test was the determination of adequate arrangement of rail anchors to control rail creepage better, and to obtain an improved rail gap uniformity. Winter gaps were measured before adjustment of the gaps was made. The average of summer gaps in the two test sections was not materially changed by the adjustment of gaps in the winter, except for one rail. The joints in this rail that would not close at high temperatures, before adjustment, now have summer gaps comparable to other joints measured. The anchorage, alternate ties boxed, in the test mile will give satisfactory results with 78-ft rail provided it is laid with expansion required to have it tight at 85 deg. Because joint slippage resistance is required to keep the joints from opening too much in the winter, especially in 78-ft rail, it is important that the track bolts be retightened frequently. In proposing expansion of the use of 78-ft rail a table is provided.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Most of the information in this report on causes of shelly spots and head checks in rail is contained in the two appendices. Appendix 8a covers inspections of service test of heat-treated and alloy steel rail installations at five locations. There are three tests of heat-treated rail and two of high-silicon rail. Heat-treated rail in tests on the Norfolk & Western Railway continues to show increased life over standard rail. High-silicon have shown greater resistance to the detrimental effects of heavy wheel loads in the low side of curves than standard rails. Appendix 8b contains studies done at the University of Illinois. Three rolling-load tests to produce shelling in high-silicon rails, standard carbon-steel rails and 50-kg rails induction hardened in Japan are presented and discussed. Two rolling-load tests on a high-silicon rail ran 1,944,400 and 1,480,000 cycles. A standard-carbon-steel rail gave unusually long tests of 4,347,000 and 4,371,000 cycles. These specimens deformed considerably before the shelling cracks were visible on the side of the headrail. Two induction-hardened 50-kg rails from Japan gave rolling-load tests of 577,400 and 718,300 cycles.

STATIC AND FATIGUE TESTS ON PRESTRESSED CONCRETE RAILWAY SLABS
The fatigue properties of prestressed pretensioned concrete railway slabs are discussed. A theoretical study of the fatigue resistance of such members is first presented, followed by a description of laboratory tests on six beams. Test results are discussed and interpreted. The theory of fatigue failure is based on three diagrams including a failure envelope based on a limited amount of fatigue test data on prestressing strands and a diagram of the fatigue characteristics of plain concrete. The two failure envelopes are combined with curves expressing the moment-stress relationship for a given beam. The investigator is able to predict the critical loading. It is concluded that the test results check reasonably well with the critical fatigue loads predicted on the basis of the stated theory of fatigue failure.

C4 052363
CUMULATIVE DAMAGE IN STRUCTURAL JOINTS
Cumulative damage in structural joints is determined, to assess the fatigue lives of members which are subjected to variable cycles of loading. Tests are made with cyclic stresses of the same frequency and magnitude as the actual service stresses, and a hypothesis is formulated to predict the fatigue life of a member or joint subjected to a variable loading cycle. It is concluded that the variations in a maximum cyclic stress obtained in railway bridges may provide a life markedly greater than expected on the basis of the maximum applied stresses. It is noted also that all the loading cycles affect the life of a member and must be considered in any evaluation of the member's fatigue resistance.

C4 052381
FATIGUE RESISTANCE OF QUARTER-SCALE BRIDGE STRINGERS OF GREEN AND DRY SOUTHERN PINE

Quarter-scale bridge stringers of green and dry southern pine were tested for fatigue due to stress. All test specimens were fabricated in pairs. One of each pair was used for a static control test and the other for a fatigue test. The green stringers had no checks. The dry stringers either had checks or were artificially checked. Both types were straight grained or had a 1:12 slope of grain. The specimens were tested by loading at third points of a 39-inch span. Fatigue tests were made by loading at 500 cycles per minute in an axial loading fatigue machine. Fatigue failures do not develop in the green specimens repeatedly stressed in bending unless actual stresses in compression are large enough to produce compression wrinkles. The indicated fatigue strength of green specimens for 10 million repetitions of stress is about 50 percent of the static strength for straight-grained specimens, and 60 percent for those with slope of grain. Fatigue strength is about 3000 psi for both straight-grained and slope-grained material. Fatigue stresses are more critical in shear in dry material than in bending, even though slope of grain is present. The static control specimens with both 1:12 slope of grain and checks failed in cross-grain tension, while all specimens tested by repeated loading failed in shear along the check regardless of the level of the repeated stress.

Prepared in cooperation with the Association of American Railroads.

C4 052389
SERVICE PERFORMANCE AND ECONOMICS OF 78-FT RAIL, SPECIFICATIONS FOR 78-FT RAIL

Tests and measurements made on two service installations of 78-ft rail were presented. The purpose of the tests on the Chicago & North-Western and the Pennsylvania Railroad was to determine if the presence of greater joint gaps on the 78-ft rail would create an increase in cost of maintaining the remaining joints, thereby reducing benefits due to the elimination of one half of the joints. Measurements show no outstanding difference between the 78-ft rail and the 39-ft rail at the Chicago and Northwestern site. At the Pennsylvania Railroad site measurements show pull-in of 78-ft rail to be almost identical to that of 39-ft rail. Joint gap measurements on the Illinois Central reveal that rail anchorage of 22 alternate ties boxed per 78-ft rail has given a more satisfactory rail gap uniformity than in earlier tests.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS OF THEIR PREVENTION

Causes of shelly spots and head checks in rail are discussed, and methods for their prevention are recommended. Research conducted by the research staff of the Engineering Division of AAR and by the University of Illinois is reported. Inspections of service tests of heat-treated and alloy rail are made at nine locations, including five tests of heat-treated rail, two of chrome vanadium alloy, and two of high-silicon rail. The final report of heat-treated rails on the Norfolk & Western Railway reveals a very definite advantage of heat-treated rail over standard control-cooled rail, with rail life increased by 2 1/2 times in the case of shelling. Economic advantage of heat-treated rail involves a rail life 4 1/2 times that of standard rail. University of Illinois reports results of mechanical and rolling-load tests to produce shelling failure and details fractures and tests of six rails which developed detail fractures in service.

C4 052402
FOURTEENTH PROGRESS REPORT OF THE ROLLING-LOAD TEST OF JOINT BARS

Tests of joint bars were covered. The tests were made in three 33-in. stroke rolling machines. The criterion for bar failure was taken to be the number of cycles of loading to propagate a fatigue crack to one-half the bar height. Brinell and Rockwell B hardness readings were taken on the upper and lower fishing surfaces of all the bars before testing. Twenty-one pieces of failed bars from service were examined and tested. Eleven tests of 115 RE, headfree, 36-in. bars with ground easements averaged 1,344,100 cycles. Four of the joints ran to 2,000,000 cycles with no failures. The ground easements of 3/64-in. in depth were adequate to eliminate gouging of the bars by the rail ends. On the four bars which failed from the top surface, the cracks started outside the easements. Six tests of cast Rajo compromise joints, type 106A failed from base with small porosity visible in four of the fractures. Examination and tests of the bars which failed in service indicated that yield points for 13 bars were below specifications. All of the bars had failed from the top surface at a gouge mark caused by a rail end.

C4 052403
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL METHODS FOR THEIR PREVENTION

Continuing investigations confirmed that heat-treated or alloy rails were effective in extending the service interval before gage corner shelling occurs in track. A description and summary of eight test installations of heat-treated and alloy rails in areas of high shelling was presented. Appendix 8-a presented the progress of shelly rail studies. Rolling-load tests of high-silicon rails and one chrome-vanadium rail were performed. Shelly rail failures from service were examined and rolling-load tests to produce detail fractures in the laboratory were performed. Detail fractures from shelling in European rails were discussed. High-silicon rails gave rolling-load tests 50 to 100 percent better than standard carbon-steel rails before developing shelling failures. Three tests of a chrome-vanadium alloy rail gave two tests over 5,000,000 cycles and one test of 1,846,000 cycles. Rolling-load tests of high-silicon rails to develop detail fractures from shelling produce failures similar to those produced in track.

C4 052406
CURVE WEAR WITH DIESEL LOCOMOTIVES ON THE BESSEMER AND LAKE ERIE RAILROAD
A series of test runs were made to obtain definite information on the amount of rail curve wear produced by diesel locomotives relative to that produced by the remainder of the train. A second series of tests was made for the purpose of relating the effectiveness of flange oilers on the locomotive and rail lubricators in the track in controlling the amount of curve wear. Instrumentation consisted of a box to catch metal abraided by diesel units from the track and a motion picture camera to photograph the passing wheel flange on the high rail. The tests show that although the rate of rail and wheel wear with a diesel unit is greater than for a heavily loaded freight car, the greater amount of rail wear is due to the train rather than the diesel units. Rail and wheel flange wear on curved track can be practically eliminated by lubrication with either flange oilers on the diesel units or rail lubricators in track, or a combination of the two.

C4 052410
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Progress in the continuing study of the causes of shelly spots and head checks was reported. The performances of various installations of heat-treated and alloy-steel rail have been tabulated. Appendix 8-a presented rolling-load tests of heat-treated chrome-vanadium rail, high-silicon rails, and 140-lb. chrome-vanadium alloy rail. Examination of shelly rails from service and rolling-load tests to produce detail fractures in the laboratory were discussed. One specimen of chrome-vanadium rail, heat-treated to 490 Brinell hardness, ran 21 million cycles in a rolling-load test. Ten specimens of high-silicon rails averaged 2,307,000 cycles in rolling-load tests. Two specimens of 140-lb. chrome-vanadium alloy rail averaged 3,625,000 rolling-load cycles. Photographs of one shelling crack in a service rail indicate the crack started at a segregation streak in the rail. All rolling-load tests to produce shelling indicate that rails with higher hardness, with corresponding increase in mechanical strength, give longer laboratory rolling-load tests.

C4 052412
INVESTIGATION OF FATIGUE STRENGTH OF RAILROAD TIMBER BRIDGE STRINGERS
Laboratory testing of southern pine and Douglas fir bridge stringers was reported. The work consisted of fatigue bending tests on full-size timber stringers and standard block shear tests on small clear specimens at Purdue University, and static bending tests on small clear specimens , fatigue bending tests on small clear specimens and tests on one-quarter scale specimens in Wisconsin. The timbers were to be tested in green condition, but partial seasoning had taken place. Specimens were loaded in the fatigue machine and deflection and shear distortion measurements were taken. Results of repeated loading indicate that if checking is present failure occurs in horizontal shear rather than in bending. Failures in horizontal shear were sudden and near the centroidal axis where checks are deepest. Shear failure generally originates at the end of the specimen which has the least overhang beyond its support. Fatigue bending tests on specimens subjected to center loading on a simple beam span indicate that fatigue failures in bending the green specimens always started with a compression failure near the loaded surface. Static and fatigue bending tests on one-quarter scale specimens indicate that green checked specimens usually fail in bending rather than horizontal shear after static and repeated loads. Checked dry specimens fail in horizontal shear in static loading and repeated loading.

C4 052418
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Five service tests of rail are discussed. There are four of heat-treated rail and one of alloy rail. In the progressive study of shelly rail rolling-load tests of flame-hardened rails, high-silicon rails, and electric furnace steel rails were performed. Examination of shelly rails from service was performed. Rolling-load tests to produce detail fractures were done. The rolling-load tests indicate that stronger rail steel should give longer life before shelling develops in service. Study and testing on simulated rails indicated that plastic deformation is the major factor in shelly failure. Design changes and metallurgical changes to limit plastic deformation would improve rail life. Use of lower wheel loads, larger wheels and higher strength material is indicated. A photoelastic study of the stresses in a model of a railhead utilizing developments in three dimensional photoelasticity for a better understanding of rail shelling was presented. Plastic models of the prototype were thinly sliced and the data obtained were subjected to a field of polarized light. Processing the data was done by the shear difference method. Principal stresses and maximum shears were studied through loading tests. Principal stresses and maximum shears were found in the transverse section of the rail under the center of the wheel.

C4 052426
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
A summary of the performance of heat-treated rail at five installations is presented. Results of rolling-load tests for each installation was presented. The progress on shelly rail studies was presented. Rolling-load rests on heat-treated rail, three experimentally flame-hardened rails and commercially flame-hardened rails were performed. Rolling-load tests to develop detail fractures and stress relaxation tests were made. The tests of the experimentally flame-hardened rails did not compare favorably with tests of heat-treated or alloy rail. Progress in the studies of stress relaxation in rail steel and deformational behavior of rails is reported. Bending fatigue tests of rail steel specimens were run to investigate whether a subcritical thermal treatment might heal progressive fatigue damage. No beneficial effect was noted. The mechanisms involved in rolling-load failures were then studied by work with low-carbon steels sensitive to the Fry "strain-etch" technique and with silver chloride which has optical properties and metal-like mechanical behavior. More work will be done with these two materials.

C4 052434
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
A summary of the performance of five test installations of heat-treated rail was presented. Appendix 9-a presented the progress of shelly rail studies at

the University of Illinois. Repeat cradle type rolling-load tests on two specimens of manganese chrome, vanadium alloy rail indicated that these rails may be several times as good as standard carbon steel rails. A test of 115-lb heat-treated standard carbon rail indicated that this type was as good as the manganese, chrome, vanadium alloy steel of the heat-treated standard carbon steel rails. An electron micrograph of nickel alloy steel showed detail in fine pearlite structure which was not revealed by a light microscope. Appendix 9-b presented a summary of progress on the investigation of stress relaxation in rail steel. The work was in two areas: 1) Relaxation of stresses in small bar specimens was studied as a function of time and temperature, and 2) rolling-load fatigue tests on small systems. Specimens cut from the top section of the rail were tested and results indicated possibly larger values of relaxation in percent of applied stress than for other specimens. Rolling-load fatigue tests produced failures that require further investigation of the effect of alleviation of damage by stress relaxing heat-treatment.

FATIGUE TESTS OF BEAMS IN FLEXURE
This report gave a description and summary of the results of fatigue tests on various types of beams similar to those used in actual structures and subjected to repeated cycles of loads. The tests consisted of subjecting the beams to repeated loads varying from a small load on the beam to the maximum in the cycle. This load cycle was repeated at about 150 cycles per minute until failure developed at some location in the beam. Fatigue data were obtained on 27 different types of beams and a total of 104 specimens were tested. A description of each series with the average fatigue strength obtained for each series at 100,000 cycles and 2,000,000 cycles was shown. The results indicate the following points: 1) The carrying capacity of a rolled beam is considerably higher than that with a fabricated beam of equivelant section modulus. 2) The carrying capacity of a beam with cover plates cannot be increased indefinitely with an increase on cover plate thickness. 3) The use of cover plates on rolled beams appears to be limited to reinforcement jobs where the beam is already in place. 4) Cover plates on beams should be full length or extended past the theoretical cut-off point, so that the stress in the beam at the end of the plate is only about 40 percent of the stress at the center. The stress-raising effect of welding across the ends of partial length cover plates is about the same as that of the longitudinal welds along the edges of the cover plates.

CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
A summary of the performance of heat-treated rail in two test installations was presented. Progress on shelly rail studies at the University of Illinois was presented in appendix 10-a. Rolling-load tests of heat-treated rails, flame-hardened rails, alloy rails and headfree rails were performed. Laboratory examination of detail fractures from shelling was performed. Design and construction of a new cradle-type rolling machine was discussed. A description of the technique used to produce electron micrographs at 35,000X magnification was given. Rolling load tests continued on 132-lb heat-treated rail revealed that yield strength was increased 65 percent, tensile strength 31 percent, elongation 18 percent, reduction of area 100 percent, and endurance limit 40 percent. Results of rolling-load tests on seven rails flame-hardened different amounts on the rail treads showed four specimens failed by head and web separation cracks, and three failed by shelling. Rolling-load and physical tests on two specimens of alloy rail steel showed that these rails have physical properties which compare closely with those of heat-treated rails. Examinations of seven detail fractures from shelling revealed that the shelling cracks started longitudinally in the steel and then turned into transverse detailed fractures.

C4 052441
REVIEW OF JOINT BAR RESEARCH
A summary of the joint bar research program at the University of Illinois was presented. The testing machine was described. Fractures from the base and top of the bars, rail fishing surface profiles, bar hardness, physical properties, decarburization, shot peening, bolt hole spacing, and cycles of failure are discussed. The results of rolling-load tests on the new RE bars for both 115-lb and 132-lb rail which show a substantial increase in fatigue life over the older bars, together with a reduction in weight, indicate that considerable improvement has been made in the design of joint bars and should afford the railroads quite a savings both in lower cost and longer life.

C4 052447
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-METHODS FOR THEIR PREVENTION
Progress on the continuous study of shelly spots and head checks in rail was presented. Heat-treated rail tests indicate that its use extended the life of a rail before gage corner shelling occured. Appendix 10-a described studies at the University of Illinois where examinations of shelly rails from service and laboratory tests to produce shelling were performed. It was observed that the black shelly spots developed by two processes. Two rolling-load test on an alloy rail were high. Examination of the failed specimen revealed non-metallic inclusions. Rolling-load tests on heat-treated rail specimens of standard chemical analysis compared with non-heat-treated companions revealed that heat-treated specimens gave 3 to 4 times the performance of the non-heat-treated specimens. Appendix 10-b presented a summary report on the examination of rails containing detail fractures found by detector cars. The purpose was to determine if the chemistry, mechanical properties, or structures of detail fracture rails varied from those of random rails. The average chemical analyses and mechanical properties of 44 rails having detail fractures and 26 random rails were so nearly the same that no distinction between the two groups was possible. The mechanical tests included hardness, tensile properties, and impact properties. Examination of deep etched structures and microstructures of detail fracture rails indicated that the steel used was of relatively good quality.

C4 052458
STRESS DISTRIBUTION IN BRIDGE FRAMES-FLOORBEAM HANGERS
Report is made on stress distribution in bridge frames and floorbeam hangers. A survey of floorbeam hanger failures is conducted, and field and laboratory studies of stress analysis are made. It is preliminarily concluded that the increase in stress concentration at the sides of the rivet holes due to rivet bearing is often quite large and may easily be the major factor in the fatigue failures at the gussets. Fatigue tests of plates connected by rivets to gussets on one side only produce progressive fracture through the plate at the rivet holes at relatively low unit stresses. Loss of clamping force in the rivets reduces the fatigue strength of such riveted joints. Due to the extensive hanger failures on some railroads, it is recommended that railroads keep close inspection of floorbeam hangers.

LABORATORY TESTS OF TWO WELDED RAILS
Laboratory tests of two continuous welded rails are conducted. One welded rail is tested for comparison with previous tests, placing the rail head in repeated tension, and another test is conducted with the base in repeated tension for comparison with rolling-load tests of bolted joints. Illustrations show the specimen in the testing machine and the manner of supporting the second welded joint to place the rail head in tension. Test values for several

specimens in tensile and Charpy tests and for the endurance limit obtained from the fatigue specimens are reported. Test results reveal that the welds are uniform in strength and that the properties of the welds compare favorably with the strength of unwelded rail steel.

C4 052460
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL-MEASURES FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail are reported and measures for their prevention are recommended. Reports of four study groups are presented. It is noted that no definite relationships or trends exist in the relationship between chemistry and shelling, or curvature, elevations, speeds, and grades. It is found that transposing shelly high rails to the low rail, if done in time, is worthwhile. Rail slow-cold worked under traffic in nonshelling locations and relaid in shelling locations possesses very little, if any, greater resistance to shelling than ordinary rail. Studies of high carbon rail indicate that it will retard but not eliminate shelling and that it has a tendency to head check and this in turn causes gage corner flaking or minute shelling. A seven-year summary report of shelly rail investigation at the University of Illinois is presented. Also presented is a summary report on the examination of 300 shelled spots selected from the track of 11 major roads, indicating that the shelled spots were predominantly of surface origin.

C4 052461
COMPARISON OF WEB STRESSES IN 131-LB RE AND 140 PS -(PENNSYLVANIA) SECTIONS
Report is made of field measurement of stresses made by the Pennsylvania Railroad in 131-lb. RE and 140 PS sections of rail. The 140 rail section is designed to compensate for the inadequacy of the 131 section, and the two sections are compared. Stresses reported include the maximum stress in the web in a vertical plane occurring under a concentrated load. It is noted that in the service tests, made under conditions where rails were failing, the maximum stress is always found on the gage side of the low rail and that is where fatigue cracks develop. It is concluded from these service measurements that the laboratory basis of design of the new section is sound and that the laboratory stress measurements forecast the reduction in service stress with satisfactory accuracy.

REPORT ON SERVICE TEST OF SOLID MANGANESE CROSSINGS FROGS AT MCCOOK, ILLINOIS
Service tests of solid manganese crossing frogs at McCook, Illinois, are reported. Stress measurements are covered in the flangeways and at other significant stress areas of five different designs of manganese castings placed in the crossings of the Baltimore & Ohio Chicago Terminal Railroad and the Atchinson, Topeka & Santa Fe Railway. Service tests include tests of the original design of casting by Taylor-Wharton and the Carnegie-Illinois casting. It is concluded that some of the designs included in the tests are more resistant to the development of fatigue cracks than others, but in none were the developed stresses low enough relative to the fatigue strength of the manganese steel to give the service life under heavy traffic that should be expected, and efforts to further reduce these stresses are recommended.

C4 052468
CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL SURFACES-DEVELOP MEASURES FOR THEIR PREVENTION
Causes of shelly spots and head checks in rail surfaces are investigated, and preventative measures are recommended. It is found that no definite relationship exists between chemistry and shelling, and no definite trend regarding curvature, elevations, speeds and grades. Transposing shelly high rails to the low rail, if done in time, is worthwhile. Rail slow-cold worked under traffic in non-shelling locations and relaid in shelling locations possesses little resistance to shelling compared to ordinary rail. It is also found that high carbon rail does not eliminate shelling but retards it more than ordinary carbon rail; however, the high carbon rail tends to head check and in turn cause gage corner flaking or minute shelling. Reports are submitted by the Norfolk & Western, Pennsylvania, Duluth, Missabe & Iron Range, and Chesapeake & Ohio Railroads.

C4 052472
INVESTIGATE CAUSES OF SHELLY SPOTS AND HEAD CHECKS IN RAIL SURFACES FOR THE PURPOSE OF DEVELOPING MEASURES FOR THEIR PREVENTION
The investigation into the causes of shelly spots and head checks in rail surfaces was presented. A definition and description of shelly spots, the most serious type of rail damage, was presented. The division of the work of this subcommittee was described. Appendix A presented the shelly rail studies conducted at the University of Illinois. Laboratory studies of failed shelly rails concluded that shelling appears to be the result of cold working of the rail steel by "line contact" with car wheels. The presence of imperfections accelerated the formation of cracks. Laboratory rolling-load tests to produce shelling were performed. Different rail steel compositions were studied through rolling-load tests. The Brinell hardness of the wheel path after rolling was measured. Full sections specimens of heat-treated carbon rail were tested under rolling-load. No conclusions were reached.

C4 052473
NINTH PROGRESS REPORT OF THE JOINT INVESTIGATION OF FISSURES IN RAILROAD RAILS
The information in this report of the joint investigation of fissures in rails was contained in five sections. Field tests for batter of end-hardened rails in service on the Chesapeake and Ohio Railway were performed. The summary of the batter values was tabulated. Rail ends with large cracks had approximately three times the batter of uncracked ends. Examination of end-hardened rails from the C and O test track in Carey, Ohio revealed that most damage, weeping cracks and flow of the metal over the ends and sideways, produced batter and drooping of the rail ends. Tests of mill cooling containers for rails were discussed. Examination of control-cooled and Brunorized rails which failed in service revealed that none of the control-cooled rails contained shatter cracks, but did have transverse fissures from blow holes and welded spots, horizontal split heads, detailed fractures from engine wheel burn, fatigue failures starting in the web, and detailed fractures from shelly spots. The Brunorized rails had developed transverse fissures from shatter cracks as nuclei. A comparison of drop and bend tests was summarized.

Conducted by the Engineering Experiment Station, University of Illinois in cooperation with the Association of American Railroads and the Rail Manufacturers' Technical Committee.

C4 052477
DISCUSSION ON STRESSES IN RAILROAD TRACK. PART 1
A discussion of the comparison of tests on stretches of welded track under observation was presented. The purpose was to learn of the magnitude and distribution of the anchorage given between the ties and ballast at the ends of the welded stretch and along its length to resist the forces set up by chance changes in the temperature of the rail, and to learn how the influences tending to change the length and alignment are met in the track. Stress measurements were made on the web of the rail, and the temperature of the rail was taken with the open ended thermocouple and portable potentiometer. The observations were reduced by temperature corrections of gage readings and made comparable for both strains and stresses. Throughout the intermediate part of the welded stretch very little change occurred throughout the variations in summer and winter temperatures. The rails changed length through an average distance of seven rail lengths for the end portions of the rails for both the summer and winter tests. For the higher summer temperatures and lower winter temperatures the stresses may be expected to increase in proportion to the increase in change of temperature from the 63 F base. Lateral deflection of angle bars occurred when bolts were tightened. Tightening of the inner bolts in worn bars also developed lateral bending stresses in the bars. The stresses were generally compressive and the bars bend about an axis appproaching the vertical and high tensile stresses occurred on the inner flanges of the bar. These will add to the tensile bending stresses produced by wheel loads.

C4 052478
DISCUSSION ON STRESSES IN RAILROAD TRACK. PART 2
Observations and tests made on the stretches of welded rail of the Delaware and Hudson Railroad, one section at Albany, and two at Schenectady, were presented. The purpose of the tests was to find changes in length in rail at any place along the stretch, anchorage or restraint at any place along the length and temperature stresses set up in the rail at any place. Readings were taken with strain gages. Temperature of the rail was taken with a thermocouple and potentiometer. Summer and winter measurements were taken. All the welded stretches kept their alignment well even on curves. The longitudinal movement at the ends of the welded stretches and at points along the length due to temperature changes was small. No noticeable movement of the ties in a direction longitudinal of the track was seen. At the end of a welded stretch a tensile or compressive force of considerable magnitude may be transmitted to the adjoining rail. Variable anchorage forces developed in the summer at points due to the presence of under-crossings and viaducts. The flexural stresses developed in the rail by the loads of traffic will be superimposed on the temperature stresses and the two sets of stresses at any point in the height of the rail must be added or subtracted according to their nature.

QUALITY OF RAILS AND MEANS OF GUARANTEEING IT. PROPOSALS CONCERNING THE 6TH EDITION OF TECHNICAL SPECIFICATION 860-0 GOVERNING THE SUPPLY OF VIGNOLE (FLAT-BOTTOM) RAILS OF NON-TREATED STEEL
At the request of the 7th UIC Commission, the D 45 Specialist Committee has been charged with studying the dimensional tolerances of rails with a metric weight greater than 60 kg. As the administrations made increasing use of heavy rails it become necessary to include in Technical Specification 860-0 for the supply of Vignole (flat-bottom) rails of non-treated steel, the maximum permissible dimensional tolerances for these heavy rails. Having regard to the results of the tests already carried out within the scope of its programme of work and the experience gained by its members, the D 45 Specialist Committee deemed it advisable not to limit its investigations merely to the problem of dimensional tolerances, but to examine the whole specification at the same time, and to group into one report all the amendments and additions which it intended making to the existing text. The most important amendments concern marking, freedom from defects, dimensional tolerances, and certain acceptance and guarantee conditions. The wording of the texts at present in force and of the texts proposed to the 7th UIC Commission have been completed by remarks explaining or justifying the decisions of the D 45 Specialist Committee.

Restrictions on the use of this document are contained in the explanatory

material.

BEHAVIOR OF THE METAL OF RAILS AND WHEELS IN THE CONTACT ZONE. EXPERIMENTAL STUDIES: 1) WORK-HARDENING SPEED WITH THE EMS 60 MACHINE (ADDITIONAL MEASUREMENTS), 2) RESIDUAL STRESSES IN HARD-GRADE STEEL RAILS (ADDITIONAL MEASUREMENTS) 3) CHECKING OF FATIGUE CRITERION PROPOSED BY MR. DANG VAN

This report is in three parts: 1) Work-hardening speed examined with the EMS 60 machine: The development of the two principal residual stresses produced on the running surface of rails made of different grades of steel has been studied as a function of the repeated passages of a loaded wheel. It has been shown that this development ceases at about approximately 1 million cycles. 2) Residual stresses in hard-grade steel: These stresses have been measured inside 2 rails of hard-grade steel, one new and the other work-hardened in service. The use of the rail in the track produces severe longitudinal and transverse compressive stresses at the surface. The stress field is affected strongly throughout the height of the rail-head. 3) Checking of fatigue criterion proposed by Mr. Dang Van: The fatigue limits of a rail steel have been determined for different cases of stressing. The results have enabled the validity of the fatigue criterion proposed by Mr. Dang Van (see Report C 53/RP 7) to be confirmed.

Restrictions on the use of this document are contained in the explanatory material.

BEHAVIOUR OF THE METAL OF RAILS AND WHEELS IN THE CONTACT ZONE. CALCULATION OF THE COMPLEX STRESS CYCLES IN THE RAIL SUBJECTED TO ROLLING LOADS. ASSESSEMENT OF THE DANGER OF DAMAGE (CONTINUED)

This study deals with new calculations of the composition of the residual stresses and the stresses induced in the rail during the passage of wheels, for different loading values, wheel diameters and wheel-tyre transverse curvatures. One thermal stress and three residual stresses have been considered. The latter have been calcuated and then measured with the help of an original strain-gauge method. The danger of rail damage has then been evaluated by means of the damage line criterion proposed by Mr. Dang Van (see C 53/RP 7 and C 53/RP 8). It has been possible in this way to define the danger factor for each loading case. It has been shown that two types of danger exist, namely, fatigue and plastic deformation.

SFSA: PREVENTING BRITTLE FRACTURE

Prevention of brittle failures in steel castings has been the goal of a technical research program of the Steel Founders' Society of America. SFSA now recommends the results of its research involving the NDTT (Nil Ductility Transition Temperature) concept. A related project involves the relationship between fracture toughness and strength. SFSA sees this pointing toward a new design philosophy of not specifying an absolutely flawless metallurgical structure but enabling an engineer to predict whether or not a flaw of given dimension will cause brittle failure.

LINEAR EQUALITY CONSTRAINTS IN FINITE ELEMENT APPROXIMATION

This is the first of a series of reports to appear in which the development of a new finite element stress analysis technique will be documented. The work is being conducted at Washington University under a cooperative research program with AMCAR Division of ACF Industries, Inc. Washington University's participation is sponsored by the U.S. Department of Transportation under the Program of University Research and by the Association of American Railroads. The main project objective is the development of a mathematical modeling capability for the benefit of the rail transportation industry that will permit design optimization of key structural components such that the probability of fatigue failure can be minimized with respect to a given load environment. The current finite element technology is not cost-effective in fatigue design applications because a very large number of successive analyses must be executed with progressively refined finite element subdivision in order to establish confidence in the accuracy of solution in those areas where stresses change rapidly.

Research sponsored by Department of Transportation and Association of American Railroads. Work done in cooperation with AMCAR Division of ACF Industries, Inc.

STANDARDIZED FORMAT FOR RAILROAD ENVIRONMENT

This paper outlines a format for recording railroad environmental spectrum data that utilizes the standard arrangement of the modified Goodman diagram. In this form the environmental data is applicable to theoretical finite life fatigue design and to variable-cycle spectrum-type fatigue testing. Maximum loadings for operational guidance, equivalent static design analysis, lading damage studies, and proof testing are also accurately portrayed. The extensive environmental data requirements for modern design dictate the need for standardization of data format and content to provide compatibility of data from various sources and facilitate formation of the national data bank required by the railroad industry.

FRACTURE MECHANICS

Failure of components is a matter of concern to both design engineers and materials engineers. Looking at this problem from a materials standpoint,

three types of failures are of particular significance because of the frequency and, at times, unexpected behavior. These three types of failures are fatigue, stress corrosion cracking and brittle or abrupt failure. This paper is concerned with brittle failure. The situations are different, of course, in the other two cases. Brittle failure in engineering materials is generally defined as failure that takes place at applied stresses below the yield strength level of the material. Designing against this type of failure has been a very important consideration.

FATIGUE DESIGN CRITERIA FOR CARBODY BOLSTERS

The purpose of the static test is to prove design and, more or less, verify stress calculations of the bolster. Where, this is a step in the right direction, it does not point out indeterminates and areas of concentrated high stresses. It is these high stress areas that will lead to fatigue failure of the bolster. Unless these areas are located and steps taken to correct these conditions, failure will continue to occur. In making these tests, employed was the use of photoelastic analysis, which has helped in pointing out high stress areas that calculations of the bolster would not indicate.

COMPONENTIZATION FOR FATIGUE DESIGN AND TESTING

This paper briefly reviews the most common cause for fatigue initiation in freight cars, the specialized data required for theoretical fatigue design, fatigue design criteria, appropriate modern fatigue testing equipment, and the types of full-scale component tests believed most applicable to the car building and railroad industry. The concept of componentization is introduced as a means for expediting both the fatigue design and testing phases of a freight car development program. An objective has been to present the overall aspects of the subject in terms understandable to the person who is not an expert in the fatigue area by presenting only the fundamentals most directly applicable to freight cars.

ENVIRONMENTAL FINITE LIFE FATIGUE TESTING, UTILIZING MINER'S HYPOTHESIS

This paper outlines one method suitable for cost effective computerized theoretical finite life structural fatigue design and determination of means for conducting laboratory fatigue tests that can predict or confirm finite service life of a component or product. Basic modified Goodman type fatigue test data is utilized with the actual environmental loading spectrum and Miner's hypothesis to determine the damaging cycles experienced in service. The total damaging portion of the environmental loading incurred during the long life of railroad equipment can then be applied in laboratory tests of practical duration. Hence, this is truly an environmental test and not what is often termed an accelerated fatigue test. The technical opinions expressed herein are those of the author and do not necessarily represent the policy of the Association of American Railroads.

DEVELOPMENT OF FATIGUE STANDARDS FOR FREIGHT CAR TRUCK COMPONENTS AND WHEELS

Factors which should be considered in the development of fatigue standards for freight car truck components and wheels are discussed. These standards would be formulated to provide a desired level of operational reliability, and they would be based on the fluctuating loads acting on the components in service. Typical data describing this environmental are presented. Statistical considerations in establishing the margin between the environmental loads and component fatigue strength are also described.

DETERMINATION OF CAR BODY CENTER PLATE FATIGUE DESIGN CRITERIA BY FULL-SCALE CAR TESTING

Fatigue design criteria are established based on full-scale car tests conducted on a 100-ton Southern Railway Hopper car. Stress levels on body center plate and its attachments to the car were determined for static car loading by means of jacking, for standing car dynamic loading under a full roll mode received on AAR rock and roll environmental prepared track testing. Correlation of determined stress loadings leads to three proposed axioms for design criteria.

THE MECHANICS OF RUPTURE--DOES IT ONLY BENEFIT SCIENCE? [BRUCHMECHANIK--NUR FUER DIE WISSENSCHAFT?]

The article examines ruptures due to brittleness without deformation of materials with high tensile strength. Functions have been calculated for different types of fissure taking into account only the residual tension and the shape of the fissure, and this enables the stress intensity at the edge of the fissure to be ascertained. A characteristic of the material is the critical intensity of the stress when the sample or component part is ruptured. This method is still limited to ideally elastic and brittle materials, but could also be extended to real materials. [German]

WHAT DESIGNERS SHOULD KNOW ABOUT FRACTURE TOUGHNESS
Is brittle fracture a brand new problem? Brittleness becomes a threat with high strength steels or thicker plates. Only within the past 20 years have we started using these higher strength steels for structures. During the same time, welding has become commonplace and has brought a strong temptation to use thicker plates. In about 90% of the cases involving cracking, if any toughness at all had been specified, trouble would probably have been avoided. Designers or owners should test the steel he gets; steel companies also have an obligation to provide information on steel toughness. They should state the range of fracture toughnesses at given temperatures.

THE BEHAVIOUR OF RAILS IN RELATION TO THEIR CONDITIONS OF USE
The principal rail failure statistics of 5 Administrations have been analysed with a view to determining the respective influence of the different features involved in the behaviour of rails in service. Some recommendations are proposed concerning the choice of rail-section as a function of the traffic, the grade and quality of the rail steel and the construction of rail joints. The problems raised by welds in continuously welded rails, by the substructure and by the environment are also mentioned. It seems that the rail withdrawals for fatigue defects increase proportionally with the total traffic load on the one hand with the cube of the average axle-load on the other.
Restrictions on the use of this document are contained in the explanatory material.

FATIGUE STRENGTH OF STEEL BEAMS WITH WELDED STIFFENERS AND ATTACHMENTS
Following an intensive study of the fatigue behavior of steel bridge members, researchers at Lehigh University recommend changes in the Standard Specifications for highway bridges published by the American Association of State Highway and Transportation Officials and in specifications of the American Welding Society and the American Railway Engineering Association. In the past, only approximate general design relationships have been possible on the basis of the limited existing experimental data. Some 157 steel beams and girders were fabricated and tested, primarily to define the fatigue strength of transverse stiffeners and attachments under constant-amplitude fatigue loading. Stress range accounted for nearly all the variations in fatigue life.
Research sponsored by the American Association of State Highway and Transportation Officials in cooperation with the Federal Highway Administration.

MEAN STRESS EFFECTS ON FATIGUE CRACK GROWTH AND FAILURE IN A RAIL STEEL
Over a limited range, the effect of mean stress has been studied on fatigue crack propagation and on the critical fatigue crack size associated with sudden fast fracture in center-notched plate specimens of a rail steel under pulsating loading. The results have been presented in terms of the stress intensity factor range K and the ratio R of the minimum to maximum stress. Increasing R was found to both accelerate cracking and reduce the critical crack size at instability. The data have been correlated with three crack growth equations currently used in the literature and it was found that the equation of Forman et al. relating crack growth rate to K and R gave the best fit. This equation was used to predict life in the finite range of the S-N curve. Fractographic examination revealed that the fracture surfaces were complex and a number of fracture modes contributed to cracking.

THE DETERMINATION OF STRESSES IN ROLLING-CONTACT ELEMENTS
Stress patterns in lubricated rolling-contact elements have been computed from surface pressures and temperatures between pairs of rolling disks, both cylindrical or both crowned, measured by means of evaporated surface transducers. The maximum mechanical shearing stresses computed for both cylindrical and crowned disks proved to be nearly equal to those that would have occurred under static contact, but the calculated depth of those stresses was reduced for cylindrical rollers in dynamic contact. The maximum shear reversals computed for rolling cylindrical disks were noticeably below the corresponding shear differences for the static cases. Local pressure anomalies, such as the pressure spike in the one particular case chosen for investigation, did not seem to alter significantly the shear-stress patterns. Thermal shearing stresses do not appear to be a significant portion of the maximum stress but do dominate over mechanical shearing stresses near the surface of the elements.

NOISE IN RAIL TRANSIT CARS: INCREMENTAL COSTS OF QUIETER CARS
U.S. rail rapid transit systems, car operations, and the car building industry are described in relation to the procurement of quieter cars. The noise environment of passengers in rapid transit cars is discussed and the major noise sources and paths of noise transmission into cars are delineated. For essentially all combinations of car noise-control modifications deemed technically and economically feasible for implementation in new vehicles, estimates are presented of the associated noise reductions, initial costs, and operating costs. It is concluded that significant reductions in in-car noise under typical operating conditions can be achieved at incremental costs that are small percentages of the total car costs.

DIRECTIONS IN TRACK STRUCTURE RESEARCH
This paper presents a survey of contemporary problems in track structure technology and the programs of research and development addressing these problems. It reports current and anticipated investigations into aspects of the service environment of railroad track structures, the mechanics of track structure degradation, the fatigue and fracture of rails, the development of rational design and maintenance techniques, the improvement of track components, and the development of non-conventional, low maintenance track structures for application to high speed high density service. Efforts involved with both the fundamentals of track mechanics, and the design of improved structures for urban rapid transit applications, as well as mainline railroad use are included.

ASSESSING THE SIGNIFICANCE OF FLAWS IN WELDS SUBJECT TO FATIGUE
The substitution of fracture mechanics crack propagation data for simple S-N curves provides additional data on welds defects, other than applied stress and the influence of geometry. It allows the fatigue process to be entered (variation in initial flaw size) and left (variation in failure criterion) at will and variations in geometry and crack share to be taken into account. The value of the method has been confirmed by accurately predicting the fatigue behavior of fillet welds containing flaws on the basis of the generalized stress parameter.

SOME RELATIONSHIPS BETWEEN FRACTURE TOUGHNESS, APPLIED STRESS OF STRAIN AND FLAW SIZE
For low values of strain divided by yield strain, more accurate measures of displacement are required so that large errors are not involved when determining strain and strain divided by yield strain values. Measurements to 1x10 to the minus 3rd power in. should be sufficiently accurate for elastic displacements of the order of 35x10 to the minus 3rd power in. Testpiece geometry and flaw type have a significant effect on non-dimensional crack open displacement versus strain over strain yield. Surface flaws (part through the thickness) exhibit more developed COD at the same applied strain level than either the double edge notched or center notched tension geometries. Data are also included for determining critical flaw sizes for failure by brittle fracture.

CONTRIBUTION TO THE THEORETICAL EXAMINATION AND EXPERIMENTAL TESTING OF RAILS [Ein Beitrag zur Theoretischen Untersuchung und Experimentallen Pruefung von Eisenbahnschienen]
The forces acting on rails under different conditions of service stress were calculated. Calculations were compared with results of fatigue tests on S49 and UIC60 rails. The variables investigated for their specific effects included locomotives vs freight cars and fast succession of trains. Fracture formation and propagation are discussed. It is concluded that high axle loads require a large rail section, and small wheel diameters also require a high tensile rail steel. The UIC60 rail of steel with 900 N/mm2 minimum tensile strength meets the two requirements and offers ample reserves. [German]

FAILURES OF RAILS AND TRACK SWITCHES [Schadensfaelle an Eisenbahnschienen und Weichen]
Statistics of failures and investigation of the rail material point out to the specific kind of failure of rails. In particular there occur fractures in the form of the running edge peeling off as well as of cross fractures. Even the rails manufactured of high-strength steels cannot cope with heavy loading, occurring in curves with a narrow radius. This led to the development of rails

with a yield point exceeding 600 N/sq mm that are being successfully used. A method for analysis of failures is suggested. [German]

C4 072791
METALLURGICAL FACTORS CONTROLLING THE FRACTURE TOUGHNESS OF WELD MICROSTRUCTURES, WITH PARTICULAR REFERENCE TO THE MICROMECHANISM OF FRACTURE INITIATION
To link fracture toughness measurements specifically to particular micromechanisms, correlations between toughness, microstructure and composition must be related directly to the mechanism of initiation by inspection of the fracture surface in the region of the specimen notch after testing. Some factors which are beneficial to resistance to cleavage may be deleterious as regards resistance to microvoid coalescence and that, for optimum toughness over a wide range of temperature, applied strain rate and stress state, compromises in composition are required. However where, in a given application, only one micromechanism of fracture is of concern, efforts can be more simply concentrated on optimizing composition and welding procedure to produce HAZ and weld metal microstructures having the maximum resistance to fracture by this particular mechanism, subject, of course, to any other requirements, such as retaining adequate tensile properties and resistance to weld cracking problems.

INCREASING THE STRENGTH OF RAILS AND THEIR RELIABILITY IN SERVICE ON THE RAILWAYS OF THE USSR
The main measures are aimed at increase of the rail strength. Partly the rail strength increase is attained by means of raising the carbon content is steel, improvement of its metallurgical quality and by addition of alloying elements. The drastic improvement of the rail strength is being attained through the heat-treatment. This article comprises also a short review of the investigation of mechanical properties of hardened rails and their performance after 4-year service. The strength is noted to be considerably increased, the contact-fatigue damage reduced greatly and the general durability raised. Authors give also the method of recovering the hardness of the metal in the zone of welded joints in CWT.

PROPERTIES OF ISOTHERMALLY QUENCHED AND ALLOY STEEL RAILS
In laboratory and production-scale trials, rails were subjected to austenitizing temperature 850 to 900 C (holding for 1-1/2 hr), cooling for 35 to 40 min in a molten bath of 50% KNO sub 3 and 50% NaNO sub 3 with a water addition of 9.68% to increase cooling efficiency. The temperature of the molten bath varied between 280 and 320 C according to the chemical composition of the steel. The rails are rinsed in hot water (50 C) after quenching. Properties were investigated on sections from carbon, silicon, chromium and Cr-Si-Mn steel rails. The isothermally quenched rails had a high tensile (130 to 160 kg/sq mm) and fatigue strength (53 to 68 kb/sq mm) and, with optimum structure, showed good resistance to brittle failure. Ductile and impact properties were satisfactory and a more favourable pattern of internal residual stresses was obtained.

This abstract is also contained in "A Bibliography on the Design and Performance of Rail Track Structures", September 1974, RRIS #072794, which was prepared for the Urban Mass Transportation Administration.

C4 072848
EFFECTS OF PRODUCTION METHODS ON RESIDUAL STRESSES IN COMPLETELY QUENCHED RAILS
Complete quenching sets up high residual stresses in rails. Tempering lowers them while only slightly reducing rail hardness. Straightening after quenching and tempering again raises the residual stresses, making the rails prone to fracture along the neck. This is due to plastic deformation during straightening in the vertical plane, and to lower the residual stresses the maximum bending deflection should be limited. The increase in the residual stresses is then compensated by the high strength values of steel obtained by quenching.

This abstract is also contained in "A Bibliography on the Design and Performance of Rail Track Structures", September 1974, RRIS #072794, which was prepared for the Urban Mass Transportation Administration.

FAILURE ANALYSIS WITH THE ELECTRON MICROSCOPE
The author of this book has studied, by transmission electron microscopy, the characteristic failure modes of metals resulting from various known mechanisms and has applied the techniques developed to determine service failures and to settle negligence claims in commercial service. Some observations made in these studies form the basis of this book. The book contains an introduction to different failure modes in metals, factors which are important in failure analysis, and specimen preparation for failure analysis by electron microscopy. The behavior of metals under various physical forces, such as static, dynamic, and cyclic loads, are reviewed. The types of corrosive attack by environment, stress corrosion, wear, hydrogen embrittlement, and high-temperature creep are discussed. The microstructural changes in metals caused by these different load, environment, and temperature effects, and the resulting modes of failure are described. The goal has been to show how these failure modes can be identified by the use of the electron microscope while holding the complicated theoretical aspects of the subject to a minimum.

THE FRACTURE PROPERTIES OF TWO FAILED CAST STEEL WHEELS FROM THE UNION PACIFIC RAILROAD
During the late autumn of 1972 the Union Pacific Railroad had what appeared to be an unusually high number of wheel failures associated with low ambient temperatures. This behavior suggested to the Union Pacific that the temperature may have dropped below the materials transition temperature. In this connection the AAR was requested to determine the fracture properties of two cast steel wheels which failed during low temperature conditions (less than 35 F). On the basis of both the Charpy and critical stress intensity factor tests both wheels did not significantly change their fracture characteristics over the entire range of operating temperatures.

COUPLER STEEL STUDY
FRA regulations stipulate that only approved couplers may be used on tank cars. Since some considerations was given a requirement for the use of Grade "E" steel in Type "F" couplers, the AAR Research and Test Department undertook a preliminary study of the properties of "C" and "E" steels in "F" couplers selected at random from stocks about to be utilized by railroads. The increase of strength between "C" steel and "E" steel does not contribute to an increase in a tendency toward brittle failure. In fact, the increase in strength is accompanied by a reduction in the transition temperature. Brittle service failures can be expected, especially in winter operating circumstances with heavy loads. The macroscopic examination reveals that the quality of the castings is lower than should be expected of material subjected to high service loading.

Contributing agencies are the Battelle Memorial Institute and the Southern Railway System.

PROGRESS REPORT--DEVELOPMENT OF AN ASSOCIATION OF AMERICAN RAILROADS DYNAMIC BOLSTER TEST
Preliminary work was completed on the analysis of the strength of truck bolsters relative to possible service type loadings. Measurements were made of maximum tensile and compressive stresses occurring in a bolster specimen under laboratory conditions simulating predicted service imposed loadings occurring with cyclic frequency. The results of the full study are expected to lead to a laboratory fatigue test for use in an acceptance specification for bolsters. The stress measurements were made for two general types of loading conditions considered to be the principal types of cyclic fatigue loadings imposed on truck bolsters in service. For both type loadings, stress measurements were made at a number of load levels. The basic procedures used in this study are presented in this report. There were some deviations required from these procedures that are explained in the report.

SUMMARY OF VISUAL INSPECTION RESULTS CRACKED OR BROKEN FREIGHT CAR COUPLERS, KNUCKLES AND YOKES
This report contains the results from a visual inspection of 1097 broken freight car couplers, knuckle and yoke components collected by five railroads during a thirty day period. The sample was collected as part of a joint AAR-Railroad program, just prior to the start of this joint RPI-AAR Railroad Coupler Safety Research and Test Project, to initially determine the approximate extent and character of current failures in couplers, knuckles and yokes. The result of this inspection, when combined with current population data, do not permit the determination of failure rate for the various components because the proportion of the total industry failures represented by the sample is indeterminate and the sample is, for most components, too small to provide the desired reliability. The results from this inspection will, however, supply valuable insight required to determine the necessary procedures, data and sample size to achieve the project objective.

REPORT ON ANALYSIS OF TANK CAR TUB ROCKETING IN ACCIDENTS
The objective of Phase 12 of the RPI-AAR Tank Car Safety Project is to explain fundamentally the phenomena of tank car fracture behavior in accidents, particularly those fractures which led to violent ruptures. The Battelle Columbus Laboratories was engaged to conduct this research, and Battelle's final report on the study has been published under Report RA-12-2-20, "Phase 12 Report on Analysis of Fracture Behavior of Tank Cars in Accidents". The analysis explained the various fracture phenomena that have occurred and which have led to various tank rupture patterns. One type involves a fracture which runs longitudinally, then turns to a circumferential tearing shear fracture. This sometimes completely encircles the tank and creates a tank section open at the fractured end and closed at the other end by the tank head. The unreleased pressure acting on the closed end creates an unbalanced force on the "tub" and causes it to rocket. Battelle analyzed this rocketing phenomena and discusses the effectives on possible design changes which would offer the potential of reducing the distance travelled by the tubs, or eliminating the rocketing completely.

YOKE SERVICE PERFORMANCE
Presents the initial 18 months of yoke removal data (for foreign cars only) reported to the newly established AAR Mechanized Car Repair Billing Exchange System in Washington, D.C. This computerized system lists the reason the yoke was removed under eight code numbers which interpreted mean: worn out, broken, missing, bent, bent beyond repair, obsolete, account other repairs, and removed in good condition. There were a total of 19,647 yoke removals reported in the initial 18 months. The number of reporting railroads (11 total) participating in the system at the end of the first 18 months accounted for a little over half of the freight car ownership in 1972 and therefore perhaps about half of the yokes removed from foreign cars by railroads (foreign cars are cars not owned by the reporting railroad). Considering this condition combined with other factors it seems reasonable to multiply the total removals reported to the AAR Billing Exchange by about 6 to obtain the total removals by the industry for the entire current service fleet of freight cars.

FINAL PHASE 09 REPORT ON TANKS, FITTINGS, AND ATTACHMENTS IN THE MECHANICAL ENVIRONMENT OF ACCIDENTS
Phase 09 of the RPI-AAR Tank Car Safety Research and Test Project concerns the behavior of tank car tanks and their appurtenances in the mechanical environment of railroad accidents. Thus, the items treated under this Phase 09 are: Tank shell-the portion of the tank between the heads, Tank fittings-the appurtenances attached to the tank shell and heads which are associated with openings through the vessel wall, and tank attachments-appurtenances attached to the tank shell and heads which are not associated with openings through the vessel wall. As an underlying principle, in the cost/benefit analyses under this study, the benefit values of design improvements, such as protective devices or "shields," are developed from accident data only from cases involving lading loss, the total dollar losses being the value of the lost lading plus that of subsequent losses caused by the lading loss. The cost of mechanical damage itself to shells or appurtenances is not considered reducible by a design change, it being assumed that the cost of repairing the "shield" is the same as that of repairing the unshielded item. Following the statement of the objective, the report comprises four main sections: (1) review of typical current tank car shell and appurtenance designs, (2) review and analysis of accident data, (3) discussion and conclusions, and (4) recommendations.

EXAMINATION OF BRIDGE EYEBARS
Four carbon steel eyebars taken from two bridges have been examined at the AAR Technical Center. Metallurgical examination and testing was performed on specimens prepared from these eyebars to study the properties and fracture behavior in both a corrosive and non-corrosive environment. Experimental results were compared to the findings of the National Transportation Safety Board's report on the collapse of the Point Pleasant, West Virginia bridge. The findings for the eyebars studies indicate that they were less susceptible to failure because: 1. Higher fracture toughness in the bars investigated. 2. Insignificant effect of a corrosive environment in accelerating the growth of a flaw leading to failure. Therefore, the results indicated that eyebar bridges constructed prior to the use of heat treated eyebars (before 1920), are less likely to develop a non-detectable eyebar crack leading to failure than those bridges where heat treated eyebars were used.

RESIDUAL STRESSES IN THE PLATE FILLETS OF TWENTY-EIGHT-INCH DIAMETER WROUGHT STEEL WHEELS
Past experience with the B-28 wheel has shown that this design is susceptible to plate cracking. This reports the results of a program to determine the state of residual stress in class U untreated and class B heat-treated wheels. Measurements were made according to the procedure outlined in the AISI Steel Products Manual for Wrought Steel Wheels and Forged Railway Axles. Measurements were taken at the front hub-plate fillet and the back rim-plate fillet on each wheel. While the maximum principal residual stresses developed in the class B wheels were two to four times higher than those developed in the class U wheels, analysis by Goodman diagram shows similar fatigue properties in both wheels.

C4 080369
AN INTRODUCTION TO THE FRACTURE MECHANICS OF RAILROAD MATERIALS
This report is intended to serve as a primer for railway personnel on the subject of fracture mechanics. Most structural materials contain flaws or cracks that are introduced during fabrication or service. Under various combinations of static and alternating loads and reactive environments, these flaws begin to grow slowly and stably. Unstable fracture leading to complete structural failure occurs when a flaw has developed to a critical size. The critical flaw size is a function of both the applied and/or residual stresses acting on the structure, and the toughness of the materials. The principles of linear elastic fracture mechanics can be used to describe the functional relationships for unstable (brittle, rapid) fracture that occurs even though nominal stresses are below the general yield strength (i.e., before full-plasticity has occurred in the structure). The effects of temperature, composition, strain rate and microstructure are discussed using data gathered from railway materials.

METALLURGICAL ANALYSIS OF FAILED RIMS ON FIVE BURLINGTON NORTHERN UNIT TRAIN TRUCK BOLSTERS
Results of fracture analysis, dimensional study, chemical analysis, Brinell hardness tests, and examination of the microstructures of five failed unit train truck bolster castings are reported. It was concluded that the failures were all triggered at the rim-bowl base fillet by various stress risers created by impacts of the horizontal liner plates against the rims. The failures propagated suddenly or in fatigue under impact of the rims with the body center plates. It was also found that the vertical liner rings had broken away from the rims of two bolsters before they were removed from service.

METHOD OF ASSESSING THE ENDURANCE OF SLEEPERS ON A TRACK USED FOR FREIGHT TRAFFIC [Metodika ocenki vynoslivosti zelezobetonnyk spal e ucetom grazonaprjazennosti linu]
The article describes a method and results of comparative assessment of the endurance of reinforced concrete sleepers under various operating conditions. The main parameter defining the work capacity of reinforced concrete sleepers in various operating conditions is the endurance threshold of the sleeper in certain transversal cross-sections. The "typical load", a value which determines the endurance of the sleepers for a specific type of freight traffic, is essentially a function of the type of rail and number of fully-loaded heavy wagons; it is calculated on the basis of: (1) the number of loading cycles borne by the sleeper; (2) the maximum load applied during these cycles; and (3) the frequency of the repetition of these cycles, according to the traffic. This method may be applied, for instance, when assessing the endurance of reinforced concrete sleepers in the case of an increase in the axle load. [Russian]

A GENERAL METHOD FOR THE FATIGUE RESISTANT DESIGN OF MECHANICAL COMPONENTS. PART 2: ANALYTICAL
This paper develops the general analytical solution to the design of mechanical components under fatigue loading. Its only limitation is that the overloading lines must be a straight line on the sigma a-sigma m diagram. The designer is free to select his own failure theory for the material he intends to use as well as to select his own fatigue fracture criterion.

This paper will also be published in the ASME Journal of Engineering for Industry.

A GENERAL METHOD FOR THE FATIGUE-RESISTANT DESIGN OF MECHANICAL COMPONENTS. PART 1: GRAPHICAL
Presented is a graphical method for the direct solution of fatigue design problems where the mode of overloading is to be taken into account. The material fatigue failure diagram is modified to give a new failure diagram called the safety diagram. The infinity of possible component designs is described by a line called the locus of design points. The intersection of the locus of design points with the safety failure diagram yields a direct design solution. Because of graphical difficulties, the method is limited to those cases where the locus of design points and the load lines are straight lines.

THE SPEED-RESPONSIVE HYDRAULIC DAMPER, THE NEXT STAGE IN DAMPER DEVELOPMENT
Riding qualities and dynamic forces on the track have been thoroughly evaluated but the understanding of dampers in relation to reduced maintenance, both vehicular and track is also pertinent. Degree of magnitude of vertical and sinusoidal irregularities are expressed as a function of acceptable acceleration, excitation frequencies and amplitude. Ride-index values important in determining riding qualities but suspension characteris-

tics in terms of reduced amplitude at higher speeds show speed-sensitive damping is desirable although the control system could be complex.

FINAL REPORT ON THE EVALUATION OF CUSHIONED UNDERFRAMES
This report covers a study and evaluation of special cushioning devices under impact conditions. The types of devices tested included sliding center sill, end of car hydraulic draft gears and column connected draft gears. Each device was evaluated with both canned goods and steel lading which respectively represented a resilient type of lading and a heavy rigid type of lading. This study indicates that the commodity protection needs under impact are not entirely a function of the special cushioning device but are also related to loading methods and types of packaging. In these tests the indications of cushioning protection provided by different shock absorption systems as summarized from the conclusions made in this report are: 1. Sliding sill type cars with 18 to 30 in. travel gave the highest degree of protection of lading through reduction of body force and resultant acceleration, followed in descending order by end of car hydraulic draft gears, column connected draft gears and standard draft gears. 2. The non-continuous or "split" design of sliding center sill provided the maximum protection to the car structure under dynamic squeeze, followed in descending order by end of car hydraulic draft gears, conventional continuous or through designs of sliding center sills and column connected draft gears. 3. Length of travel of sliding center sill is not an absolute indication of overall performance, particularly under dynamic squeeze conditions. 4. Small differences in sliding sill travel do not significantly change the performance characteristics. 5. Floating loads shift excessively, even with sliding center sill cars. 6. Energy absorption means are needed at the couplers in sliding center sill cars. 7. Sliding sills require high column strength to prevent bending.

HIGH SPEED TRACK AND ITS MAINTENANCE
The author discusses the conditions necessary for technically and economically acceptable track construction on high-speed routes with mixed-traffic working, taking into consideration the track alignment and the construction elements. Already at the planning and design stage, the track-building conditions and economical maintenance of heavily-worked routes must be given full consideration, and also adhered to later during regular operation. Proper staff training is also important. But further tests, for example with concrete-slab track structure under heavy working loads, are necessary before final decisions are made.

FRACTURE MECHANICS AND RESIDUAL FATIGUE LIFE ANALYSIS FOR COMPLEX STRESS FIELDS
This report reviews the development and application of an influence function method for calculating stress intensity factors and residual fatigue life for two-and three-dimensional structures with complex stress fields and geometries. Through elastic superposition, the method properly accounts for redistribution of stress as the crack grows through the structure. The analytical methods used and the computer programs necessary for computation and application of load independent influence functions are presented. A new exact solution is obtained for the buried elliptical crack, under an arbitrary Mode I stress field, for stress intensity factors at four positions around the crack front. The IF method is then applied to two fracture mechanics problems with complex stress fields and geometries. These problems are of current interest to the electric power generating industry and include (1) the fatigue analysis of a crack in a pipe weld under nominal and residual stresses and (2) fatigue analysis of a reactor pressure vessel nozzle corner crack under a complex bivariate stress field.

THE EFFECTS OF VARIATIONS IN HEAT TREATMENT ON THE STRENGTH AND TOUGHNESS OF RAIL STREEL
Because of the growing number of incidents due to rail failures, research is being made into possible improvements. The AAR and Carnegie-Mellon University have jointly sponsored a research programme into the possiblity of improving rail strength (which determines what axle load can be supported without any permanent rail deformation), and toughness (defined as the measure of the steel's resistance to brittle fracture or the slowness with which a defect spreads) by simply altering the heat treatment conditions (rolling or austenization temperature, isothermal transformation temperature or cooling rate). The general tendencies of the phenomenon have been determined. Strength and hardness are unaffected by austenization temperatures between 1470 degrees F and 1830 degrees F but toughness decreases. Resistance increases as isothermal transformation temperature rises (between 1010 degrees F and 1155 degrees F and toughness would reach its maximum at about the lowest temperatures tested). This unfinished study should make it possible to decide whether the improvements that can thus be obtained are adequate for justifying a transformation of the heat treatment process or whether this line of research is pointless.

LIFE CYCLE COSTING: A KEY TO FREIGHT CAR COMPONENT EVALUATION
The cost of repairing and replacing freight car components represents a very sizeable expenditure for the railroad industry. Of major concern to the railroad industry are the "costs" associated with various components. These costs include not only the direct costs of procuring and servicing such components but also related costs such as occur in derailments, train delays, and train handling mishaps. Phase II of the International Government-Industry Research Program on Track Train Dynamics is concerned with improving freight train performance and operating safety through the development of performance specifications and design guidelines for car components. If this activity is to be effective, it is essential that present and potential costs of component ownership be thoroughly evaluated. The authors have pursued this end through the development of a life Cycle Cost Model. Once necessary data sources are developed, this model will be used to evaluate research and implementation strategies for the program.

CAUSE FOR THE FORMATION OF GROOVES ON THE WHEELS OF BLOCK-BRAKED RAILROAD ROLLING STOCK AND THEIR PREVENTION [Ursache der Rillenbildung und Deren Vermeidung bei Raedern Klotzgebremster Schienefahrzuege]
Grooves on the friction surface of block-braked car and locomotive wheels are not formed as a result of hard structural consitituents in the cast-iron brake blocks, but rather as a result of partial melting and displacement of the wheel steel softened by heating in excess of the solids temperature during the friction process. The displaced steel collects for the most part on the braking surface of the block in the form of foil laminations. The cause for this phenomenon lies in an excessively high softening temperature of the brake block material. To prevent the occurrence of this defect, it is suggested to use cast iron containing low-melting structural constituents in adequate quantity and distribution. [German]

C4 095414
ANALYSIS OF TRACK PARAMETER HETEROGENEITY AS A COMPLEMENT TO GEOMETRICAL METHODS OF TRACK CONDITION RATING
The condition of a track may be defined by track rating indices (W indices at the PKP) taken from recordings by a track inspection car, or obtained by geometrical measurements (longitudinal dip and cross-sectional irregularities, without load or with a moving load, lateral displacement, etc.). By track heterogeneity, the writer means the differences that such indices reveal on lengths of line with identical make-up, similar age, and used by the same traffic. These heterogeneities, which may be caused by the laying or maintenance of the track, or by constructional features with different characteristics, are also likely to result in great differences in the rapidity with which these lengths of line deteriorate, necessitating earlier continuous track renewal. The article proposes methods of assessing these heterogeneities by tests based on classic statistics laws. Numerical examples thus deal with: heterogeneities in the W index, by the X to the 2nd power test; heterogeneities in the track gauge by a method called the "ZM test" taken from an American book referred to in the bibliography; correlations between rail dip and lateral displacement under a moving load, by an analysis of sequential correlation. These complex analyses are not used as a basis of routine maintenance decisions, but in investigations for the purpose of explaining abnormal phenomena.

M/W COSTS: HOW THEY ARE AFFECTED BY CAR WEIGHTS AND THE TRACK STRUCTURE
Using a combination of theory and actual field measurements, the author develops the relative maintenance costs associated with axle loads and the type and condition of the track. The article attaches definite values to variables such as total tonnage carried, track condition and car size. The Illinois Central Gulf considers that 53% of total track expense and capital investment is incremental--varying with the tonnage moving over the railroad. This incremental cost is then broken into its own increments based on rail deflection, rail bending stress, rail life and miscellaneous costs.

FLAME HARDENING OF RAIL BY THE HAMMON CONTINUOUS PROCESS AND PHYSICAL AND ROLLING LOAD TEST RESULTS
Since the standard carbon rail is removed from track due to abrasion, head flow on the low rail of the curves and shelling on the high rail, it is of interest to the industry to investigate any process that alleviates this problem. Failures due to shelling alone amount to 40 percent of all types of failures. Alloy rail steel chemistries and heat treatment have been found helpful in extending rail life where the above conditions existed. In the area of heat

treatment, various types of flame hardening of the rail head have been found applicable economically and available in all parts of the United States. Summarizing, features of this process that may be of interest to railroads are: 1. Evaluation of rail flame hardened by this process at the Research Center and the University of Illinois indicates that it should give good service performance. 2. It is claimed that it will be economical because of its ability to use propane or natural gas for heating the rail. 3. Rail of any length can be continuously flame hardened, before or after welding. 4. The equipment can be mounted on railroad cars to be used either at the welding or cropping site.

LABORATORY INVESTIGATION OF PRESTRESSED CONCRETE RAILWAY BRIDGE BEAMS

This report contains a description and analysis of laboratory tests made during 1960, 1961, and 1962 on 23 full-size prestressed concrete beams. These beams are 18 in. deep, 15 in. wide, and 19 ft. long and were patterned after the full-size slabs reported in AREA Proc. Vol. 59, p. 133. This investigation was directed toward a study of the effect of size of strand and level of prestress on their static and fatigue strength, and is an extension of one conducted at Lehigh University on similar beams, and reported in AREA Proc. Vol. 60, p. 1. From this tests, it can be concluded that: 1. In the static tests, the cracking loads and the deflection were affected by the level of prestress but not by the size of strand. Taking into consideration the difference in concrete strength the ultimate strength apparently is not affected by level of prestress or by size of strand. 2. Fatigue strength was influenced by the level of prestress. 3. The test results were inconclusive with regard to the relationship between fatigue strength and size of strand. 4. The mode of failure in the static tests was by crushing of the concrete accompanied by large strains of steel strands, while breakage of the steel strands caused failure in the fatigue tests. 5. The ultimate load varied from 2.5 to 3.0 times design load for static tests and from 1.3 to 1.8 times design load for fatigue tests. 6. Fatigue life decreased as the cycling load increased. 7. Strains and deflections changed only slightly for those beams which did not fail for 2,000,000 cycles of repetitive loading. 8. There was no evidence of strand slip. 9. Recorded ultimate static moments compared favorably with values computed by using the formula given in the current AREA Specifications. 10. The fatigue strength of beams could be predicted by using an idealized stress-moment diagram combined with a failure envelope for the steel strands.

LABORATORY INVESTIGATION TO DETERMINE STATIC AND REPEATED LOAD STRENGTH OF FULL-SIZE SOUTHERN PINE GLUED LAMINATED STRINGERS

This report contains the analysis of data recorded during the laboratory investigation of 24 full size southern pine glued laminated stringers at the Association of American Railroads Research Center and a description of certain physical properties as determined by the Forest Products Laboratory at Madison, Wisconsin. The purpose of the investigation was to determine the static and repeated load strength of the stringers and the effect of load placement. The stringers were loaded in increments of the shear design load with the load points that were 4 ft-8 in. apart and with the first load point at 1-1/2d, 2-1/4d and 3d from center line of bearing. Design load was that load which produced an allowable design shear stress of 180 psi. The following observations may be made from the recorded data: 1. The three stringers tested statically at load points 1-1/2d, 2-1/4d, and 3d failed at 5.34, 4.71, 3.72 shear design increments. Failure was in bearing for 1-1/2d and 2-1/4d loading; and tension for 3d loading. The deflection and flexural strains were linear up to failure. Pending failure was not noticeable and it occurred quite rapidly 2. Four stringers which did not fail after 2,000,000 cycles of repeated loading were later tested statically. One stringer was tested at 1-1/2d, one at 2-1/4d, and two at 3d loading. The shear design increments were 5.04, 4.41, and 3.83 respectively. The stringer at 1-1/2d and the two at 3d did not fail since the capacity of the loading jack was reached first. At 2-1/4d the stringer failed in horizontal shear. 3. Five stringers were tested under repeated loads positioned at 1-1/2d. Of the two stringers loaded at 2.13 times shear design load, one did not fail and one failed at 882,000 cycles because of a knot within the lamination. One stringer was subjected to a shear stress design load ratio of 2.33 and it did not fail. Another stringer was subjected to a shear design load of 2.72 and failed in bearing at 1,365,000 cycles. The final stringer was subjected to 3.11 shear design load and it failed in horizontal shear at 666,200 cycles. 4. Seven stringers were tested under repeated loads positioned at 2-1/4d. One stringer was tested at a shear design load 2.18 or 25,500 lbs per load point and it did not fail. Another stringer subjected to the same shear load ratio failed in horizontal shear after only 417,000 cycles of repeated loading. Failure was attributed to a knot.

RAIL STUDY BESSEMER AND LAKE ERIE RAILROAD

Because of the ever increasing concern with shelling of rail and its possible connection with wheel loads and the present day trend to still heavier wheel loads, a study was conducted on the Bessemer and Lake Erie Railroad to analyze their rail conditions in conjunction with their use of 90-ton cars for transporting of ore. This railroad has been using these 90-ton capacity hopper cars since 1931, with practice being to load ore for southbound movement to capacity, thus creating loads averaging 32,300 lbs. per wheel. It has been noted over the years that even with these wheel loads and rather high annual tonnages, the Bessemer has had little or not shelling of their rail. This study was prompted to see if an answer could be derived as to why no shelling problem exists here. In particular, two locations on the railroad were checked where the present rail in track is 131 lb., laid in 1938, and has had over 400,000,000 gross tons of traffic, most of which consisted of are carried in these 90-ton hopper cars. The northmost location is at Springboro, Pennsylvania, where there is a length of one mile of the 131 lb. rail in track (north and south of Mile Post 116). The other location is through and to the south of Grove City, Pennsylvania, Mile Post 60-63, where there is a 3-mile section of 131 lb. rail in track. Both of these sections of 131 lb. rail now carry both northbound and southbound tonnage, but prior to single tracking and installation of C.T.C. in 1957, this trackage was the southbound main track in both instances and carried the predominant southbound ore traffic. At both locations of 131 lb. rail, rail profiles were taken, degree and superelevation of curves were noted, predominant speeds of tonnage trains in both directions were noted, condition of the entire track structure and, in particular, condition of the rail both on tangent and curves were noted. Photographs were taken to show the rail condition. Because of curvature in the locations not exceeding 3 degrees, other locations on the railroad were

chosen to make like studies, these locations having the same or less annual tonnages, and having different weights of rail of shorter service life, but having greater degree of curvature. Rail profiles and photographs were taken at these locations also. Along with the study of the rail and track conditions, a study of the 90-ton B & LE hopper cars was conducted, obtaining all pertinent data, prints, and photographs having to do with their construction and maintenance. The Bessemer's rail replacement policy is guided by the formula--T = .703xWxD.565 where T = Life of rail in million gross tons. W = Weight of rail in lbs. per yard. D = Traffic density in million gross tons per year.

Conducted under sponsorship of AAR Joint Committee on Relation Between Track and Equipment.

SERVICE INVESTIGATION OF VARIOUS TYPES OF JOINT BARS ON SANTA FE AND NORTHWESTERN RAILWAYS

This report covers the service investigation of various types of joint bars and variations of bolt spacing on the Atchison, Topeka and Santa Fe Railway near Streator, Illinois and on the Chicago and Northwestern Railway at Sterling, Illinois. 1. All design of joint bars have been adequate throughout the service period of 16 years. 2. Four bolts in 36 in joints with 9-9 1/8-9 in spacing are adequate to hold the rail, but do not provide sufficient rail end support, hence, create additional batter and droop of the rail ends compared with 6-bolt bars. 3. There appears to be little difference in the performance of the current AREA bolt hole spacing of 6-6-7 1/8-6-6 in compared with the 6 1/2-6 1/2-5 1/8-6 1/2-6 1/2 in spacing where such a comparison can be made in the Santa Fe test. Inasmuch as the current AREA spacing has been shown to produce less stress concentration at the bolt holes and this service test has shown no disadvantage in other respects, it has confirmed the desirability of continuing the current AREA bolt hole spacing.

Conducted under sponsorship of AREA Committee 4-Rail.

METALLURIGICAL, PHYSICAL AND ROLLING LOAD TEST RESULTS OF RAIL ROLLED FROM CONTINUOUSLY CAST BLOOMS

The development of information relative to any new process applicable to producing rail more economically is of interest to the industry. The opportunity of investigating the application of continuous casting in rolling rail presented itself when the M.W. Kellog Company became interested in investigating this process on behalf of a Mexican client. The AAR Research Center cooperated in developing the metallurgical, physical and rolling load test results of rail rolled to the S49 section from continuously cast blooms. The results on the same type of of tests as described above tested in the 12 in stroke rolling load machine are shown on Table 4. The S49 rails and the oxyacetylene pressure butt welded rail joints did not fail. The flash butt welded rail joints failed prematurely due to grinding cracks away from the weld caused by heavy cold grinding as shown in Figs. 8 and 9. The drop test results of the rail as shown on Table 5 indicate that the rail met the AREA specification. Fig. 10 illustrates the effect of the drop test. As mentioned before, very few butt welded rail joints have withstood the standard drop test for rail. The structure of these fractures were noted to be fiberous. The results of the investigation of the S49 rail rolled from continuously cast blooms at the AAR Research Center and comparable results of the investigation by Dr. Janiche indicate that rail produced by this process is of equal quality to rail produced by the standard process. The results are surprising in this first attempt of producing rail in this manner. As the art of of continuous casting in reference to rail is advanced, all of the defects such as segregations will undoubtedly be eliminated. The economy of the process is predicated on the elimination of mold and teeming practices as well as soaking pits and primary mill installations. It is of interest to call attention to the last paragraph of the attached report which states that the UIC specification for rolling rail calling for a bloom cross section of at least 20 times larger than the rail cross section was not met in this case. In the above rolling, the ratio amounted to 15 to 1 in the case of the 30 d rail and 9 to 1 in the case of the S49 rail.

FREIGHT CAR DYNAMICS--ONE CARBUILDER'S APPROACH

Amcar Division of ACF Industries, like the other carbuilders, is taking on additional responsibilities for all aspects of car dynamics design and test, particularly with respect to carbody structure. Explained is the ACF computerized system for analysis of carbody structural dynamics, intended to combat fatigue problems. Mathematical modeling is used to develop load paths and stress profiles of complex structures. Road testing is important in developing environmental data and ACF has acquired an instrument car for this purpose. Modified Goodman Diagrams are developed and their use is discussed.

This is a paper from the proceedings of the 11th Annual Railroad Engineering Conference held at Southern Colorado State College, Pueblo, Colorado, October 23-24, 1974. Other individual papers from this conference have been accessioned separately for RRIS. SOME OBSERVATION ON FATIGUE PHENOMENA IN A LARGE PLATE SPECIMEN OF SPRING STEEL AFTER SHOT-PEENING TREATMENT

To obtain the fundamental data for the nondestructive finding of fatigue damage in vehicle parts, the fatigue due to pulsating repeated bending in a large plate of spring steel which had been shot-peened to increase its fatigue strength as a vehicle part, was investigated. It was clarified that there were two ways to find the fatigue damage: to observe the changing state of the surface residual stress and to detect the internal cracks non-destructively.

THE FRACTURE TOUGHNESS OF CARBON-STEEL, ALLOY-STEEL AND HEAT-TREATED RAILWAY RAILS
The static and dynamic fracture toughness of standard carbon steel rail was determined using precracked Charpy bars. The static, fracture toughness was found to be higher than the dynamic fracture toughness across the entire range of railway operating conditions. Since rails are subjected to dynamic loading conditions, dynamic fracture toughness tests were conducted on specimens from alloy-steel and heat-treated rails in order to compare fracture properties. In addition, the standard British rail steel and two heat-treated grades of British rail steel were evaluated. It was found that carbon levels above 0.55 w/o did not affect fracture toughness while increasing silicon decreased fracture toughness in both high and low carbon rails. In line with earlier work, it was found that decreasing pearlite spacing increased fracture toughness. In addition, the effects of manganese, chromium and molybdenum are discussed.

THE EFFECTS OF MICROSTRUCTURAL VARIATIONS ON THE STRENGTH AND TOUGHNESS OF RAIL STEELS
An experimental program was carried out on fully-pearlitic rail steel to determine the effects of microstructural variations on tensile and impact properties. A heat treating schedule was developed to isolate the effects of prior austenitic grain size, pearlite interlamellar spacing, and to a minor extent, pearlite colony size. Grain size was varied by a factor of ten, and pearlite spacing by a factor of two. Room temperature yield strength increased monotonically with decreasing interlameller spacing, with the latter controlled by the transformation temerature and prior austenitic grain size. Charpy impact tests were performed to obtain an evaluation of toughness, and showed that toughness increased with decreasing grain size, and was largely independent of an influence of pearlite spacing. Dynamic fracture toughness values, (KID), obtained from instrumented impact testing of precracked Charpy bars, were compared with the standard Charpy results, and yielded Similar findings. Thus, it was found that strength and toughness are controlled by different microstructural parameters, and can be varied independent of each other to optimize service performance.

SUMMARY OF PERFORMANCE OF STANDARD-CARBON AND VARIOUS WEAR-RESISTANT RAILS IN TEST CURVES ON THE CHESSIE SYSTEM-SECOND REPORT
This report contains the summary of the second annual inspection of a service test installation of fully heat-treated, induction head-hardened, intermediate- manganese and standard control-cooled rail on the Chessie System. The field inspection is part of the cooperative effort on rail research of the American Railway Engineering Association, the American Iron and Steel Institute and the Association of American Railroads to observe and analyze those rails in curved track that display some potential for improvement in wear-resistance and retarding the onset of shelling. Measurements were made and recorded of curvature, superelevation and gage of four service test curves located near Oakland, Maryland, General track conditions were observed also. Rail head cross-section contours were taken and recorded of the 80 test rails contained in these curves. Rail wear has been calculated for the second year of service for the various types of rail in test.

ADVANCED DESIGN TECHNOLOGY FOR RAIL TRANSPORTATION VEHICLES
This is an interim report on a cooperative research project between Washington University and AMCAR Division of ACF Industries Inc. The purpose of the project is development of a new finite element stress analysis capability which is more cost effective and better suited for fatigue life evaluation than existing finite element computer programs. The report contains a general outline of the method, description of the algorithm structure and methods by which the computational efficiency can be further increased. A benchmark problem established by experimentation and by computation using an existing finite element computer program (STARDYNE) is presented.

The Association of American Railroads and AMCAR Division of ACF Industries, Inc. provided for partial funding of this project.

ANALYSIS OF RAILROAD CAR TRUCK AND WHEEL FATIGUE. PART I-SERVICE LOAD DATA AND PROCEDURES FOR THE DEVELOPMENT OF FATIGUE PERFORMANCE CRITERIA
The development of fatigue performance standards for freight car truck components and wheels requires a knowledge of the fluctuation service load

environment, and a basis for stating the conservatism of the design with respect to the environment. On this program special emphasis was given to determining the load environment by analyzing data from 53 test runs conducted on the Erie Branch test track of the Bessemer and Lake Erie Railroad. A number of test parameters were varied, such as speed, type of truck, modifications to the suspension system, etc., to determine those parameters having the greatest influence on the severity of the load. Vertical loads were measured at the side-frame-pedestal/roller-bearing-adapter interface and lateral loads were determined at the wheel/rail interface. The cyclic load data are summarized in a series of load spectra. Factors which must be considered in the development of fatigue performance standards from these spectra include reliability goals, the statistical spread of both load and fatigue strength data, and the philosophy followed in the design of the truck itself.

PREVENTION AND CURE OF RAIL CORRUGATION
The author has discovered that corrugation is a function of track modulus and wheel loading. There is a critical range of shear and compressive stress within which rail corrugation takes places but below or above this range the phenomenon is absent, possibly because wear particles are either not generated or they are removed altogether. Not only will correct matching of track modulus, to axleloads carried avoid generation, but elimination of a mismatch will also cause existing corrugation to disappear without the need for grinding.

FRACTURE RESISTANCE OF RAILROAD WHEELS
The effects of manufacturing method, chemical composition, heat treatment, temperature, and loading rate on the plane strain fracture toughness KIC of railroad wheels have been determined. Carbon content of the wheels is shown to be the principal factor which controls their toughness. One hundred wheels which fractured in service are analyzed by means of fracture mechanics procedures. The locations, configurations, and size of thermal and plate cracks which initiated brittle fracture are reviewed, and estimates made of the stress levels which resulted in failure. Estimates have been made of the minimum size of crack which could result in the failure of wheels under adverse service conditions. These are discussed with respect to the minimum size of defect which can be reliably detected by NDT. Included in the report are state-of-the-art reviews on thermal and plate cracking and on the stresses developed in railroad wheels.

TIE RENEWALS AND COSTS
This report of AREA Committee 3 involves statistics on tie renewals and average tie costs for 1974 as compiled by the Economics and Finance Department of AAR. The details are given in tabular form. Along with conclusions about the rates at which Eastern, Southern and Western railroads inserted ties, it is shown that the "indicated" wooden tie life for all U.S. Class I railroads is 47 years. The average cost of ties increased by 43% from 1973 to 1974. There was only an increase of 5% in tie renewals in 1974. The average number of concrete ties inserted was the same in both years but the tie cost went up 44%.

AN INVESTIGATION OF FACTORS CONTRIBUTING TO WIDE GAGE ON TANGENT RAILROAD TRACK
Wide gage--a fatigue failure of the track to maintain the nominal lateral distance between rail heads--is one of several modes of track failure on which the AAR-FRA-RPI-TDA Track Train Dynamics Program has focused attention. To investigate the generation of wide gage on tangent track, experiments were conducted to measure track dynamic response and long-term fatigue life of track sections on the Union Pacific Railroad in Idaho. Results of these experiments have defined the important factors in this mode of track fatigue.

PROPOSED SOLUTIONS TO THE FREIGHT CAR TRUCK PROBLEMS OF FLANGE WEAR AND TRUCK HUNTING
This paper reports on the progress of a development program whose objective is to devise cost effective solutions to the problems of excessive flange wear and truck hunting. It is expected that later papers will deal with separate aspects of this program in greater detail. Three solutions for freight cars are proposed: (1) a retrofit steering assembly kit for application to the trucks of existing roller bearing cars, (2) modification of the side frame and bolster castings to incorporate a more cost effective steering assembly for new trucks and (3) a completely new truck design incorporating improvements in car suspension as well. All three designs include a steering feature which will reduce wheel and rail wear in curves and elminate truck hunting. The second and third designs also provide better brake shoe/wheel alignment for additional savings in wheel wear. The appendices define the terminology used and identify the design characteristics of conventional trucks which lead to the present high cost of ownership.

This paper was contributed by the Rail Transportation Division of the ASME for presentation at the Winter Annual Meeting, Houston, Texas, November 30-December 4, 1975.

ANALYTICAL AND EXPERIMENTAL DETERMINATION OF NONLINEAR WHEEL/RAIL GEOMETRIC CONTRAINTS
The wheel/rail geometric constraint relationships for actual wheel and rail profiles are generally nonlinear functions of wheelset lateral displacement. Two of these relationships which strongly influence the lateral dynamics of railway vehicles are the effective conicity and gravitational stiffness. An algorithm for the digital computer is presented that calculates these nonlinear relationships for arbitrary wheel and rail head profiles. An experimental apparatus was developed to determine the location of the wheel/rail contact points as a function of wheelset lateral displacement for arbitrary profiles. Experimental data obtained with this apparatus are presented for various cases which validate the results of the analytical procedure.

To be presented at the Winter Annual Meeting.

AXIALLY STRESSED RAILROAD TRACK ON AN ELASTIC CONTINUUM SUBJECTED TO A MOVING LOAD
The recent introduction of the welded railroad track raises the possibility that high axial compressive forces may occur in the rails due to constrained thermal expansions. This in turn may reduce the critical velocity of the track to within the operational velocities of present day trains. Recently the effect of axial forces upon the critical velocities of the track was analyzed by A.D. Kerr using the Winkler model for the base response. In this study, the effect of the axial compressive force on the critical velocity of the track is studied assuming for the base an elastic half space with inertia.

EFFECT OF RESIDUAL STRESSES IN HARDENED RAILS ON THE FORMATION AND PROPAGATION OF STRESS FISSURES DUE TO CYCLIC STRAINS [Vlijanie ostatocnyh naprjazenij V Zakalennyh rel'sah Vozniknovenie i rasprostranenie ustalostnyh trescin pri Cikliceskom izgibe]
The authors have reached the following conclusions: The railhead, as a result of heat treatment or cold straightening, can develop a considerable drop in the stress limit, a drop in the number of cycles completed before stress fissures occur, a drop in the number of cycles completed during the stress fissure propagation period, a reduction in the critical size of each stress fissure, or a drop in the curability of hardened rail, 2) the residual compression stresses which occur in the rail head accentuate the above characteristics. [Russian]

FATIGUE STRENGTH OF STEEL WIRE FOR PRESTRESSED CONCRETE SLEEPER
This paper describes calculation of the fatigue strength of steel wire used for prestressing concrete cross ties. From the results of rotating bending fatigue tests of deformed prestressing wires and plain wires pretreated in various ways, the following conclusions were obtained: (1) Suitable deformed prestressing wires are available for concrete cross ties; (2) Some surface damage may decrease the fatigue strength of the prestressing wire (corrosion, notching and sparks, for instance); (3) JNR's present prestressing loads are sufficient. The effects of spark damage to wires are particularly critical.

LI TRIES FOR MORE TIE LIFE BY REDUCING TIE-PLATE WEAR
To reduce the cutting of wooden cross ties by tie plates, the Long Island Rail Road has initiated tests of Pandrol rail fastenings with special plates having shoulders that accommodate the legs of the spring clips. The goal was to increase the 28-year tie life experienced on heavy-density routes. A 13-mile stretch of new continuous welded rail has been secured with the Pandrol fastenings; tie plates are secured with three Lock Spikes. Tie life is enhanced by eliminating movement of the plates on the ties and a stiffer track structure is thought to have been produced. In addition to the longer service from ties, the Pandrol assembly simplifies the changing of defective rails and avoids problems of spike killing of ties and the loss of plate gauge every time a rail is changed.

CALCULATIONS BASED ON AVERAGE USEFUL LIFE [Das Rechnen mit gemittelten Nutzungszeiten]
To determine the capital cost of articles made up of parts with different average useful lives, it is usual to use averages. The author shows that calculating averages in this way lead to systematic error which makes results wrong. He explains the error and proposes a new method. Using an example with figures, he also shows the practical application of the method suggested and at the same time, the disparity between the results of the two methods. [German]

WEAR ON EXTERNAL SURFACES OF WHEELS AND RAIL DUE TO FRICTION [Verschleissvorgang im Grenzschichtbereich der Reibpaarung Rad/Schiene]
The stresses borne by rail and wheel elements are analysed on the basis of several fundamental definitions of wear by Fleischer. A number of studies were carried out on plastic deformation, running surfaces and wear characteristics. Partial oxidation can occur when the external surfaces of wheels or rails are deformed because the materials come into contact with the surrounding atmosphere. Oxidised metallic particles are then worn away. Wear is often affected by the characteristics of the process itself or by layers of martensite which are produced by shoe brakes. [German]

DEVELOPMENT OF CORRUGATIONS ON SURFACES IN ROLLING CONTACT
The self-generation of corrugation on metal surfaces in rolling contact has been studied experimentally in a rolling contact disc machine and theoretically using a computer simulation. The system vibrates in the "contact resonance" mode excited by surface irregularities, and these vibrations may be severe enough to cause plastic indentation of the surface in one revolution which then amplifies the vibration in the next revolution.

C4 131533
CRACK GROWTH RATE ITS MEASUREMENT AND A CONTROLLING FACTOR IN ROLLING CONTACT FATIGUE
An optical method has been developed for measuring the extent of cracking in test specimens which have failed by fatigue under rolling contact conditions. The data from these measurements are expressed in terms of the overall crack growth rate, and it is found that an excellent correlation exists between fatigue life and the rate at which cracks branch and propagate. The correlation appears to be independent of stress, lubricant chemistry, and probably metallurgy; this shows that crack branching rate controls fatigue life. The results do show that lubricant chemical factors affect fatigue life through the crack branching rate.

FREIGHT CAR TRUCK OPTIMIZATION: TRUCK ECONOMIC DATA COLLECTION AND ANALYSIS
A first interim report covering the development of the TDOP economic methodology was published by the Federal Railroad Administration in April 1975. It contains the truck investment economic evaluation procedures intended for the use of the railroad industry and their suppliers. The primary objective of the Truck Economic Data Collection and Analysis Program is to test the procedures for establishing the significant actual operating costs of existing Type I general purpose trucks. This second interim report covers the progress of the program. A generalized truck cost information system was designed for the collection and integration of truck economic data. The collection of test data for off-line truck maintenance costs was completed. Test data collection was initiated for on-line truck maintenance and other associated costs and operating conditions. Preparatory work was begun to develop the appropriate data analysis guidelines. A preliminary analysis of some of the test data clearly revealed the truck's reported off-line wear and failure cost performance. Railroad companies and their suppliers are encouraged to consider adopting the tested procedures of the TDOP economic methodology. A progressive implementation of this methodology will provide them with the timely opportunity to develop a truck economic evaluation capability of their own.

ROAD AND LABORATORY INVESTIGATION OF TRUCK BOLSTERS FOR UNIT TRAIN CARS
Problems of "excessive" wear and failure have arisen in new cars in unit train service, some due to over-the-road running, others to handling of light cars. Similar problems can arise in trains of non-uniform, but regularly assigned, car types in continuous high-mileage, high speed, rapid turnaround service. Railroad cars permanently assigned to unit train service travel many more miles yearly than cars in conventional freight service. At terminals their loading and unloading is expedited to reduce turnaround time. Consequently, the load spectrum that a conventional-service car would encounter over years, is compressed, for the unit train car, into a much shorter time interval. This paper describes the experiences with truck bolsters from a coal-hauling fleet of unit train cars.

OBSERVATIONS ON THE EFFECT OF HEAVY WHEEL LOADS ON RAIL LIFE
The Bessemer and Lake Erie Railroad has operated 90-59 open-top cars since 1931 and has some statistics on rail wear and rail life under the stresses imposed by such equipment. Rail life on tangent track has been around 440 million gross tons for jointed rail and beyond 650 million gross tons for continuous welded rail. Statistics are also available for Curvemaster and controlled cooled rail on curves. On newer ore carrying railways, rail life appears to be appreciably shorter. Among possible reasons are the bidirectional operation of loaded trains on B&LE, the mixing of various capacities of cars, and the predominance of traffic on solid, rather than roller-type, journal bearings.

RAIL WEAR AND CORRUGATION PROBLEMS RELATED TO UNIT TRAIN OPERATIONS: CAUSES AND REMEDIAL ACTION
This paper is a case study of rail wear problems on Canadian National's main line through the Rocky Mountains as a result of unit train operation. The problems are gauge-face wear on the high rail on curves, rail head flow on the low rail and corrugations having a wavelength varying from 8 to 30 inches on the low rail. Prior to introduction of unit trains there were almost no such problems. A study of the lateral forces is described. Remedial action requires a concentrated effort by Engineering, Equipment and Transportation groups with no quick "fix" available. Absence of any action will only cause track deterioration and if it is desired to more bulk commodities in unit trains, the problem must be attacked in an organized manner.

The Transportation Research Board is an agency of the National Research Council, which serves the National Academy of Sciences and the National Academy of Engineering. The Board's purpose is to stimulate research concerning the nature and performance of transportation systems, to disseminate information that the research produces, and to encourage the application of appropriate research findings. The Board's program is carried out by more than 150 committees and task forces composed of more than 1,800 administrators, engineers, social scientists, and educators who serve without compensation. The program is supported by state transportation and highway departments, the U.S. Department of Transportation, and other organizations interested in the development of transportation.

The Transportation Research Board operates within the Commission on Sociotechnical Systems of the National Research Council. The Council was organized in 1916 at the request of President Woodrow Wilson as an agency of the National Academy of Sciences to enable the broad community of scientists and engineers to associate their efforts with those of the Academy membership. Members of the Council are appointed by the president of the Academy and are drawn from academic, industrial, and governmental organizations throughout the United States.

The National Academy of Sciences was established by a congressional act of incorporation signed by President Abraham Lincoln on March 3, 1863, to further science and its use for the general welfare by bringing together the most qualified individuals to deal with scientific and technological problems of broad significance. It is a private, honorary organization of more than 1,000 scientists elected on the basis of outstanding contributions to knowledge and is supported by private and public funds. Under the terms of its congressional charter, the Academy is called upon to act as an official—yet independent—advisor to the federal government in any matter of science and technology, although it is not a government agency and its activities are not limited to those on behalf of the government.

To share in the task of furthering science and engineering and of advising the federal government, the National Academy of Engineering was established on December 5, 1964, under the authority of the act of incorporation of the National Academy of Sciences. Its advisory activities are closely coordinated with those of the National Academy of Sciences, but it is independent and autonomous in its organization and election of members.
